Abstract

Ultrasonics or ultrasound is the sonic waves with frequencies higher than the upper audible limit of humans and is used in numerous studies and applications. Ultrasonic waves are applied in a variety of industries, including the manufacturing and process industries, medicine, domestic, civil, marine communications, wind turbines, and many more. In the medical field, ultrasound is used for both diagnostic and therapeutic applications. In industries, it is used during manufacturing, flaws, or voids for quality assessment and chemical processing. Due to its numerous advantages, ultrasonic testing is one of the most extensively

utilized nondestructive testing (NDT) methods for the examination of structures. The present chapter is mainly focused on the significance of ultrasonic testing and related metrology. Emerging ultrasonic measurement techniques are also briefly discussed, as they would lead to greater measurement capabilities in the future. It is expected that the comprehensive overview of the progress in ultrasound in recent years would prove to be a useful information and knowledge bank for the student, researchers, engineers, scientists, and metrologists working or involved in the field.

Introduction and Historical Background

The ultrasonic field is defined as the study and utilization of mechanical vibrational waves having frequencies above the human audible threshold frequency of 20 kHz. The ultrasonic waves pertaining to the characteristics of the sound travel in a similar fashion as light waves. Ultrasonic waves require a medium such as liquid, solid, or gas to propagate. The wavelength of the ultrasound in the medium depends upon the elastic characteristics of the medium and particle motions (Pandey and Pandey 2010). There are three ways in which ultrasound can be used, applying directly to the product, coupling with the device, and submerging the object in the sampler or ultrasonic immersion tank. Before World War II, ultrasound pioneers were inspired by sonar, the practice of generating sound waves in water and analyzing the back echoes that may identify the location of the submerged objects. Sokolov investigated the use of ultrasonic waves to identify objects from 1929 to 1935. For the first time, in 1931, Mulhauser was granted a patent for employing ultrasonic waves to discover the faults in solids using two transducer methods. Later, Firestone (1940) and Simons (1945) developed ultrasonic pulse-echo testing using a single transducer approach. Just after World War II researchers in Japan began investigating the medical diagnostic possibilities using ultrasound (Hellier 2013; Thabet et al. 2018). In the medical, ultrasound is used for health and safety concerns. Worldwide medical experts have then presented the use of ultrasound to detect gallstones, breast lumps, and cancer. Although the use of a high, 15 MHz frequency for detection of histologic structure of the living intact human breast was proposed as early as 1952, it took over five decades for commercial imaging probes to operate in the range of this frequency. The early ultrasonic devices displayed data in A-mode on an oscilloscope screen with blips. After that, a B-mode presentation with a two-dimensional grayscale image was discovered. The ultrasonic principle is based on the wave characteristics wherein ultrasonic waves are traveled into the specimen and then received back and analyzed for the information of the material under test. Many modern defect detectors with a mathematical function and ultrasonic approaches are

already available on the market for precise and fast location detection of flaws (Roshan et al. 2019; Kumar and Mahto 2013). The ultrasound has numerous applications in different domains like medical, industrial, manufacturing, underwater communication, adulteration detection, material quality assessment, concrete testing, and material characterization (Samokrutov et al. 2006; Ermolov 2005; Cawley 2001; Drewry and Georgiou 2007; Muthumari and Singh 2011). Ultrasound sensors technology is being used in automotive parking systems, flow measurement, and industrial metrology operations in ongoing development advancements. Ultrasonic has become a multidimensional field of study because of its various useful industrial and medical applications. There are various reasons why ultrasound is preferred over other techniques: relatively safe (no radiation like an X-ray), eco-friendly, the ability to maintain the original properties of the material, and cost-effective. It does not even require any pre-processing or post-processing of the samples. The ultrasonic technique is sensitive to both surface and subsurface discontinuities and consumes less energy compared to any other process. Its adaptability allows it to switch from one setup to another in a matter of minutes; devices have a long lifespan and require little maintenance. In some cases, particularly when using the pulse-echo approach, only one-side access to the sample is required (Lavender 1976; Cherfaoui 2012; Dwivedi et al. 2018).

Sources for the Generation of Ultrasonic Waves

There are numerous methods for the generation of ultrasound like mechanical, electrostatic, electrodynamic, electromagnetic, magnetostrictive, piezoelectric, and laser (Krautkrämer and Krautkrämer 2013). The mechanical method, sometimes known as the Galton Whistle method, is an early method for generating ultrasonic waves. For the generation of ultrasound in the frequency range of 100 kHz to 1 MHz, mechanical shock or friction is used. The electrostatic approach can produce ultrasonic waves in the range of 10–200 MHz. In the electrodynamic approach, ultrasound is produced using the magneto-inductive effect. Magnetostriction is the mechanical deformation of ferromagnetic materials in a magnetic field. Through direct interaction between the optical electromagnetic field and the material acoustic field, crossed laser pulse excitation generates high amplitude, counter-propagating ultrasonic waves (acoustic phonons of specified wave vector). The method allows for the optical creation of ultrasonic waves that can be tuned to at least 20 GHz (Nelson et al. 1981). Ultrasonic waves are generated directly into the sample by RF pulses applied in a coil positioned near a metal sample in the presence of a magnetic field (Dobbs and Llewellyn 1971). This is commonly known as an electromagnetic acoustic transducer (EMAT). The Piezoelectric effect is the most prevalent mechanism for producing ultrasound for various applications. The inverse piezoelectric action is used to generate ultrasound in response to the electrical signal applied to the transducer (Pandey and Pandey 2010).

Ultrasonic Metrology

Metrology is the science of measurement and its application. It is not about simply performing the routine measurements; it is about the infrastructure that ensures our confidence in the measurement's correctness. Scientific discoveries and innovation, industrial manufacturing, and worldwide trade enhancing the quality of life and protecting the global environment all rely on metrology. It is critical as a catalyst for any nation's industrial revolution, growth, and overall development (Aswal 2020). Metrological standards and activities contribute to the scientific and economic sustainability of the country. The protocols for the evaluation of performance characteristics of the developed device, testing methodology, manufacturing practices, product standards, scientific protocols, compliance criteria, labeling, or other technical policy criteria should be followed as per standard guidelines for metrological assessment (ISO 17025). Ultrasonic metrology plays a crucial role in providing traceability to medical and industrial equipment (Segreto et al. 2016; Zeqiri 2007). The calibration standard/parameters and their measurements associated with ultrasonic metrology are shown in Fig. 1.

Fig. 1 The layout diagram presenting the calibration of parameters/standards in ultrasonic metrology

In medical, total ultrasonic power/intensity is the critical parameter to be considered for both diagnostic and therapeutic applications. Ultrasound is progressively being used in variety of therapeutic applications due to its ability to cause irreversible changes in tissue when applied with suitable frequency, and intensity. Modern ultrasound diagnostic devices employ harmonic imaging on a routine basis and operate at center frequencies of about 15 MHz. The development of high-quality ultrasonic hydrophones based on membrane design has been the most significant breakthrough in ultrasound metrology (Harris 1996). Existing acoustic standards and guidelines require the acoustic output of imaging transducers to be characterized using calibrated hydrophones (Lewin 2010). International Standard ISO 14708-1: 2014 provides criteria for active implantable medical devices that are generally applicable and tests that must be performed on samples of an active implantable medical device to demonstrate conformity (ISO 14708-1:2014; BS EN 45502-1: 2015). In industries, ultrasonic metrology deals with the calibration of NDT equipment such as ultrasonic flaw detectors (UFD), ultrasonic transducers, and ultrasonic standard blocks (IIW-V1, IIW-V2, reference rods, and step wedge) for the various properties measurement (Ushakov and Davydov 2006; Rawding 1963; Dubey et al. 2015). To calibrate the ultrasonic reference block, both ultrasonic contact and immersion techniques are employed (Kalpana et al. 2022). Ultrasonic metrology has a wide range of applications, comprising material assessment, condition monitoring, physiotherapy, cleaning, navigation, and crack identification. For industrial application standards, IEC TS 63081:2019 is followed for key quantities relevant to ultrasonic materials characterization, specifies methods for direct measurement of many key ultrasonic materials parameters. Also, there are Indian and International standards followed by laboratories such as IS 4904:2006and ISO 2400:2012 for V1 block characterization. In concrete testing IS 12211 is followed for the quality assessment. Figure 2 depicts a few ultrasonic standard blocks used in industries.

Techniques and Systems for Ultrasonic Testing

In industries, ultrasonic testing is considered the most suitable method for quality inspection and assessment. The ultrasonic non-destructive testing approaches used are described below.

Concrete Testing

Concrete is a composite construction material consisting of sand, gravel, crushed rock, or other coarse and fine aggregates bound together in a stone-like mass by a binder like cement and water. Concrete is the oldest construction material worldwide. Some cracking is expected if substantial tensile stress is created in the concrete structure. The compressive strength of the confined concrete is required to measure. The quality of concrete is measured by ultrasonic testing. The ultrasonic concrete testing method is a contact method, and the proper contact between transducer and

Fig. 2 Ultrasonic standard blocks used for the calibration

Table 1 Grading of concrete structure based on ultrasonic pulse velocity measured through the concrete

Longitudinal ultrasonic velocity (km/s)	Concrete quality
Above 4.5	Excellent
3.5–4.5	Good
3.0–3.5	Medium
Below 3	Doubtful

material is made by applying acoustical couplant (grease, ultrasound gel or water, etc.). The testing of concrete needs to be accessible from both sides of the material as for the inspection purpose through-transmission approach is used. The ultrasonic pulse-echo method can also be used in concrete testing, but it required maximum optimization and efficiency in the method with increased resolution (Wollbold and Neisecke 1995). By both approaches, ultrasonic pulse propagation velocity in concrete structures provides useful information on the structure's strength and quality. The quality assessment in the concrete is evaluated by measuring ultrasonic pulse velocity in the material being inspected as shown in Table 1 (IS 13311-1).

Ultrasonic pulse velocity (UPV) has been designated as an official testing method. Because the high-frequency wave propagation through the concrete has no negative effects on the integrity of the concrete structure under test, the UPV approach is a true NDT technology. The transmitting transducer pulse applied to the concrete surface is allowed to transmit and generate ultrasonic waves into the material. At the other end, the receiving signal from the separate transducer gives information on pulse transit time in the concrete material (Helal et al. 2015). The velocity of the ultrasonic pulse provides detailed information about the sample under examination. Standard criteria for ultrasonic pulse velocity testing can be found in the standards (1) ASTM C 597: Standard Test Method for Pulse Velocity Through

Concrete (2) BS EN 12504-4:2004 Testing Concrete (ASTM International; BS EN 12504-4:2004). The UPV method is a great way to investigate the uniformity and durability of concrete quickly and easily. Literature also shows study has also been done on determining the morphology of concrete using NDT, which describes the UPV method as an ideal tool for measuring the homogeneity of the concrete. The study found that UPV testing can be used to discover relatively small faults in concrete structures that could cause structural concerns (Tushar et al. 2015; Lorenzi et al. 2015).

Electromagnetic Acoustic Transducer Testing (EMAT)

Electromagnetic acoustic transducer (EMAT) is a non-contact method for the generation and detection of ultrasonic waves in electrically conducting materials. So this method interacts with the material without making any physical contact with the test material. EMAT generation and detection process involve three factors, a high-frequency coil, a strong magnet, and the test object. The schematic of EMAT is shown in Fig. 3. EMAT generates ultrasonic waves using electromagnetic coupling with the material. The testing is based on the principle of generation of Lorentz force within the skin depth or magnetostriction method or both together. The induced eddy current in the presence of a static magnetic field causes the creation of time-varying magnetic flux. Time-varying magnetic flux induced by receiving coil generates the voltage across the coil. EMAT, which consists of a magnet and an electrical coil, employs electromagnetic forces to inject sound energy into the test object via Lorentz force and magnetostriction combination. EMAT testing provides various advantages in the field of ultrasonic inspection. One of the main advantages of this technique is ultrasonic waves which can be detected in the conducting material by EMAT without making any physical contact; thus hot or moving objects can be used for measurement purposes. Another major advantage of this technique is that various ultrasonic wave modes can be generated in the material by using a coil of different patterns and magnet arrangements. There are some disadvantages too of EMAT. This technique is extremely sensitive to noise so in the detection of the defects, the signal

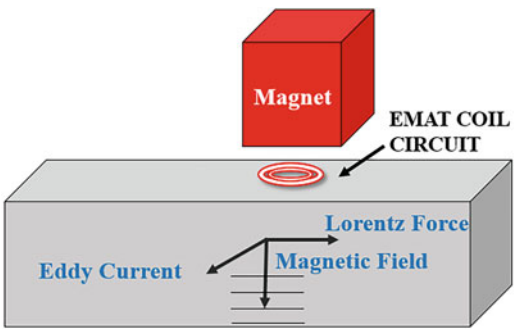

Fig. 3 The schematic of the EMAT method

received also contains noise. EMAT technique plays an important role in the inspection of the material in rail, pipeline inspection, and industrial applications. It allows for the detection of coating disbandment as well as the identification of various coating types (Zhai et al. 2014).

Ultrasonic Pulse-Echo and Through Transmission Testing

The ultrasonic pulse-echo method is most widely used in ultrasonic testing. The convenience and affordability of contact ultrasonic testing make it a popular choice for on-site inspections. In pulse-echo testing same transducer emits and receives ultrasonic energy. The signal received is in the form of echoes generally originated due to acoustic impedance mismatch at an interface, crack, or flaw. The strong signal is reflected from the back of an object. In this method, the probe is made in direct contact with the specimen, and no need to access both sides of the sample. In contact method couplant like gel, grease, oil, or water is used. On the other hand, ultrasonic through-transmission testing utilizes a transducer to transmit ultrasonic waves to the object, and a separate receiving transducer to receive the ultrasonic energy. Both methods can be used for the measurements and evaluation of dimension, material characterization, and identification of flaws in the surface or interior part of the material. For the detection of flaws, one has to measure the transit time of the ultrasonic waves and monitor ultrasonic velocity (Raišutis et al. 2008; Yadav et al. 2021; Rajagopalan et al. 2007).

The longitudinal ultrasonic velocity (c) is determined by the formula

$$c = \frac{2d}{t}$$

where d is the thickness of the sample in meters and t is the time of flight of ultrasonic waves in seconds.

Air Coupled Ultrasonic Testing

Ultrasonic inspections necessitate the use of an acoustic coupling medium. To achieve excellent results, uniform coupling between the sample and probe is required. However, due to air bubbles and line scale, it is difficult to provide a constant coupling of large components. An acoustical mismatch between transducer and test sample limits the measurement. The major advantage of using air-coupled testing (ACT) is that no coupling medium is required as shown in Fig. 4.

The typical air-coupled testing system consists of transducers, a transmitter for intense pulse excitation, an ultra-low preamplifier, a receiver amplifier, and a digital to analog converter, as well as a computer for configuration and assessment of the results (Stoessel et al. 2002; Gaal et al. 2019). The sensitivity of transducers for air-coupling is the most significant characteristic and is given by

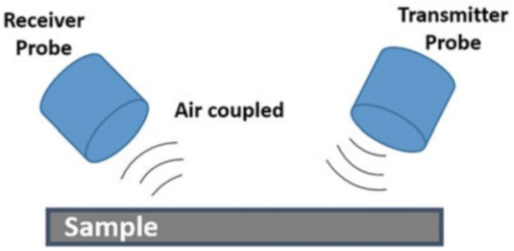

Fig. 4 The schematic of the ultrasonic air-coupled testing

$$S = 20 \log (\mathrm{VR}/\mathrm{VT})$$

where VT is the excitation in volts and VR is the receiver signal amplitude in volts.

Despite the acoustic mismatch, air-coupled testing can provide a much clearer indication of faults than water-coupled testing.

The challenge in the ACT is to maintain a large acoustic impedance difference between Air and Solid (test objects); also the material surface reflects 99% of the ultrasonic signal (Kays et al. 2007; Yilmaz et al. 2020).

Ultrasonic Interferometers for Liquid Testing

Ultrasonic propagation velocity is generally determined using one of two methods: continuous wave or pulse-echo method. The ultrasonic interferometer approach which utilizes continuous excitation is widely used for measuring ultrasonic propagation velocity in liquids. The thermo-acoustic, physical, and chemical properties of liquid can be determined using ultrasonic velocity. The principle of operation is based on the precise determination of wavelength in the medium. A quartz crystal fixed at the bottom of the liquid cell produces ultrasonic waves at a particular frequency. A moveable metallic plate positioned parallel to the quartz crystal reflects these waves. Standing waves are generated in the medium and current maxima or minima are produced when the distance between the transducer and the plate is exactly multiple of the ultrasonic half wavelength. In an ultrasonic interferometer, radiofrequency voltage is applied to excite the piezoelectric transducer (Sharma et al. 2019, 2020).

For ultrasonic velocity measurement, the excitation frequency and the distance between successive maxima and minima are considered. The following equation is used to calculate ultrasonic velocity (v):

$$v = \lambda \times f$$

where λ is the wavelength of ultrasound propagating in liquid and f is the excitation frequency.

Fig. 5 Ultrasonic interferometer apparatus developed for the measurement of ultrasonic velocity and attenuation in liquids

CSIR-NPL developed an ultrasonic interferometer shown in Fig. 5 which is capable to measure ultrasonic velocity and ultrasonic attenuation in liquid samples (Sharma et al. 2019). The system is now commercially available in the market.

The parameters that are derived from ultrasonic velocity are compressibility, effective Debye temperature, excess enthalpy, hydrogen bonding, intermolecular free length, solvation number/hydration number, Vander wall's constant, Rao's constant, Wada constant, and the study of molecular interaction.

Laser Ultrasonic Testing

Laser ultrasonic testing (LUT) is a type of ultrasonic NDT in which ultrasound is generated and detected by using lasers. The generation mechanism generally does not allow for wave type selection, and longitudinal, shear, and surface waves (or plate waves) are all released at the same time, which might be advantageous or disadvantageous depending on the application. Like traditional ultrasonics, laser-ultrasonics has similar applications, such as thickness measurement, flaws and crack identification, and material characterization. LUT testing is used because of its various advantages including couplant-free operation, ease of automation, relatively long distance to the object under test, harsh industrial environment feasible, difficult measuring positions possible, and high ultrasound bandwidth. With LUT ultrasound can be generated up to GHz frequency. Laser ultrasound is generated by two mechanisms: thermoelastic and ablation or vaporization method. The thermoelastic mechanism is the NDT approach while vaporization and ablation are invasive and based on the ablation of the sample. In LUT a short laser pulse irradiated on the

material surface causes localized thermal expansion that generates thermoelastic waves in the materials and can be detected by the optical interferometers. The signals obtained can be utilized to determine the material's elastic and density properties as well as discontinuities such as cracks or delamination (Cheng et al. 2013; Monchalin 2007).

Applications of Ultrasound

Ultrasound is extremely useful in various sectors. Table 2 provides a summary of some of the ultrasound applications.

Recent Technologies

For many decades, ultrasonic testing (UT) has been used, and ultrasound technology has been improved significantly. Workflow improvements in current generation ultrasound machines include automation/semi-automation of measurement, auto-image optimization, and reducing repetitive user tasks. The machinery used in NDT like ultrasonic flaw detectors have become portable devices having speedy analysis and accurate mathematical measurements. All the operator has to do is attach the transducer, and the instrument will automatically adjust variables like frequency and probe drive. EMAT technologies are being preferred due to their couplant-free operation. Now laser EMAT ultrasonic systems are also used for defects and time of flight measurement. However, the typical ultrasonic testing method requires acoustic interaction between piezoelectric transducers and test structures. In some cases, it is impossible to implement such as heated or complex-shaped, or fast-moving components. So in that particular case laser EMAT, ultrasonic testing is preferred (Boonsang and Dewhurst 2005; Lévesque et al. 2002; Senthilkumar et al. 2021).

In medical ultrasonic applications, elastography distinguishes liver tumors from healthy tissue, as well as determines the presence of fibrosis in the liver. Histotripsy, a high-intensity ultrasound therapy, is being studied at the University of Michigan for the non-invasive treatment of blood clots. Miniature ultrasonography at a low cost is used these days, and medical ultrasound imagers, like computers, have been getting smaller and smaller. Vscan Extend, handheld, pocket-sized ultrasound, portable healthcare devices, Sonosite, and Lumify portable systems are some of the latest point-of-care ultrasound systems in the market. When it comes to 3-D ultrasound, the technology is always improving. Scientific studies have progressed beyond basic 2-D and 3-D imaging to offer innovative approaches to assemble images to speed up and simplify analyses. Recent studies show that artificial intelligence (AI) has huge potential to assist repetitive ultrasound tasks, such as automatically identifying good-quality acquisitions and providing instant quality assurance. The AI methodology in the medical is used to evaluate adnexal masses, the risk of lymph node metastases in endometrial cancer, pelvic organ function, and

Table 2 Application of ultrasound in specific sector with example

Field	Trade/sectors	Descriptions
Industrial	Oil and gas	Due to the advantage of low power ultrasound, it does not alter the inherent property of the medium, low cost, and high efficiency; ultrasound has significant potential applications in the petroleum industry. Power ultrasound penetrates oil/water medium-well also creates and transmits high energy-specific density (10–1000 W/cm^2) (Luo et al. 2021; Qiu et al. 2020). The ultrasonic impact is used in oil transportation and storage to lower oil viscosity, reduce pumping costs, and clear oil storage tanks of asphalt and paraffin deposits that reduce tank volume and enhance corrosive activity (Palaev et al. 2019a, b)
	Defense	Ultrasonic testing is used once the rocket motor structure's resin structure and layered rubber insulation have been completed and gives a precursor to the crucial data needed to determine the system's structural integrity, defects, and micro inspection (Nudurupati 2021)
	Manufacturing	In manufacturing automated ultrasonic testing enables the viewing of the geometry of the tested element, allowing for the determination of its correctness and the magnitude and position of faults in welding for joints assessment. In industries, ultrasound is used in a wide range of processes, such as cleaning, welding plastics and metals, cutting, forming, testing materials, separating, mixing, de-gassing, atomizing, localizing, measuring, and many others
	Rail industry	In rail, rail tracks are subjected to extreme stresses, which can affect their structural integrity during usage and result in rail breakage. To monitor these types of defects, ultrasonic testing is useful (Bombarda et al. 2021)
	Food industry	It is important to harvest crops at their peak ripening stage. These days studies have extensively focused on developing nondestructive, noninvasive, and noncontact methods for determining food quality (Yildiz et al. 2019). It is determined that fruit characteristics are correlated with ultrasonic parameters (velocity and attenuation) (Yildiz et al. 2018; Natarajan and Ponnusamy 2020)
Research and development	Metrology	The key application of ultrasonic testing in metrology is the radiation force balance, which measures total output power, and the piezoelectric hydrophone, which measures acoustic pressure level. Ultrasonic metrology ensures users can make traceable measurements it maintains and disseminate primary standards for the measurement of key acoustical quantities (Zeqiri 2007; Mineo et al. 2017). Rail industries widely use ultrasonic testing for the inspection of rails. Both standard and angle beam techniques, as well as pulse-echo and pitch-catch techniques, are employed
	Cleaning	Ultrasonic cleaners are used to clean substrate surfaces in a variety of applications because of their ability to remove contaminants. By ultrasonic cleaning blind holes, thread roots, parts with complex geometry, minute surface

(continued)

Table 2 (continued)

Field	Trade/sectors	Descriptions
		contours, and several otherwise impossible cleaning tasks can be easily accomplished (Azar 2009). In ultrasonic cleaning, the high frequency (25–50 kHz) and high-intensity (up to 250 W/cm^2) ultrasound are used
	Spectroscopy	High-resolution ultrasonic spectroscopy is an analytical technique for monitoring molecular and microstructural alterations in liquids and semi-solid materials in a direct and non-destructive manner. High-frequency (MHz range) compression and decompression waves (longitudinal deformations) are used in ultrasonic spectroscopy to investigate the elastic properties of materials determined by intermolecular interactions and microstructural studies (Buckin et al. 2002; Buckin 2018)
Medical	Diagnostic	Ultrasound can image internal body organs non-invasively. Ultrasound is used to diagnose and accordingly treat medical conditions. Ultrasound in contrast to X-rays does not emit any radiation and has minimal risk. It is widely regarded as having a very low hazard, mostly as a result of the fact that it forms the image using non-ionizing radiation
	Therapeutic	The therapeutic ultrasound goal is to interact with body tissues in such a way that they are altered or eliminated. Ultrasounds are used to cure and treat medical conditions. In therapeutic ultrasound waves with frequencies of 1–2 MHz are generally preferred to drive the transducer (Pei et al. 2012)

breast lesions, assess aneuploidy risk, predict fetal lung maturity, perinatal outcome, shoulder dystocia, and brain damage, also estimate gestational age in late pregnancy, and classify standard fetal brain images as normal or abnormal (Drukker et al. 2020).

Ultrasonic Metrological Activities and Technologies at CSIR-NPL

The CSIR-National Physical Laboratory, India (NPLI), is responsible to maintain the national standards in the fields of ultrasonic and non-destructive testing. The activity has indigenously developed primary ultrasonic power measurement facility used for the measurement of total, time-averaged ultrasonic power generated by transducers. The frequency range is from 0.5 to 20 MHz and uses the radiation force balance (RFB) approach for ultrasonic power measurement in the range from 10 mW to 20 W. The system's functionality was validated by participating in the BIPM international key comparison (CCAUV.U-K3.1). The international key comparison is in the field of power measurement aimed to compare various National Measurement Institute's (NMIs) ultrasonic radiation conductance measurement capabilities (Haller et al. 2016). Other calibration facilities include calibration of ultrasonic standard reference blocks such as the IIW-V1, IIW-V2 (according to IS: 4904),

step wedge, ultrasonic pulse velocity (UPV) rod, cylindrical FBH blocks (according to ASTM E-127), ultrasonic flaw detector (as per BS: 4331-II/ASTM E-317 and IS: 12666), and ultrasonic probe (beam profile, bandwidth as per ASTM E-1065). Testing ultrasonic facilities are available for the measurement of propagation velocity, impedance, and attenuation for solids and liquids. The ultrasonic department has various facilities, and researchers are working in the direction of the development of technologies.

Conclusion

Ultrasound is significant since it opens up new options in a variety of fields such as industry, medicine, aerospace, food processing, undersea applications, manufacturing, and research and development. This chapter presents a concise report on various measurement techniques in ultrasonic, and ultrasonic metrology, and a review of metrological and technical requirements of documentary standards is presented. Over the last few years, numerous research efforts have been focused on the dependability of ultrasound, and many of them are detailed in this chapter. The present study discusses the various aspects of ultrasonic testing applications. This field has become more demanding, and applications are increasing day by day as we are surrounded by technologies. This chapter shows that some of the ultrasonic NDT techniques are having some limitations and unique advantages as well. The study obtained the most recent research on current testing and examined it to identify potential application areas.

Abstract

The ultrasonic nondestructive technique (US-NDT) is the mostly preferred technique for material characterization. It has gained much attention in the area of materials science as there is no impairment of properties and does not affect the future usefulness of the sample under testing. The ultrasonic techniques are the versatile tools to investigate the material properties such as microstructure, elastic modulus, and grain size and the mechanical properties, velocity, attenuation, etc. This field has evolved mainly in the last few decades and is involved in developing new materials and modifying available materials by gaining a better understanding of characteristics under different physical conditions. These materials are thus referred to as condensed materials which have proven their potentials in many applications. Out of emerging materials, the exceptional structural, elastic, electrical, magnetic, phonon, and thermal characteristics of rare-earth compounds have attracted attention, as they are of technological significance. These materials crystallize into a basic NaCl structure, making them interesting samples for experimental and theoretical study. One of the most important reasons for the theoretical investigation of rare-earth compounds was the existence of a single crystal of chosen materials. After it was demonstrated that some rare-earth compounds can be grown epitaxially on III-V semiconductors, the interest in these materials has expanded even more recently. It has paved the path for their use in the manufacturing industry, infrared detectors, optoelectronic devices, spintronics, and several research domains.

Keywords

Condensed materials · Elastic constants · Ultrasonic velocity · Thermal properties · Ultrasonic attenuation

Introduction

Ultrasonic NDT is gaining societal importance in medical, industrial processing and defense, robotics, and materials characterization (Raj 2000). Due to rising competition and the demand for improved material productivity for use in electrochemical energy and renewable energy systems, the material-producing industries are focusing more on severe process and quality control requirements. This necessitates the use of two crucial methods:

(i) Materials characterization
(ii) Industrial metrology principles for quality control

The examination of numerous characteristics, such as elastic behavior, associated mechanical properties, material microstructure and morphological features, etc., is part of the materials characterization process. The following approaches are available for complete material characterization:

(i) Destructive testing (DT)
(ii) Semi-destructive testing (SDT)
(iii) Non-destructive testing (NDT)

Ultrasonic NDT: Material Characterization Technique

Ultrasonic echolocation is the use of sound waves and echoes to determine where the object is positioned (Chandrasekaran 2020). It is applied in NDT to fetch information regarding the wised variety of material analysis applications without affecting the samples' properties. Ultrasonic testing can be used to find holes, cracks, or corrosion in materials, inspection of weld, and imperfections in solids. Acoustic emission, a category of NDT study, uses ultrasonics for detecting the structural flaws in materials (Grosse 2013; Vary 1980; Nanekar and Shah 2003). High-frequency sound waves can also be used to compute and identify some fundamental mechanical, structural, or compositional characteristics of solids and liquids (Yamanaka et al. 1999; Xiang et al. 2014; Kumar et al. 2003). The ultrasonic material analysis is based on a fundamental physics principle: the mobility of any wave is altered by the medium through which it passes. Thus, changes in any one or more than one of four easily measurable parameters associated with the passage of a high frequency sound wave through a material-transit time, attenuation, scattering, and frequency content can often be correlated with changes in physical properties such as elastic modulus, density, hardness, and homogeneity or grain structure. The piezoelectric, electrostriction, and magnetostriction effects are primarily used to create and detect ultrasonic waves (Singh 2014).

Ultrasonic nondestructive testing (US-NDT) is preferred over other basic tools for characterization as the samples being tested are left undamaged by the process. It is also a very precise kind of inspection, making it ideal for material quality control and assurance (or products).

The NDT approach may be used to characterize the microstructures of a range of materials, as well as to analyze defects and determine physical attributes including density, thermal conductivity, and electrical resistivity. Ultrasonic measurements recorded during material manufacture and heat treatment can be used to ensure that the desired microstructure is obtained and to prevent the formation of faults, such as flaws in welds between different materials. Understanding how ultrasound interacts with microstructure is also crucial for tackling a variety of material issues. Defect detection is hampered by attenuation and backscattering, notably in rare-earth

monopnictides with coarse grains or complicated microstructures. As a result, minimizing attenuation is important in order to optimize the utility of ultrasonic testing. Material description investigations, such as nondestructive grain size measurement, can also benefit from microstructure information. Another important measure in ultrasonic characterization is wave propagation velocity, which can reveal crystallographic texture. The elastic constants and density of rare-earth monopnictides are closely linked to ultrasonic velocity. The elastic constants, in particular, are useful for determining material stability and stiffness (Bala et al. 2022). The goal of this chapter is to go over the methods for calculating ultrasonic characteristics of materials. Ultrasonic measurements, which rely on elastic waves propagating through a material, are one of the most widely used non-destructive evaluation (NDE) techniques (both experimentally and conceptually) and have played a vital role in illuminating the materials' global characteristics.

Ultrasonic Metrology

Ultrasonic metrology is one of the key metrological fields for industrial research because of its wide applications in industrial processing, manufacturing, and testing. The theoretical and experimental studies in wave mechanics provide a better understanding of the sound fields radiating from ultrasonic transducers and from reflectors or acoustic emitters. The results of these studies are used to develop measurement methods and reference standards for acoustic emission and pulse-echo ultrasonic system which are becoming increasingly important for quality control. The approach includes analyzing transient wave propagation in different directions based on numerical approach/theoretical computations. The use of ultrasonics is to measure the intrinsic and extrinsic parameters which include material elasticity, stress, surface hardness strength, etc.

Today's most sophisticated metrology systems drive quality assurance (QA) which has become a fundamental digital task which in and of itself facilitates efficient and cost-effective production processes. In a very real sense, QA data today controls how products are made and drives the bottom line and the repeatability in production which is vital in all pan-industrial manufacturing scenarios.

Rare-Earth Materials

Presently, rare-earth (RE) compounds are the materials of particular interest due to their power functionality and wide applications in metallurgical machinery, petrochemical, ceramic glass, agricultural, industrial, and textile industries (Massari and Ruberti 2013). Recently, RE materials have gained importance in electrochemical energy storage.

These are the key materials that cannot be ignored by both new energy, energy conservation, and efficiency enhancement routes and are often known as "the gold of world industrial manufacturing." These reputations basically reflect the three

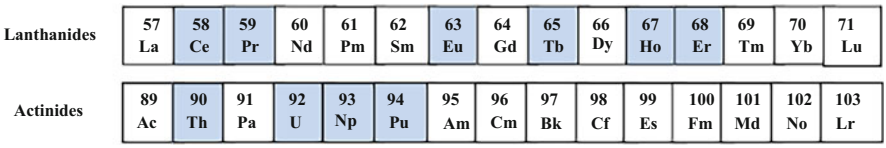

Fig. 1 Series of lanthanides and actinides as listed in Periodic Table

characteristics of rare earths: one is rarity, the other is powerful functionality, and the third is wide application. Rare earths can play a vital role in a variety of conventional industrial domains, notably in industries. In addition to these fields, the application of rare earths in new materials also has a broad space, such as permanent magnet materials, catalysts, high temperature superconductors, laser materials, precision ceramics, giant magnetostrictive materials, and electrothermal materials (Zhang et al. 2020).

The Modern Periodic Table consists of two rows of Ce-Lu and Th-Lr collectively known as f block which are divided into lanthanides (Ce-Lu) and actinides (Th-Lr). These are the "inner transition elements" involving the filling of inner-subshells such as 4f or 5f. Figure 1 shows the series of lanthanides (La) and actinides (An) (Moeller 1970).

The general properties of transition elements are as follows:

(i) They possess several oxidation states.
(ii) They are usually high melting point metals.
(iii) They are usually paramagnetic in nature.

The study is focused on two different material groups, XPn and XCh, where X = La and An; pnictides, Pn = N, P. As, Sb, and Bi and chalcogenides, Ch = S, Se, and Te.

Our main aim in this chapter is to do the analysis of past and current data by associating quantifiable uncertainty to measurements taking into the fact that multiple variables can influence readings. By this we are providing fit-for-purpose data.

This will eliminate the need to apply complicated mathematical formula to offset data discrepancies and thus improving accuracy.

Monopnictides (Pn) and Monochalcogenides (Ch)

In recent years, both the rare-earth monopnictides and monochalcogenides, REPn and RECh, are of great interest because most of them are characteristically low carrier sturdily correlated systems with a simple fcc (face-centered cubic) rock-salt type crystal structure. In such materials each RE atom coordinates with six neighboring atoms. The pnictides (N, P, As, Sb, and Bi) with electronic configuration ns2np3 ($n = 3, 4, 5$) and the chalcogenides (S, Se, and Te) with ns2np4 ($n = 4, 5$) configurations are the anions in the REPn and RECh type of compounds. Anomalous

physical phenomena such as the dense Kondo behavior, the metal–insulator transitions, the valence fluctuation behavior, the complicated magnetic states, etc. have been observed in these compounds. Most of them behave as semimetals. The rare earth metals nitride compounds in particular are the attention-seeking compounds. This group consists of intrinsic ferromagnetic semiconductors to half metals and thus has prospective to become spintronic materials.

The RE monochalcogenides are interesting ionic solids as these have attracted scientific community because of their electrical and magnetics properties. The semiconducting behavior is observed in case of divalent state and metallic when the rare earth ion is in trivalent state. The bonds have ionic character. The RE monopnictides and monochalcogenides form an interesting set of materials. To understand several physical phenomena in these material groups, the systematic study has been performed and is of significant attention for pure and applied research (Duan et al. 2007; Natali et al. 2013; Petit et al. 2010).

Applications of Ultrasonics in Research

Ultrasonic waves have a variety of uses in a variety of areas, some of which are listed below:

- Cavitation
- SONAR (Sound Navigation and Ranging)
- Biological ultrasonics
- Industrial ultrasonics
- Processing
- Ultrasonics in electronics
- Chemical uses
- Ultrasonic thermometry

Measurement Techniques for Metrology Solutions

Picosecond Ultrasonics (PULSETM Technology)

It has been widely utilized in thin metal film metrology because of its quick, non-contact, non-destructive nature and ability to measure many layers simultaneously. The simultaneous assessment of velocity and thickness for transparent and semi-transparent films has a lot of potential for not just process monitoring but also insight into device performance. Picosecond ultrasonics (Stoner et al. 2001) provides a full metrology solution in advanced radio frequency (RF) applications, including the measurement of diverse thin metal films for a wide range of thicknesses with exceptionally high repeatability. This could meet stringent process control requirements, simultaneous multilayer measurement capability, and simultaneous

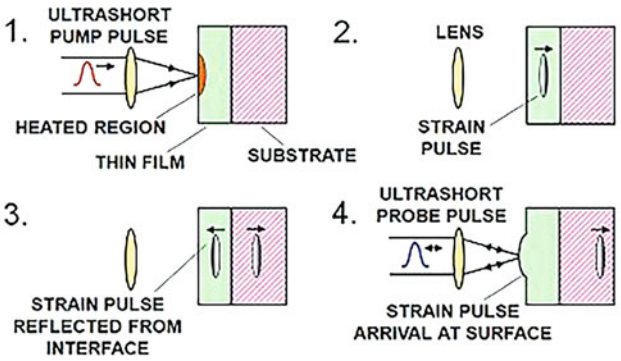

Fig. 2 Picosecond ultrasonic technology (PUT). (© Wikipedia)

measurement of sound velocity and thickness for piezoelectric films which play a vital role in the performance of RF devices.

Picosecond ultrasonic technology (PUT) is a nondestructive, non-contact laser acoustic technique for measuring film thickness, sound velocity, Young's modulus, density, and roughness. It has become the standard instrument for metal film thickness measuring in semiconductor fabs all over the world. A 100 fs laser pulse (pump) focused onto the film surface in Fig. 2 launches an acoustic wave in the film. The acoustic wave travels at the speed of sound through the film away from the surface. A component of the acoustic wave is reflected and returns to the surface at the interface with another material, while the remainder is transmitted. As the reflected acoustic wave reaches the wafer surface, the probe pulse detects it. The strain of an acoustic wave causes a change in optical reflectivity, which may be detected.

The thickness of a material may be easily derived using first principles utilizing standard sound velocity in the material. Film density, sound velocity, Young's modulus, and surface roughness can all be quantified in addition to thickness, depending on the application and the stacking of films. For single layer and whole stack thickness measurements, PUT delivers great reproducibility and stability. Because of the narrow beam spot and quick measurement time, direct measurements on real device structures are possible, as well as numerous dye measurements. The PUT's capacity to simultaneously measure thickness and sound velocity distinguishes it. The PUT has a unique technological advantage in that it can measure both thickness and sound velocity at the same time.

Ultrasonic Testing (UT)

The measurements and examinations are carried out using high-frequency sound energy (Balageas et al. 2016). Ultrasonic inspection is used to discover and evaluate flaws, take dimensional measurements, characterize materials, and more. As shown

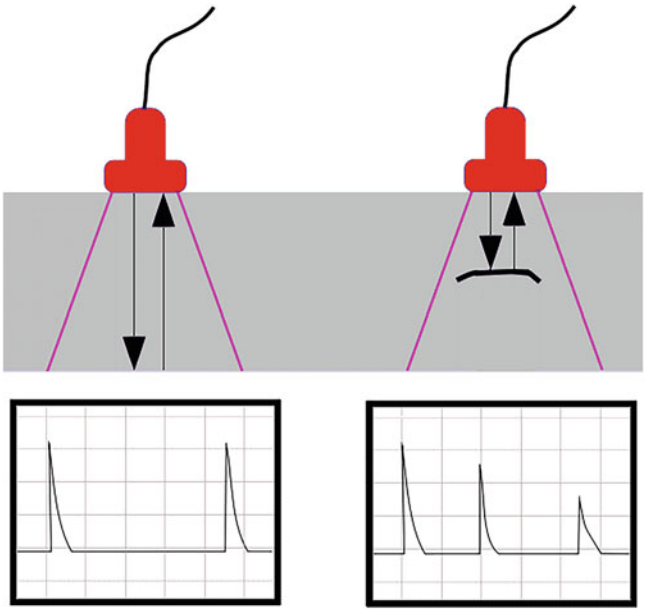

Fig. 3 UT inspection system. (© Wikipedia)

in Fig. 3, a standard pulse/echo inspection arrangement is utilized. The pulser/receiver, transducer, and display devices are among the components of the UT inspection system.

Pulser/receiver: It's a high-voltage electrical pulse-producing electronic device. The pulser drives the transducer, which produces high-frequency ultrasonic radiation. Sound energy is injected and propagates in the form of waves through the materials. When there is a break in the wave path (such as a fracture), some of the energy is reflected back off the defect surface. The transducer converts the reflected wave signal into an electrical signal, which is then shown on a screen.

The reflected signal intensity is shown against the time from signal production to when an echo is received in the applet below. The signal travel time can be directly related to the distance that the signal travelled. Information regarding the reflector's location, size, direction, and other characteristics may occasionally be gained from the signal.

Transducer: The pulser, which creates high frequency ultrasonic energy, drives the transducer. Waves propagate across the materials as the supplied sound energy travels through them. When a discontinuity in the wave path, such as a fracture, is detected, some of the energy is reflected back off the fault surface. The transducer converts the reflected wave signal into an electrical signal, which is then shown on a screen.

Display Devices: The reflected signal intensity is shown against the time between when the signal was generated and when an echo was received. The distance travelled by the signal may be directly attributed to the signal travel time.

Information regarding the reflector's location, size, direction, and other characteristics may occasionally be gained from the signal.

Theoretical Evaluation of Elastic Constants and Related Parameters

Elastic Constants

All materials are made up of atoms or molecules which are connected to each other by interatomic forces. The magnitude of these interatomic forces acts as a criterion for determining the vibration properties of the atoms and molecules of the medium. The solids with different structures have variable nature of forces, and hence the wave propagation characteristics also differ here (Decius and Hexter 1977; Stone 2013).

When an external force is applied to the crystal, the deformation takes place. When the external force is removed, internal forces oppose the deformation and return the sample to its original condition. This property is defined by "elasticity." The elastic constants of crystals link the structure of the lattice with its macroscopic behavior. The theoretical formulation for the evaluation of elastic constants is based on two common methods.

The first is the ab initio modeling of materials from their known crystal structures (Ching et al. 2009; Güler and Güler 2014). This method is based on the study of the total energy of appropriately strained states of the materials (volume conserving technique), whereas the other way (stress-strain method) is based on the examination of changes in calculated stress values resulting from changes in strain (Hiki 1981). In the present investigation, we used the stress-strain method to obtain higher-order elastic constants (HOECs) such as second-, third-, and fourth-order elastic constants (SOECs, TOECs, and FOECs) developed by Mori and Hiki (1978) under the assumption that stress is proportional to strain within the elastic deformation limit expressed by Hooke's law. For anisotropic materials, Hooke's law is as follows:

$$\sigma_{ij} = C_{ijkl}\eta_{kl} \tag{1}$$

and its inverse

$$\eta_{kl} = S_{ijkl}\sigma_{ij} \tag{2}$$

Here, $i, j, k, l = 1, 2, 3$, C_{ijkl} is the fourth rank tensor of elastic stiffness or elasticity tensor and contains $6 \times 6 = 36$ independent components; σ_{ij} and η_{kl} are the second-rank stress and strain tensors for the anisotropic (aeolotropic/anisotropic) materials, and S_{ijkl} is the elastic compliance tensor. The elastic stiffness of the material determines the propagation properties of elastic waves in anisotropic media. The components of Lagrangian strain tensor η_{kl} under finite deformations are given by

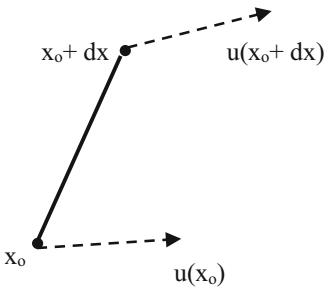

Fig. 4 The generalized displacement of the atoms in a crystal lattice

$$\eta_{kl} = \left(\frac{1}{2}\right)\left[\left(\frac{\partial u_k}{\partial x_l}\right)\left(\frac{\partial u_l}{\partial x_k}\right) - \delta_{ij}\right] \quad (k, l = 1, 2, 3) \tag{3}$$

where the displacement vector components **x** and **u** are the initial and final position of material points shown in Fig. 4. The vector **x** is the Cartesian coordinates of a point of the continuum in the unstrained state, and **u** is of the deformed state at time t. Thus, $u_i = u_i(x_1, x_2, x_3, t)$.

Under the circumstances of high stress and strain, the deviation from Hooke's law will take place. The complexity in the nonlinear theory of elasticity increases which leads to the introduction of HOECs. The determination of HOECs is important for identifying anharmonic characteristics of materials. Atomic displacements impact anharmonic properties such as thermal conductivity, nonlinear elasticity, and thermal expansion, as well as static and dynamic properties of lattices (Cowley 1963).

Now, the elastic potential energy density of the continuum is expressed by free energy expanded through Taylor series expansion in terms of the elastic strain components.

$$\phi = \frac{1}{2!}C_{ijkl}\eta_{ij}\eta_{kl} + \frac{1}{3!}C_{ijklmn}\eta_{ij}\eta_{kl}\eta_{mn} + \frac{1}{4!}C_{ijklmnpq}\eta_{ij}\eta_{kl}\eta_{mn}\eta_{pq} \tag{4}$$

Here, $C_{ijkl,}$ C_{ijklmn}, and $C_{ijklmnpq}$ are the usual SOECs, TOECs, and FOECs. The nth-order ($n \geq 2$) elastic constants defined by Brugger (1964) as

$$C_{ijklmn\ldots} = C_{IJK\ldots} = \left.\frac{\partial^n \phi}{\partial\eta_{ij}\partial\eta_{kl}\partial\eta_{mn}\cdots}\right|_{\eta=0} \tag{5}$$

The shorthand notation of elastic tensor C_{ijkl} (Voigt 1966; Love 1927) which is given by Voigt has been used for the indices ranging from 0 to 6:

$$11 \rightarrow 1,\ 22 \rightarrow 2,\ 33 \rightarrow 1,\ 23 \rightarrow 4,\ 31 \rightarrow 5,\ 12 \rightarrow 6$$

Thus, the elasticity tensor is now expressed as C_{IJ}. Also, the explicit forms of quadratic, cubic, and quartic terms of free energy are

$$
\begin{aligned}
F_2 &= \frac{1}{2!} C_{ijkl}\eta_{ij}\eta_{kl} \\
&= \frac{1}{2} C_{11}\left(\eta_{11}^2 + \eta_{22}^2 + \eta_{33}^2\right) + C_{12}(\eta_{11}\eta_{22} + \eta_{22}\eta_{33} + \eta_{33}\eta_{11}) \\
&\quad + 2C_{44}\left(\eta_{12}^2 + \eta_{23}^2 + \eta_{31}^2\right)
\end{aligned}
$$

$$
\begin{aligned}
F_3 &= \frac{1}{3!} C_{ijklmn}\eta_{ij}\eta_{kl}\eta_{mn} \\
&= \frac{1}{6} C_{111}\left(\eta_{11}^3 + \eta_{22}^3 + \eta_{33}^3\right) \\
&\quad + \frac{1}{2} C_{112}\left\{\eta_{11}^2(\eta_{22} + \eta_{33}) + \eta_{22}^2(\eta_{33} + \eta_{11}) + \eta_{33}^2(\eta_{11} + \eta_{22})\right\} + C_{123}\eta_{11}\eta_{22}\eta_{33} \\
&\quad + 2C_{144}\left(\eta_{11}\eta_{23}^2 + \eta_{22}\eta_{31}^2 + \eta_{33}\eta_{12}^2\right) \\
&\quad + 2C_{166}\left\{\eta_{12}^2(\eta_{11} + \eta_{22}) + \eta_{23}^2(\eta_{22} + \eta_{23}) + \eta_{31}^2(\eta_{33} + \eta_{11})\right\} \\
&\quad + 8C_{456}\eta_{12}\eta_{23}\eta_{31}
\end{aligned}
$$

and

$$
\begin{aligned}
F_4 = \frac{1}{4!} C_{ijklmnpq}\eta_{ij}\eta_{kl}\eta_{mn}\eta_{pq} &= \frac{1}{24} C_{1111}\left(\eta_{11}^4 + \eta_{22}^4 + \eta_{33}^4\right) \\
&\quad + \frac{1}{6} C_{1112}\left\{\eta_{11}^3(\eta_{22} + \eta_{33}) + \eta_{22}^3(\eta_{33} + \eta_{11}) + \eta_{33}^3(\eta_{11} + \eta_{22})\right\} \\
&\quad + \frac{1}{4} C_{1122}\left(\eta_{11}^2\eta_{22}^2 + \eta_{22}^2\eta_{33}^2 + \eta_{33}^2\eta_{11}^2\right) \\
&\quad + \frac{1}{2} C_{1123}\eta_{11}\eta_{22}\eta_{33}(\eta_{11} + \eta_{22} + \eta_{33}) + C_{1144}\left(\eta_{11}^2\eta_{23}^2 + \eta_{22}^2\eta_{31}^2 + \eta_{33}^2\eta_{12}^2\right) \\
&\quad + C_{1155}\left\{\eta_{11}^2\left(\eta_{31}^2 + \eta_{12}^2\right) + \eta_{22}^2\left(\eta_{12}^2 + \eta_{23}^2\right) + \eta_{33}^2\left(\eta_{23}^2 + \eta_{31}^2\right)\right\} \\
&\quad + 2C_{1255}\left\{\eta_{11}\eta_{22}\left(\eta_{23}^2 + \eta_{31}^2\right) + \eta_{22}\eta_{33}\left(\eta_{31}^2 + \eta_{12}^2\right) + \eta_{33}\eta_{11}\left(\eta_{12}^2 + \eta_{23}^2\right)\right\} \\
&\quad + 2C_{1266}\left(\eta_{11}\eta_{22}\eta_{12}^2 + \eta_{22}\eta_{33}\eta_{23}^2 + \eta_{33}\eta_{11}\eta_{31}^2\right) + 8C_{1456}\eta_{12}\eta_{23}\eta_{31}(\eta_{11} + \eta_{22} + \eta_{33}) \\
&\quad + \frac{2}{3} C_{4444}\left(\eta_{23}^4 + \eta_{31}^4 + \eta_{12}^4\right) + 4C_{4455}\left(\eta_{23}^2\eta_{31}^2 + \eta_{31}^2\eta_{12}^2 + \eta_{12}^2\eta_{23}^2\right)
\end{aligned} \tag{6}
$$

The total free energy density at a finite temperature T is given by

$$
F^{\text{Total}} = F^0 + F^{\text{vib}} = \left(F^2 + F^3 + F^4\right) + F^{\text{vib}} \tag{7}
$$

F^0 is the crystal's internal energy per unit volume, with all ions at rest at their lattice sites, and F^{vib} is the vibrational free energy given by

$$
F^{\text{vib}} = \frac{k_B T}{N V_c} \sum_{i=1}^{3sN} \ln 2 \sinh(\hbar\omega_i / 2k_B T) \tag{8}
$$

where V_c represents the volume of an elementary cell, s represents the number of ions in the cell, N represents the number of cells in the crystal, and k_B represents the Boltzmann constant.

Higher-Order Elastic Constants

SOECs, TOECs, and FOECs at a given temperature provide the strain derivatives of F^0 and F^{vib}, which are determined by adding the vibrational contribution to the static elastic constants given by Brugger (1964):

$$C_{IJ}(T) = C^0_{IJ} + C^{\text{vib}}_{IJ}; C_{IJK}(T) = C^0_{IJK} + C^{\text{vib}}_{IJK}; C_{IJKL}(T) = C^0_{IJKL} + C^{\text{vib}}_{IJKL} \tag{9}$$

where the superscript "0" indicates the static elastic constant at 0 K and the superscript "vib" indicates the vibrational portion of the elastic constant at a certain temperature.

The classic rigid-ion model applied on NaCl structure (Borg and Dienes 1992), in which the interaction energy between the pair of atoms arises from changes in the wave functions as the atom approaches, has been examined. The resulting total energy, ϕ, for the interaction as a function of atom separation, r, is the sum of two components: a long range interaction (lr), i.e., Coulomb potential, $\phi(r_o)$, and short-range interaction (sr), i.e., Born-Mayer short-range repulsive potential, $\phi\left(\sqrt{2}r_o\right)$, which is given in general by

$$\begin{aligned}\phi(r) &= \phi_{lr}(r) + \phi_{sr}(r) = \phi(r) = \phi(r_o) + \phi\left(\sqrt{2}r_o\right) = \phi(r) \\ &= \pm\left(\frac{e^2}{r_o}\right) + A\exp\left(\frac{-r_o}{b}\right)\end{aligned} \tag{10}$$

where e denotes the electronic charge, $\pm$ sign for like and unlike ions, r_o is the nearest-neighbor distance, b denotes the hardness parameter, and A stands for strength parameter given by

$$A = -3b\frac{e^2}{r_o}S_3{}^{(I)}\frac{1}{6\exp(-\rho_o) + 12\sqrt{2}\exp\left(-\sqrt{2}\rho_o\right)}; \rho_o = r_o/b \tag{11}$$

Tables 1 and 2 (Mori and Hiki 1978) provide detailed formulations for the static and vibrational components of SOECs, TOECs, and FOECs.

Here,

$$\begin{aligned}x = h\omega_o/2k_BT, \omega_o^2 &= \left(\frac{1}{M_+} + \frac{1}{M_-}\right)\left(\frac{1}{Hbr_o}\right), \quad H \\ &= \left\{(\rho_o - 2)\phi(r_o) + 2\left(\rho_o - \sqrt{2}\right)\phi\left(\sqrt{2}r_o\right)\right\}^{-1}\end{aligned} \tag{12}$$

k_B is the Boltzmann's constant; h is the Planck's constant. The values of lattice sums are obtained taking into consideration the Coulomb interactions between all the ions in the crystal up to the second nearest neighbor.

Table 1 Static and vibrational terms associated with SOECs, TOECs, and FOECs

Static	Vibrational
Second-order elastic constants (SOECs)	
$C_{11}^{0} = \frac{3}{2}\frac{e^2}{r_o^4}S_5^{(2)} + \frac{1}{br_o}\left(\frac{1}{r_o}+\frac{1}{b}\right)\phi(r_0) + \frac{2}{br_o}\left(\frac{\sqrt{2}}{2r_o}+\frac{1}{b}\right)\phi\left(\sqrt{2}r_0\right)$ $C_{12}^{0} = C_{44}^{0} = \frac{3}{2}\frac{e^2}{r_o^4}S_5^{(1,1)} + \frac{1}{br_o}\left(\frac{\sqrt{2}}{2r_o}+\frac{1}{b}\right)\phi\left(\sqrt{2}r_o\right)$	$C_{11}^{vib.} = f^{(1,1)}G_1^2 + f^{(2)}G_2$ $C_{12}^{vib.} = f^{(1,1)}G_1^2 + f^{(2)}G_{1,1}$ $C_{44}^{vib.} = f^{(2)}G_{1,1}$

$$S_3^{(1)} = -0.58252; \quad S_5^{(2)} = -1.04622; \quad S_5^{(1,1)} = 0.23185$$
$$S_7^{(3)} = -1.36852; \quad S_7^{(2,1)} = 0.16115; \quad S_7^{(1,1,1)} = -0.09045$$

Using the above formulation, the SOECs, TOECs, and FOECs are computed in further chapters.

Pressure Derivatives

When a cubic crystal is subjected to higher hydrostatic pressure, the arrangement of the component of the crystal's specific structure is preserved. The idea of effective elastic constants is used to characterize nonlinear elastic characteristics, C_{IJ} (P). The Taylor series expansion explored by Birch (1947) yields the equations for the effective second-order elastic constants, C_{IJ}(P), as a function of pressure P. The first and second-order pressure derivative expressions are calculated.

$$C_{IJ..}(P) \approx C_{IJ..} + \frac{dC_{IJ..}(P)}{dP} P = C_{IJ..} + C'_{IJ..} P \tag{13}$$

The values of pressure derivatives, $C'_{IJ..}$, are computed using SOECs and TOECs as expressed in Table 3. It also lists the partial contractions of the FOECs calculated using these pressure derivatives.

Mechanical Properties

Elastic moduli give a macroscopic and global perspective of a material's stiffness. It reflects the interatomic bonding energies as well as the interatomic connections. Many of a crystalline material's mechanical and physical qualities are related to its elastic properties. The bulk modulus (B), shear modulus (G), Young's modulus (Y), and Poisson's ratio are all calculated elastic constants that are used to determine the crystal's reaction to external forces (v). These properties aid in the determination of material strength and are required for material characterization. The applied forces, which might be in the form of pressure or temperature, provide information regarding material structural changes.

The three independent elastic constants are linked to elastic moduli in Table 4 for single crystals that are elastically anisotropic. Single crystal elastic constants values are further used to compute polycrystalline properties under Voigt (V), Reuss (R), and Hill (H) approximation (Voigt 1966; Reuss 1929; Hill 1952).

Table 3 Pressure derivatives expressed as a function of SOECs and TOECs

First-order pressure derivatives	Second-order pressure derivatives
$\frac{dC_{11}}{dP} = (2C_{11} + 2C_{12} + C_{111} + 2C_{112})/C_A$ $\frac{dC_{12}}{dP} = (-C_{11} - C_{12} + 2C_{112} + C_{123})/C_A$ $\frac{dC_{44}}{dP} = -(C_{11} + 2C_{12} + C_{44} + C_{144} + 2C_{166})/C_A$	$\frac{d^2C_{11}}{dP^2} = \left[(1+3C_B)C_{11} + (4+3C_B)(C_{111} + 2C_{112}) + C_{1111} + 4C_{1112} + 2C_{1122} + 2C_{1123}\right]/(C_A)^2$ $\frac{d^2C_{12}}{dP^2} = [(1+3C_B)C_{12} + (4+3C_B)(2C_{112} + C_{123}) + 2C_{1122} + 5C_{1123}]/(C_A)^2$ $\frac{d^2C_{44}}{dP^2} = \left[(1+3C_B)C_{44} + (4+3C_B)(C_{144} + 2C_{166}) + C_{1144} + 2C_{1155} + 4C_{1255} + 2C_{1266}\right]/(C_A)^2$
$\frac{dC_{111}}{dP} = -(-3C_{11} - 6C_{12} + 3C_{111} + C_{1111} + 2C_{1112})/C_A$ $\frac{dC_{112}}{dP} = -(C_{11} + 2C_{12} + 3C_{112} + C_{1112} + C_{1122} + C_{1123})/C_A$ $\frac{dC_{123}}{dP} = -(-C_{11} - 2C_{12} + 3C_{123} + 3C_{1123})/C_A$ $\frac{dC_{144}}{dP} = -(C_{11} + 2C_{12} + 3C_{144} + C_{1144} + 2C_{1255})/C_A$ $\frac{dC_{166}}{dP} = -(-C_{11} - 2C_{12} + 3C_{166} + C_{1166} + 2C_{1255})/C_A$ $\frac{dC_{456}}{dP} = -(-C_{11} - 2C_{12} + 3C_{456} + 3C_{1456})/C_A$	Where $C_A = \frac{1}{(C_{11}+2C_{12})}$ $C_B = (4C_{11} + C_{111} + 6C_{112} + 2C_{123})/C_A$ $Y_{11} = C_{1111} + 4C_{1112} + 2C_{1122} + 2C_{1123}$ $Y_{44} = C_{1144} + 2C_{1155} + 4C_{1255} + 2C_{1266}$ $Y_{12} = 2C_{1112} + 2C_{1122} + 5C_{1123}$

Table 4 Elastic moduli for the symmetrical cubic crystal

Elastic properties	Formulae	Definition
Isotropic shear modulus	$G = (G_V + G_R)/2$ where, $G_V = (C_{11} - C_{12} + 3C_{44})/5$ $G_R = 5[(C_{11} - C_{12})C_{44}]/[4C_{44} + 3(C_{11} - C_{12})]$	It shows the relation between shear stress and shear strain. G_V is Voigt's shear modulus corresponding to the upper bound of G values, and G_R is Reuss's shear modulus corresponding to the lower bound of G values
Bulk modulus	$B = (C_{11} + 2C_{12})/3$	It provides a good link between the macroscopic elasticity theory and the atomistic viewpoints such as lattice dynamics
Young's modulus	$Y = \frac{9GB}{G+3B}$	It relates a unidirectional stress to the resultant strain and defines the stiffness of the materials
Poisson's ratio	$\nu = (3B - 2G)/(6B + 2G)$	It is defined as the ratio of lateral contraction to the longitudinal extension
Anisotropic ratio	$A = 2C_{44}/(C_{11} - C_{12})$	It represents the ratio of two elastic-shear coefficients extremes
Tetragonal shear modulus	$C_s = C_{44}$ for shear on <100> $C_S = \left(\frac{C_{11}-C_{12}}{2}\right)$ for shear on <110>	

Born Stability Criteria

For an unstrained cubic crystal to be mechanically stable, the elastic stability criteria given by Born (1940) must be satisfied. It is necessary that the following inequalities must be fulfilled for the representation of free energy by positive defined quadratic form.

$$C_{11} + 2C_{12} > 0, C_{44} > 0, C_{11} - C_{12} > 0 \tag{14}$$

Cauchy's Relations

The Cauchy's relation for elastic constants in cubic crystals has been confirmed (Cousins 1971) and is true only if:

1. The forces of contact between the atoms or molecules of a crystal are central forces, as in rock salt.
2. Each atom or molecule is the point of symmetry.
3. A harmonic potential can be used to represent the interaction forces between the building pieces of a lattice vibration in a crystal.

These relations for SOECs and TOECs of a cubic crystal are defined by Cousins (1967)

$$C_{12} = C_{44}; C_{112} = C_{166}; C_{123} = C_{456} = C_{144} \tag{15}$$

Generally, Cauchy's relations hold good at 0 K.

Elastic Waves in Anisotropic Materials

Elastic waves produced by mechanical vibrations of material media under applied stress are the consequence of collective vibrations of the medium's atoms and molecules. The magnitude of interatomic forces helps in determining the vibration properties of the medium's atoms and molecules. For solids with varied structures, the nature of these forces and, as a result, their wave propagation properties are variable. The materials chosen in our case are of rock-salt type (face-centered cubic). The computed elastic constants are related to the velocities of acoustic plane waves using the approach as suggested by investigators (Blackman 1955; Thurston and Brugger 1964) which are either pure longitudinal or pure transverse and are only propagated in the principal symmetry directions <100>, <110>, and <111> for cubic materials. The ultrasonic velocities in different crystallographic directions are computed using the classical linear theory of elasticity; the solution of equation of motion given by Eq. (16) for a freely vibrating body (Bedford and Drumheller 1994) for elastic wave propagation in a homogeneous anisotropic solid is obtained and listed in Table 5.

Table 5 Ultrasonic velocities along three crystallographic directions

Direction of wave propagation	Polarization direction	Wave mode	Expression
<100>	<100>	Longitudinal	$V_L = \sqrt{\frac{C_{11}}{\rho}}$
	<010>	Shear	$V_{S1} = \sqrt{\frac{C_{44}}{\rho}}$
	<001>	Shear	$V_{S2} = \sqrt{\frac{C_{44}}{\rho}}$
<110>	<110>	Longitudinal	$V_L = \sqrt{\frac{C_{11}+C_{12}+2C_{44}}{2\rho}}$
	<001>	Shear	$V_{S1} = \sqrt{\frac{C_{44}}{\rho}}$
	< 1−10 >	Shear	$V_{S2} = \sqrt{\frac{C_{11}-C_{12}}{2\rho}}$
<111>	<111>	Longitudinal	$V_L = \sqrt{\frac{C_{11}+2C_{12}+4C_{44}}{3\rho}}$
	< −110 >	Shear	$V_{S1} = V_{S2} = \sqrt{\frac{C_{11}-C_{12}+C_{44}}{3\rho}}$

$$\sigma_{ij,j} = \rho \ddot{u}_i \tag{16}$$

where $\ddot{u}_i$ indicates the partial derivative of displacement with respect to time and $\sigma_{ij,\,j}$ is the partial derivative of stress with respect to coordinate index j and ρ is the density of medium given by

$$\rho = \frac{nM}{N_a a^3} \tag{16a}$$

where, n, number of atoms per unit cell with $n = 2$ for body-centered cubic (bcc); $n = 4$ for fcc and $n = 8$ for diamond lattices; N_a, Avogadro's number; M, molecular mass, respectively.

Anisotropic materials can propagate both shear and longitudinal waves. The propagation velocities through such media are determined by the orientations of the stresses in relation to the medium's directions. It's worth noting that (a) the two shear waves degenerate into the same velocity in some directions, and (b) the shear wave in some wave guides is actually torsional in nature, with only one torsional wave velocity because the torsional mode automatically averages the stress in two perpendicular directions.

This also aids in the calculation of the Debye average velocity, Vm, which is a crucial parameter in determining thermal characteristics such as Debye temperature and thermal relaxation time of materials (Singh et al. 2011; Mason and Rosenberg 1966). The Debye average acoustic velocity is given along <100> and <111> directions by

$$V_m = \left[\frac{1}{3}\left\{\frac{1}{V_L^3} + \frac{2}{V_{S1}^3}\right\}\right]^{-1/3}; \; V_{S1} = V_{S2}$$

and along <110> direction

$$V_m = \left[\frac{1}{3}\left\{\frac{1}{V_L^3} + \frac{2}{V_{S1}^3} + \frac{1}{V_{S2}^3}\right\}\right]^{-1/3}; \; V_{S1} \neq V_{S2} \tag{17}$$

The Debye temperature (θ_D) is used to explain several lattice thermal processes and to define phonon excitation. θ_D correlates with several physical characteristics of solids, such as specific heat, elastic constants, and melting temperature, as an important parameter. Acoustic vibrations are the only source of vibrational excitation at low temperatures. As a result, the Debye temperature derived using elastic constants is the same as that predicted from specific heat measurements at low temperatures (almost at room temperature).

$$\theta_D = \frac{\hbar}{k_B}\left[\frac{3n}{4\pi}\left(\frac{N_a \rho}{M}\right)\right]^{1/3} V_m \tag{18}$$

where, n, number of atoms in the molecule and $\hbar = h/2n$.

Breazeale's Nonlinearity Parameter, β

The waveform distortion caused by ultrasonic waves travelling through a solid substance is induced by the medium's microstructural characteristics. The existence of three types of acoustic modes for a given direction of wave propagation in an anisotropic material is known from section "Elastic Waves in Anisotropic Materials." The harmonic production may be distinguished using the numerous interaction mechanisms of these acoustic waves. The nonlinearity of the component's material, which is characterized by a nonlinear stress–strain relationship, causes harmonic production. A nonlinearity parameter, β, can be used to quantify the degree of nonlinearity present in a material. Theoretically, it constitutes a separate material characteristic and is characterized in terms of HOECs from the nonlinear stress–strain relationship.

It characterizes the simple harmonic generation of longitudinal waves given by the negative ratio of non-linear term to the linear term in the nonlinear wave given by Philip and Breazeale (1983):

$$\beta = -(3K_2 + K_3)/K_2 \tag{19}$$

where K_2 and K_3 are linear combination of SOECs and TOECs, respectively, given in Appendix A.

Grüneisen Parameters

Grüneisen parameters (GP), which describe the relative strain dependence of elastic wave velocity and shed additional light on the thermal and mechanical characteristics of materials, are used to investigate the anharmonicity of a crystal lattice. It aids in the description of characteristics such as lattice-specific heats at high temperatures, thermal conductivity, thermal expansion, temperature fluctuation of elastic constants, and so on. The Grüneisen parameters define the phonon contribution to a variety of anharmonic solid characteristics such as lattice specific heat, thermal expansion, thermal conductivity, and so on. These parameters are represented as different weighted averages of the first-order Grüneisen tensor (Nava and Romero 1978).

$$\gamma^j_{\alpha\beta} = -\omega_i^{-1}\partial\omega_i(q)/\partial\eta_{\alpha\beta} \tag{20}$$

where ω, angular frequency, and $\eta_{\alpha\beta}$ are the six strain components ($\alpha, \beta = 1, 2, 3$). For instance, the thermal expansivity is relative to the specific heat weighted,

$$< \gamma_{\alpha\beta} >= \sum_{q,j} C_{q,i}\gamma^j_{\alpha\beta} / \sum_{q,i} C_{q,i} \tag{21}$$

Thermal conductivity weighted averages of the product may be used to represent the thermal Grüneisen parameters, γ, and the ultrasonic attenuation's (shear) Grüneisen parameter. Brugger (1965) calculated the components of the Grüneisen tensor in terms of SOECs and TOECs for anisotropic elastic continuum. Appendix B contains formulae for Grüneisen parameters (Klemens and Mason 1965) in various crystallographic orientations.

Ultrasonic Attenuation

The energy is dissipated by numerous mechanisms such as absorption, diffraction, and scattering as the ultrasonic wave passes through the object. The reasons for attenuation may be divided into two categories.

First is the scattering caused by discontinuities at grain boundaries, phonon-phonon (p–p) scattering, electron-phonon (e–p) scattering, inclusions, etc. Secondly, the absorption of ultrasound may be explained on the basis of thermoelastic effects, dislocation damping due to screw and edge dislocations, ferromagnetic effects, relaxation, and the effects of neutrons and electrons upon the sound beam. Scattering effects are generally much greater than the absorption effects.

The study of ultrasonic attenuation in crystals as a function of temperature is a useful tool for understanding the process of ultrasonic wave interaction with crystal lattice and intrinsic characteristics of all sorts of substances, including metallic, covalent, semiconducting, and dielectric crystals. The knowledge regarding the interaction of ultrasonic waves with individual phonons in the region $\omega\tau_{th} \ll 1$ (Mason 1967), where ω is the angular frequency and τ_{th} is the thermal relaxation time, may be deduced from variations in ultrasonic attenuation as a function of temperature.

Attenuation Due to e–p Interaction

The exchange of energy happens in metals free electrons and interacting lattice, according to Debye's theory of specific heat at low temperatures. At high temperatures, the electron mean free path is not equivalent to phonon wavelength; hence there will be no attenuation owing to electron-phonon interaction. The e–p interaction is very important for studying the optical and electronic properties. It is also responsible for many phenomena such as Kohn effect, temperature-dependent electrical resistivity, conventional superconductivity, etc. The ultrasonic attenuation of the wave becomes important for study below 100 K. Further, at extreme lower temperature along with other factors, dislocation losses vanish. Only e–p interaction remains effectual. In present case all the investigations have been done at 100 K. So, there is no consideration of e–p interaction in the chosen materials.

Attenuation Due to p–p Interaction

Akhiezer (1939) proposed this type of theory for the first time in the region ($\omega\tau_{th} \ll 1$) which was later simplified by Bömmel and Dransfeld (1960), and more complete version for the case $\omega\tau_{th} \gg 1$ was considered by Woodruff and Ehrenreich (1961). Finally, Mason (1967) enunciated the simplest form of this theory. He introduced the usage of Grüneisen parameters, $< \gamma_i^j >$, which has been already explained in section "Grüneisen Parameters." When the stress is applied, the non-equilibrium separation of phonon modes takes place. Thus, the change in elastic constants occurs and the ultrasonic attenuation, α, is given by

$$\alpha = \frac{\Delta C \omega^2 \tau_{th}}{2\rho V^3 (1 + \omega^2 \tau_{th})} \tag{22}$$

When the strain, S_j, is applied, the changes occur in the frequency of propagation mode given by

$$\omega_i = \omega_{io} = \left(1 - \sum\nolimits_{j=1} \gamma_i^j S_j\right) \tag{23}$$

We get, on differentiation

$$\gamma_i^j = -\frac{\partial \omega_i / \partial S_j}{\omega_{io}} \tag{24}$$

The thermal energy associated with the modes considering Debye approximation theory is

$$U_{th} = 3\hbar \sum\nolimits_i \frac{N_i}{\omega_{gi}^3} \int_0^{\omega_{gi}} \frac{\omega^3 d\omega}{e^{\hbar\omega/k_B T} - 1} \tag{25}$$

On performing differentiation on the total elastic energy and sum of thermal energy of all modes, we get

$$T_j = \left[C_{ij}^0 + 3 \sum\nolimits_l E_i \left(\gamma_i^j\right)\right] S_j + 3 \sum\nolimits_l E_i \gamma_i^j \tag{26}$$

where T_j represents the stress corresponding to the strain, S_j. E_i is the thermal energy associated with the mode propagating along a particular direction. The increase in elastic moduli is observed given by

$$\begin{aligned} \Delta C &= 3 \sum E_i \left(\gamma_i^j\right)^2 \quad \text{for shear modes} \\ \Delta C &= \left[3 \sum E_i \left(\gamma_i^j\right)^2 - \gamma^2 CT\right] \quad \text{for longitudinal modes} \end{aligned} \tag{27}$$

Using this value of ΔC in Eq. (22)

$$\alpha = \frac{\omega^2 \tau_{th} E_o (D/3)}{2\rho V^3 \left(1 + \omega^2 \tau_{th}^2\right)} \tag{28}$$

The expressions for calculating ultrasonic attenuation due to p–p interaction [$(\alpha/f^2)_L$ and $(\alpha/f^2)_S$] using Eq. (28) are

$$\left(\alpha/f^2\right)_L = \frac{2\pi^2 \tau_{th} E_0 D_L}{3\rho V_L^3}; \quad \left(\alpha/f^2\right)_s = \frac{2\pi^2 \tau_{th} E_0 D_S}{3\rho V_S^3} \tag{29}$$

where α is the ultrasonic attenuation constant, f denotes frequency of the ultrasonic wave, ρ is the density, V is the sound wave velocity, V_L and V_S are the ultrasonic velocities for longitudinal and shear waves, respectively, E_0 is the thermal energy density, κ is the thermal conductivity, and γ_i^j denotes Grüneisen number (i, j are the mode and direction of propagation, respectively). D, the acoustic coupling constant, is the change in elastic modulus caused by strain given by

$$D = 9\left\langle \left(\gamma_i^j\right)^2 \right\rangle - \frac{3\left\langle \gamma_i^j \right\rangle^2 C_v T}{E_0} \tag{30}$$

where C_v is the specific heat per unit volume and τ_{th}, the thermal relaxation time for the exchange of acoustic and thermal energy given by Herring (1954) which is

$$\frac{1}{2}\tau_L = \tau_S = \tau_{th} = \frac{3\kappa}{C_v V_m^2} \tag{31}$$

where κ is the thermal conductivity. Both C_v and E_0 are function of θ_D/T, which differ by a numerical factor and are obtained by AIP Handbook (Gray 1972). As a result, the major mechanisms that will raise the attenuation considerably above 50 K and higher include p–p interaction, dislocation damping, and thermoelastic loss. At room temperature, the p–p interaction is the dominant source of ultrasonic attenuation in all types of materials, including metallic, semiconducting, and dielectrics (Barrett and Holland 1970; Jyoti et al. 2021).

Loss Due to Thermoelastic Mechanism

When compared to total attenuation, thermoelastic loss causes very little attenuation. The p–p interaction causes the energy loss of ultrasonic waves, which may be calculated using Mason's method (1967). Hysteresis absorption is caused by the p–p interaction. Determining the thermal phonon relaxation time is therefore of importance. The propagation of an acoustic phonon and the re-establishment of the equilibrium as the relaxation phenomena have been postulated to yield the equilibrium distribution of phonons in a crystal.

The thermal phonons may be thought of as a fluid with a viscosity that results in f^2 absorption when the sound wavelength is substantially longer than the mean free path of the thermal phonons in the material. The requirement for this conclusion to hold owing to thermoelastic relaxation $(\alpha/f^2)_{th}$ process may also be expressed as

$$\left(\alpha/f^2\right)_{th} = \frac{4\pi^2 < \gamma_i^j >^2 \kappa T}{2\rho V_L^5} \quad \omega\tau_{th} \ll 1 \tag{32}$$

The total attenuation is given by

$$\left(\alpha/f^2\right)_{\text{Total}} = \left(\alpha/f^2\right)_{\text{Akhiezer}} + \left(\alpha/f^2\right)_{th} \tag{33}$$

Attenuation Due to Dislocation Damping

Dislocation damping, a process that has been proven to be beneficial in metals and rocks, is the last of the potential mechanisms to be addressed here. Absorption may be caused by dislocations in four different ways:

- The dislocation length's resonance absorption. This loss is dependent on f^2.
- A dislocation relaxation process (Bordoni loss), which is f dependent as well.
- A dislocation breaking away from the impurity pinning locations causes a strain-dependent hysteresis loss.
- The mobility of kinks in the dislocation length causes a strain-independent hysteresis loss.

Due to the thermal mechanism in the crystal, dislocations are subjected to phonon viscosity damping effects (Mason 1960). The viscosity of phonons contributes directly to acoustic attenuation and indirectly to dislocation motion damping given by

$$\eta = \frac{E_0 \kappa}{C_v V_m^2} \tag{34}$$

The dislocation, also known as the linear imperfection in a crystal, is made up of a combination of screw and edge dislocations. In the literature (Mason and Rosenberg 1966), the dislocation damping due to screw and edge dislocations has been computed.

$$B_{\text{screw}} = 0.071\eta \text{ and } B_{\text{edge}} = \left(0.0532\eta + 0.0079(\mu/B)^2\chi\right)/(1-\nu)^2 \tag{35}$$

where ν, μ, B, χ and η are Poisson's ratio, shear modulus, bulk modulus, and compressional viscosity.

Thermal Conductivity

Understanding the thermal conductivity of crystal lattice is critical for improving thermoelectric and optoelectronic device performance. Thermal conduction in a material refers to the rate of heat flow between opposing sides of an infinite slab with a 1 K temperature differential and is defined as the rate at which heat flows through phonon transport in a temperature gradient. It is reliant on the interatomic potential's anharmonicity (Ashcroft and Mermin 1976).

It is important to have a better knowledge of the thermal characteristics of rare-earth materials. Low thermal conductivity materials are required in thermal barrier coatings (for gas turbines) and thermoelectrics, for example. Thermal anisotropy is also required for heat spreading applications such as electronic packaging and magnets. To determine the magnitude and temperature dependence of lattice thermal conductivity, a simple model of lattice heat conduction proposed by Slack (1973, 1979) and Berman (1976) was used to estimate the magnitude and temperature dependence of thermal conductivity, which takes the form

$$\kappa = A.\frac{\overline{M_a}\theta_D^3 \delta n^{1/3}}{\gamma^2 T} \tag{36}$$

where δ (in Å) is the volume per atom, $A = 3.04 \times 10^{-8}$, n is the number of atoms in a molecule, γ is the Grüneisen constant, $\overline{M_a}$ (in amu) is the average atomic mass, and T is the temperature (in K).

Furthermore, the thermal conductivity of materials is related to the ultrasonic wave velocity associated with lattice vibration. As a result, the lattice's lowest thermal conductivity along with various crystal orientations (Cahill et al. 1992) is given by

$$\kappa_{\min} = \frac{k_B}{2.48} q^{2/3}(V_L + V_{S1} + V_{S2}) \tag{37}$$

where "q" is the atomic number per unit volume. This property is important when the material is subjected to thermal stresses and optical distortions. The thermal conductivity helps in obtaining the values of thermal relaxation time (τ_{th}) which is directly proportional to ultrasonic attenuation. It also provides base for calculation of dislocation damping coefficient due to screw and edge dislocations.

Computational Analysis

All computed data have an inherent uncertainty or error associated. Adapting to the good scientific practices assists in recognizing these limitations and, thus, providing a clear indication of the precision and reliability involved in any procedure. The correct interpretation of the measured or computed results requires knowledge about its uncertainty. The size of the uncertainty from each source with random error in the data is estimated and has been listed in Tables 6 and 7.

Table 6 Elastic constants for PrN and NpAs at different temperature range (in GPa)

Elastic Constants

The variation of SOECs with temperature has been examined, and it has been discovered that C_{11} and C_{44} increase while C_{12} decreases as temperature rises. The variability in atomic interactions with temperature causes the elastic constant to increase or decrease, similar to what is observed in B_1 structured materials (Kumar et al. 2012).

SOECs of Group IIIrd Phosphides

The SOECs are calculated using a method that has been described in literature (Bhalla et al. 2013). The deviations between the estimated values of elastic constants using the current approach and previously published values are listed in Table 7. This discrepancy is due to changes in the methods used to estimate elastic properties; nonetheless, the similarity in order validates the viability of our method for calculating elastic constants using the basic interaction potential model approach.

Ultrasonic Velocity

Table 8 shows the computed longitudinal and shear elastic wave velocities in the temperature range 100–500 K. The ultrasonic velocity is directly proportional to SOECs and density (Singh et al. 2011).

Grüneisen Parameters

The ultrasonic Grüneisen parameters (UGPs) are determined using SOECs and TOECs for various modes and vary depending on the combined effect of the elastic constants and the material's molecular weight. It is important in the study of materials with anharmonic characteristics. Physical characteristics of materials such as thermal expansion, thermal conductivity, and temperature fluctuation of elastic constants are described. The resulting values of average UGPs are observed to vary very little with increasing molecular weight, although the average squares of the Grüneisen parameters decrease as molecular weight increases (Table 9).

Table 8 Ultrasonic velocities V_L and V_S of TbP (all in the units of 10^3 m/s)

	<100>	
Temp (K)	V_L	$V_{S1}=V_{S2}$[a]

Current Applications

Currently, the rare-earth elements and compounds are generating lot of interest among scientists and technology developers because of their very important role in green applications. There are numerous areas where rare-earth is being used for increasing the efficiency and enhancing the properties of the samples.

Area	Application
Electronics and technology	Optoelectronic devices, semiconductors, silicon chips, high-temperature superconductors, computers, and cell phones
Renewable and thermal energy	Electrothermal energy storage (ETEs), hybrid automobiles, rechargeable batteries

Conclusion

The data obtained in the research work provides a better insight to the properties of RE materials. It enables for further research into prospective industrial applications such as nondestructive testing (NDT), thermal conductors and insulators, spintronics, device fabrication, high-temperature materials, electronic industry, scientific research, and experimentation. The preliminary results of this study can be

used for further experimental investigation using the pulse echo overlap (PEO) technique for ultrasonic measurements, as well as traditional analytical techniques such as polarizing microscopy, surface tension analysis, solid-state nuclear magnetic resonance (NMR), scanning electron microscopy (SEM), X-ray diffraction (XRD), and transmission electron microscopy (TEM) add a whole new dimension to the study of the material.

In the future, the fundamental properties of these monopnictides and monochalcogenides will be widely used in the construction of hybrid devices, such as high-energy spectroscopy, hybrid automotive engines, laser sources, television screens, and electronic industries, among other things.

Abstract

This chapter presents different types of hardness test method, and calibration of testing machines (both direct and indirect method). Conventional static hardness methods (Brinell, Rockwell and Vickers) and dynamic Leeb rebound hardness with corresponding uncertainty calculation is discussed in this chapter. The recent advance of instrumented hardness is also presented and its important m and field of application.

Introduction

Hardness is the resistance of the material to plastic deformation induced by indentation. Hardness test is considered the most rapid test and the most popular test used for mechanical properties of materials. Types of hardness are classified as shown in Fig. 1. The conventional indentation hardness methods (Brinell, Rockwell, and Vicker) were introduced in the early part of the twentieth century. These hardness methods became the most useful tool for quality control for products in industry and testing property of materials (Mohamed 2014; Mohamed 2008). The testing method for the three scales of hardness test is fundamentally similar. An indenter with specific shape for each method is brought into contact with the material to be tested; then apply a specific test force to the indenter until the indenter makes a permanent deformation in the tested material. The resulting indentation is measured by a specific method for each scale. Brinell and Vickers hardness tests are based on measuring the area of area of the indentation after the removal of the test force. The Rockwell hardness test is based on measuring the depth of the indentation. The classification of the hardness methods is shown in Fig. 1.

To determine dynamic hardness, the indenter is forced under high loading rate which leads to impact or chock the test material. Thus, the indenter could be shot the tested material like a projectile onto the target surface (Low 2006; El-Ezz 2007). The

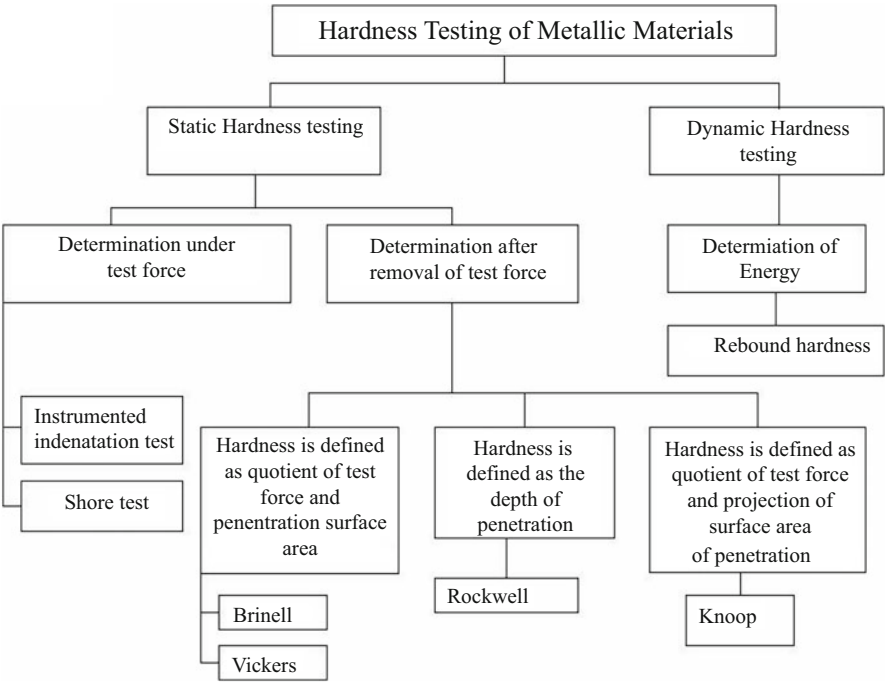

Fig. 1 Classifications of hardness

test material must be permanently deformed, so the kinetic energy should be chosen to assure plastic deformation of tested material. The dynamic hardness value depends on the measured quantities like impact energy, impact velocity, impact momentum, time of collision, deformation energy, indentation size, rebound energy, etc.

Metrological Chain for Hardness Test

There are four levels in the metrological chain as shown in Fig. 2.

International Level

The first and highest level which starts the metrological chain. International comparisons for different hardness scales are carried out.

National Levels

Primary hardness reference blocks are calibrated by the primary hardness machines in the national level, at the National Metrology institutes. The primary hardness

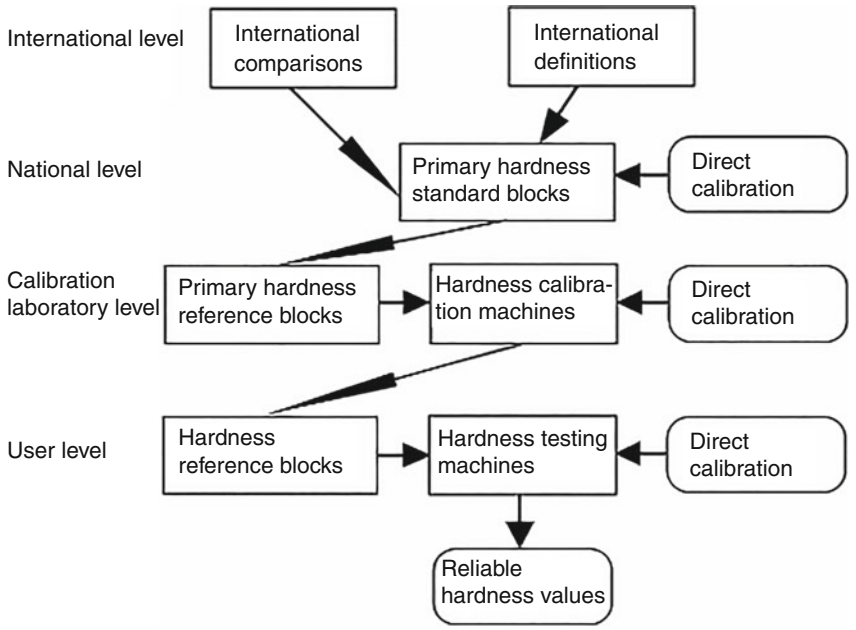

Fig. 2 Metrological chain for the definition and transmission of the hardness scales (Herman 2011)

machines are calibrated by direct method, and international comparisons are used to check and verify the behavior and accuracy of the primary machines.

Calibration laboratory level: The hardness reference blocks are calibrated at the calibration laboratories by calibration machines calibrated by direct and indirect methods to achieve traceability to the national standards.

User level: The hardness reference blocks which calibrated at calibration laboratory level are used in the user level to check the performance of the hardness testing machines used in the industry and other fields at user level (Germak et al. 2010; Herrmann et al. 2004a).

The Main Structure of Primary Hardness Testing Machine

Basically, a dead weight hardness testing machine consists of the following:

1. Machine structure
   (a) Test load values (dead weights). The load generation system (dead weights) should be traceable to the primary standard of mass in kilogram and local value of acceleration due to gravity in meter/sec2 within the range of uncertainty of ± 100 ppm.
   (b) Supporting frame (fixed frame). The supporting frame should be rigid enough to resist buckling due to the compressive load.
   (c) Load selection system. It is a simple system used to select the desired load values.
2. Indentation measuring system. It measures the produced impression due to applied load.
3. Control system. It aims to control test cycle through controlling the test time and speed of indentation, etc. (Properties of engineering materials 2004; Shigley and Mischke 1996; Thomas and Brown 2005; Lingaiah 2002; Herrmann et al. 2004b; ISO/DIS 7500–1 2016).

Conventional Static Hardness Methods

Direct Calibration

In direct calibration of the three conventional hardness machines (Brinell, Vickers, and Rockwell), the main influencing parameters of the hardness testing machines shall be calibrated (ISO 6508-1 2016; ISO 6506-1 2014; ISO 6507-1 2018; ASTM 2017a, b, c); these influencing parameters are as follows:

- Force calibration.
- Measuring system.
- Verification of the indenter geometry.
- Verification of the testing cycle.

Direct verification should be carried out under controlled environmental conditions at a temperature of (23 ± 5) °C (ISO 6507-2 2018; ISO 6506-2 2014; ISO 6508-2 2016; ES-5178-1 2016; ES-5179-1 2016; ES-5180-1 2016).

Force Calibration

The calibration of force shall be carried out by force proving instrument with class 1 or better according to ISO 376 (ISO 376 2011), and the instrument used for force calibration shall be traceable to national standards. Each force in the Brinell, Vickers, and Rockwell scale shall be calibrated by three measurements for each force at least at three positions of the indenter movement (ASTM 2017c; ISO 6507-2 2018; ISO 6506-2 2014; ISO 6508-2 2016).

Each measurement shall not deviate by more than ±1% of the nominal test force for Brinell hardness (ISO 6506-1 2014), and each force measurement in the Vickers hardness shall not exceed the tolerance limit given in Table 1 (ISO 6506-2 2014).

For Rockwell hardness scale, each preliminary force F_0 shall be calibrated, and the tolerance of measurement shall be ±2%, and the tolerance of the total force F shall be ±1% (ISO 6506-2 2014).

Calibration of Measuring System for Brinell Hardness

The measuring system of the hardness machines is based on two measuring criteria: the first depends on measuring the length of diameter indentation and the other depends on calculating the diameter from the projected area.

For diameter measurement system, each objective lens shall be calibrated by using the standard scale. The measuring system of diameter shall be graduated to allow the measuring diameter to be within ±0.5%. Minimum of four intervals shall be measured in each working range. The difference between each measurement and the reference value is not greater than 0.5% using eq. 1

$$\Delta L_{rel} = \frac{\overline{L} - L_{RS}}{L_{RS}} \tag{1}$$

where ΔL_{rel} is the relative deviation.

$\overline{L}$ is the measured mean value.
L_{RS} is the reference value.

For systems which measure the projected area, every objective length shall be calibrated. At least four standard circular reference images covering the range of areas are measured. The maximum error shall not exceed 1%.

Table 1 Tolerances of Vickers scale test force

Ranges of test force F, N	Tolerance %
F ≥ 1.961	±1
0.09807 ≤ F >1.961	±1.5

Table 2 Resolution and the maximum permissible error for Vickers measuring system

Diagonal length mm	Resolution of measuring system mm	Maximum permissible error mm
$d \leq 0.040$	0.0002 mm	0.0004 mm
$0.040 > d \leq 0.200$	0.5% of d	1% of d
$d < 0.200$	0.001 mm	0.002 mm

Table 3 The tolerance of the ball indenters

Ball diameter mm	Tolerance mm
10	0.005
5	0.004
2.5	0.003
1	0.003

Calibration of the Measuring System for Vickers Hardness

The resolution of the measuring system must be suitable for measuring the diagonal of the smallest indentation. Table 2 shows the minimum resolution and the maximum permissible error, and for measuring the diagonals of the indentation, each objective lens shall be calibrated by using the standard scale. A minimum of five intervals on the working range shall be verified.

Calibration of Depth Measuring System for Rockwell Hardness

The depth measuring system shall be verified using gauge block and shall have a maximum expanded uncertainty of 0.0003 mm. A minimum of four increments through the full range of the depth shall be measured. The working depth is 0.25 mm for regular Rockwell scales (A, C, D, B, E, F, G, H, K) and 0.1 mm for superficial Rockwell scales (N, T). The depth measuring system must indicate within ± 0.001 mm for the scales A to K and within ± 0.0005 mm for scales N and T, i.e., within ± 0.5 of a scale unit, over each range.

Brinell Ball Indenter Verification

To verify the size of the ball indenter, the minimum average measurement of three readings must be within the specified values given in Table 3.

Hardness: The ball shall be tested in accordance with ISO 6507-1. The hardness shall be not less than 1500 HV.

The tungsten carbide composite ball can be tested directly on its spherical surface or by sectioning the ball and testing on the ball interior.

b) Density: $\rho = (14{,}8 \pm 0{,}2)$ g/cm3.

Verification of the Diamond Vickers Indenter Geometry

The shape and dimension of the indenter geometry can be verified by direct measurement or by using profile projector and measure these dimension on its projection on the screen.

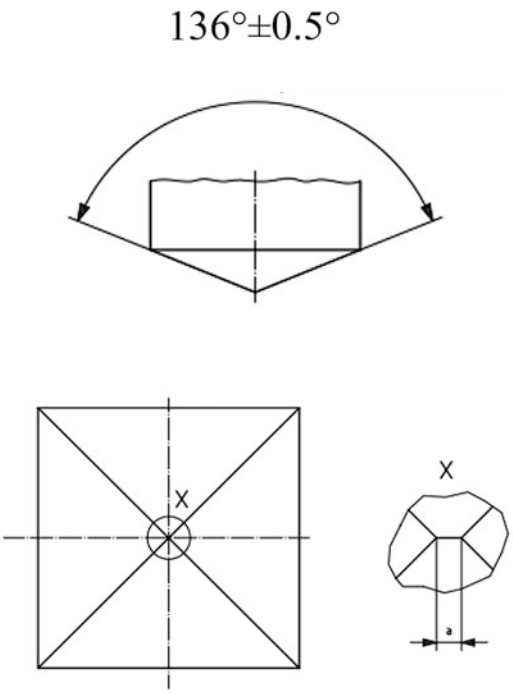

Fig. 3 Vickers indenter geometry

Table 4 Maximum length of line of conjunction

Range of the test force	Maximum permissible length of the line of conjunction a mm
F ≥ 49.03	0.002
1961 ≤ F <49,03	0.001
0,098 07 ≤ F <1961	0.0005

The angle between the opposite faces of the diamond pyramid shall be 136° ± 0.5 as shown in Fig. 3.

The angle between the axis of the indenter and the indenter-holder (normal to the seating surface) shall be less than 0.5 degree. The four faces shall meet at a line with maximum permissible length (a) shown in Table 4.

Direct Calibration and Verification of the Rockwell Diamond Indenter

The verification shall be done at a minimum of four unique equally spaced axial planes.

The instruments used for verification of the diamond indenter geometry shall have expanded uncertainty of 0.1° for the angle and 0.005 mm for the radius. The diamond cone shall have an included angle of (120 ± 0.35)°. The tip end of the indenter must be in a spherical shape. The radius of the spherical shape for each

single value shall be within (0.2 ± 0.015) mm. The mean value shall be within (0.2 ± 0.01) mm. Local deviations from a true radius shall not exceed 0.002 mm.

Verification of Testing Cycle

The testing cycle of the hardness machine shall be verified at the time of the manufacturing, at the failure of the indirect calibration, when the indirect calibration exceeds 13 months, and when any maintenance or repairs are done on the machine which may affect the testing cycle.

The testing cycle shall not differ from the reference value by more than 1 sec.

Uncertainty of Measurements

Uncertainty of the Test Force The combined uncertainty of force measurement is calculated from eq. 2

$$u_F = \sqrt{u_{FRS} + u_{FHTM}} \tag{2}$$

where:

$\mathbf{u_{FRS}}$ is the relative standard uncertainty of measurement of the force transducer (from calibration certificate).

$\mathbf{u_{FHTM}}$ is the relative standard uncertainty of the test force generated by the hardness testing.

machine.

F_{RS} (Nominal Test fFrce).

The calculation of force measurements is shown in Table 5.

where SF_i is the standard deviation of the force measurement at each position (European Co-operation for accreditation 2002; Herrmann 2016; Brice et al. 2003a, b).

Max u_{FHTM} for the three positions in Table 5 is used in the calculation of the uncertainty in Table 6.

Expanded uncertainty

$$U_F = K \times \sqrt{u_{FRS} + u_{FHTM}} \tag{3}$$

Table 5 Measurement of force calibration

Test force calibration at different position	Reading 1 F1 N	Reading 2 F2 N	Reading 3 F3 N	Mean value $\overline{F}$ N	Relative deviation ΔF_{rel} %	Relative standard uncertainty u_{FHTM}
1	F11	F12	F13	$\overline{F1}$	$\frac{\overline{F1}-F_{RS}}{F_{RS}} \times 100$	$\frac{SF_1}{\overline{F1}} \times 100 \times t$
2	F21	F22	F23	$\overline{F2}$	$\frac{\overline{F2}-F_{RS}}{F_{RS}} \times 100$	$\frac{SF_2}{\overline{F2}} \times 100 \times t$
3	F31	F32	F33	$\overline{F3}$	$\frac{\overline{F3}-F_{RS}}{F_{RS}} \times 100$	$\frac{SF_3}{\overline{F3}} \times 100 \times t$

Table 6 Calculation of the uncertainty of the test force

Quantity Xi	Value	unit	Sensitivity coefficient C_i	Distribution	Devisor	Relative uncertainty contribution
Force transducer	U_{FRS}	%	1	Normal	K	$u_{FRS} \times ci/K$
Force measurement	Max u_{FHTM}	%	1	Normal	1	$u_{FHTM} \times ci$

Calculation of the maximum relative deviation of the test force must include the uncertainty of calibration of the test force

$$\Delta F_{max} = |\Delta F_{rel}| + U_F \tag{4}$$

Uncertainty of the Measuring System The calculation of the uncertainty of the indentation measuring system is calculated from the equation

$$u_L = \sqrt{u^2_{LRS} + u^2_{ms} + u^2_{LHTM}} \tag{5}$$

Where:

u_{LRS} is the relative uncertainty of measurement of (reference standard) from the calibration certificate.
u_{ms} is the relative uncertainty of measurement due to the resolution of the measuring system.
u_{LHTM} is the relative standard uncertainty of length measurement of the hardness testing machine.

The calibration of measuring system is shown in Table 7.

Max u_{LHTM} for the four intervals in Table 4 is used in the calculation of the uncertainty in Table 8.

Calculation of the maximum relative deviation of the measuring system must include the uncertainty of calibration of the measuring length.

$$\Delta \mathrm{Lmax} = |\Delta \mathrm{Lrel}| + \mathrm{UL} \tag{6}$$

Indirect Calibration for Brinell Hardness

Indirect calibration shall be done by using calibrated reference block in the temperature of (23 ± 5)°C. Each force/ball size scale shall be calibrated by the suitable

3	200 < HBW	10 < HBW	N/A	±3	±3

reference block. A minimum of two reference blocks shall be selected from two different ranges specified in Table 9 (ISO 6506-3 2014).

For each reference block, five measurements must be distributed uniformly over the surface of the reference block; for each reference block, let d1, d2, d3, d4, and d5 be the average of the measured diameter for each indentation arranged in increasing order and H1, H2, H3, H4, and H5 the corresponding hardness values; the average of the measured diameter for each indentation arranged in increasing order is calculated from Eq. 7 as follows:

$$\overline{d} = \frac{d1 + d2 + d3 + d4 + d5}{5} \tag{7}$$

The repeatability of the hardness testing machine r = d5−d1.
The error of the machine E is calculated from Eq. 8 as (ISO 6506-3 2014)

$$E = \overline{H} - H_C \tag{8}$$

where H_C is the certified value of the hardness block:

$$\overline{H} = \frac{H1 + H2 + H3 + H4 + H5}{5}$$

Uncertainty of the Brinell Indirect Calibration

The uncertainty of measurement of the indirect calibration of the hardness testing machine is calculated from Eq. 9 as follows:

$$u_{HTM} = \sqrt{u^2{}_{CRM} + u^2{}_{CRM-D} + u^2{}_H + u^2{}_{ms}} \tag{9}$$

where:

u_{CRM} is the calibration uncertainty of the hardness reference block according to the calibration certificate.
u_{CRM-D} is the drift of the reference block since its last calibration.
u_H is the standard uncertainty of hardness testing machine when measuring CRM.
u_{ms} is the standard uncertainty due to the resolution of the hardness testing machine.

$$u_H = \frac{t \times s_H}{\sqrt{n}} \tag{10}$$

where:
t = 1.14 for n = 5.

s_H is the standard deviation of the hardness measurement.

Budget of the Uncertainty of Indirect Measurement

Quantity	Distribution	Unit	Sensitivity coefficient Ci	Divisor	Uncertainty contribution
u_{CRM}	Normal	HBW	1	K	u_{CRM}/K
u_{CRM-D}	Rectangular	HBW	1	$\sqrt{3}$	$u_{CRM-D}/\sqrt{3}$
u_H	Normal	HBW	1	1	u_H
u_{ms}	Rectangular	Mm	$\frac{\partial H}{\partial d} = -\frac{H}{d} \times \frac{D+\sqrt{D^2-d^2}}{\sqrt{D^2-d^2}}$	$\sqrt{3}$	$u_{ms} \times ci/\sqrt{3}$

Maximum deviation of the hardness testing machine must include the uncertainty of measurement

$$\boldsymbol{\Delta H} = U_{HTM} + |\overline{b}| \tag{11}$$

Indirect Calibration for Vickers Hardness

Indirect calibration shall be done by using calibrated reference block in the temperature of (23 ± 5) °C. Each force shall be calibrated by the suitable reference block. A minimum of two reference blocks shall be selected from two different ranges specified as follows (ISO 6507-3 2018):

- >225 HV.
- 400 HV to 600 HV.
- >700 HV.

For each reference block, five measurements must be distributed uniformly over the surface of the reference block; for each reference block, let d1, d2, d3, d4, and d5 be the average of the measured diagonals for each indentation arranged in increasing order and H1, H2, H3, H4, and H5 the corresponding hardness values; the average of the measured diameter for each indentation arranged in increasing order is calculated from Eq. 7 as follows:

$$\overline{d} = \frac{d1 + d2 + d3 + d4 + d5}{5} \tag{12}$$

The repeatability of the hardness testing machine r = d5−d1.

The error of the machine E is calculated from Eq. 8 as

$$E = \overline{H} - H_C \tag{13}$$

where H_C is the certified value of the hardness block

$$\overline{H} = \frac{H1 + H2 + H3 + H4 + H5}{5}$$

The repeatability r of the hardness testing machine shall not exceed the following limits in Table 10, and the error of machine shall not exceed the tolerances shown in Table 11.

Table 10 Limits of the repeatability of the Vickers testing machine

	Repeatability of the testing machine max

Uncertainty of the Vickers Indirect Calibration

The uncertainty of measurement of the indirect calibration of the hardness testing machine is calculated from Eq. 9.

Budget of the Uncertainty of Indirect Measurement

Quantity	Distribution	Unit	Sensitivity coefficient Ci	Divisor	Uncertainty contribution
u_{CRM}	Normal	HV	1	K	u_{CRM}/K
$u_{CRM\text{-}D}$	Rectangular	HV	1	$\sqrt{3}$	$u_{CRM\text{-}D}/\sqrt{3}$
u_H	Normal	HV	1	1	u_H
u_{ms}	Rectangular	Mm	$\frac{\partial H}{\partial d} = 2\,H/d$	$\sqrt{3}$	$u_{ms} \times ci/\sqrt{3}$

$$\boldsymbol{\Delta H} = U_{HTM} + |\overline{\boldsymbol{b}}|$$

Uncertainty of the Rockwell Indirect Calibration

The uncertainty of measurement of the indirect calibration of the hardness testing machine is calculated from Eq. 9 (ISO 6508-3 2016).

Budget of the Uncertainty of Indirect Measurement

Quantity	Distribution	Unit	Sensitivity coefficient Ci	Divisor	Uncertainty contribution
u_{CRM}	Normal	HR	1	K	u_{CRM}/K
$u_{CRM\text{-}D}$	Rectangular	HR	1	$\sqrt{3}$	$u_{CRM\text{-}D}/\sqrt{3}$
u_H	Normal	HR	1	1	u_H
u_{ms}	Rectangular	HR	1	$\sqrt{3}$	$u_{ms} \times ci/\sqrt{3}$

Advanced Instrumented Indentation Testing

Instrumented indentation testing (IIT) is the recent and most important method to measure the mechanical properties of materials, also called depth sensing indentation. It is the same in the principle of the conventional hardness tests such as Brinell, Rockwell, Vickers, and Knoop. The principle is a hard indenter; usually the indenter of diamond shape is brought into contact with the tested specimen (Mark 2017), and the test force, F, and the displacement, h, of the indenter are measured simultaneously. However, the difference between the traditional methods and IIT method is that the traditional method measures only the deformation for one applied force and for the IIT method measures the force and displacement continuously during the contact of the indenter with the material. This continuous measurement makes the advance for the ITT method. The indentation depth hc, which is assigned to the contact of the indenter with the material, characterizes the plastic deformation under

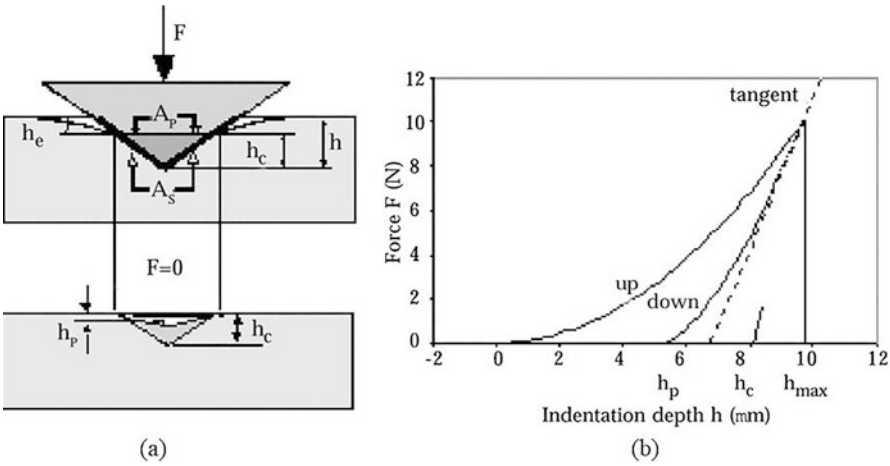

Fig. 4 Simplified representation of indentation process (Herrmann et al. 2004a)

the indenter. In addition, an elastic deformation of the surface occurs that is described by h_e. Figure 4 represents the ratios under the assumptions already summarized: Neither elastic resiliencies of the indentation inside the surface nor changing effects (pile-up) occur (Burik et al. 2015). A typical force-displacement dependence for an application of force and a removal of force (referred to as indentation curve) are shown in Fig. 4(b). If the indentation were purely elastic, there would be no difference between curves of increasing and decreasing forces. The area enclosed by the indentation curve characterizes the plastic indentation. The symbols hp., hr., h_c, and h_{max} occurring on the abscissa are explained in closer detail in the previous section and partly assist in analysis in an upcoming section. Part 1 of ISO 14577 (Brice et al. 2003b) deals with the fields of application (nano, micro, and macro range), the indenter types (Vickers pyramid, Berkovich pyramid, hard metal sphere, spherical diamond indenter), and the requirements for a reproducible measurement of the indentation curve (ISO 14577-1 2015; ISO 14577-2 2015). The definition of the hardness and other material parameters is given in the annex of Part 1 of this standard for pyramidal indenters.

IIT is very suitable for low thickness material such as thin films, particles, or other small features. The important property is the Young's modulus (E) which is the relationship between stress and strain in the elastic zone. This property is the most important property for design, which can know from this property the strain from stress and vice versa. In metals, the indentation causes the stress and strain on the specimen, which the hardness depends on. The hardness is the simplest method to measure the yield stress within a class of metals; the higher hardness gives higher strength of metal. In addition to Young's modulus and hardness, IIT has also been used to measure complex modulus in polymers and biomaterials yield stress and creep in metals and fracture toughness in glasses and ceramics (ISO 14577-3 2015).

The indenter contacts, and sense the surface. The sensing is depending on the stiffness of the mechanism of supporting the indenter columns. The user input the rate , and the limits of the test.

1. The test may be force controlled or distance controlled so the indenter stops pressing when the max force or maximum displacement is reached.
2. The user inputs the dwell time which the indenter stops with constant maximum force.
3. The test piece is then unloaded, and the indenter is moving upward at the rate suitable to the loading rate until 10% of maximum force.
4. The force is held constant at this small percentage. The purpose of this test segment is to acquire enough data to determine how much of the measured displacement should be attributed to thermal expansion and contraction of the equipment and/or test material, called "thermal drift." If thermal drift is expected to be small relative to the overall penetration of the test, this segment may be omitted.
5. The sample is fully unloaded (Fig. 5).

Fields of Application

The standard (Brice et al. 2003b) has a high universality, as both indentation depths of less than 200 nm and test forces up to 30 kN as well as different geometric of the indenters are included. Three fields of applications have been defined:

Nano range h $<$200 nm.
Micro range h $\geq$ 200 nm and F $\leq$ 2 N.
Macro range F $>$ 2 N.

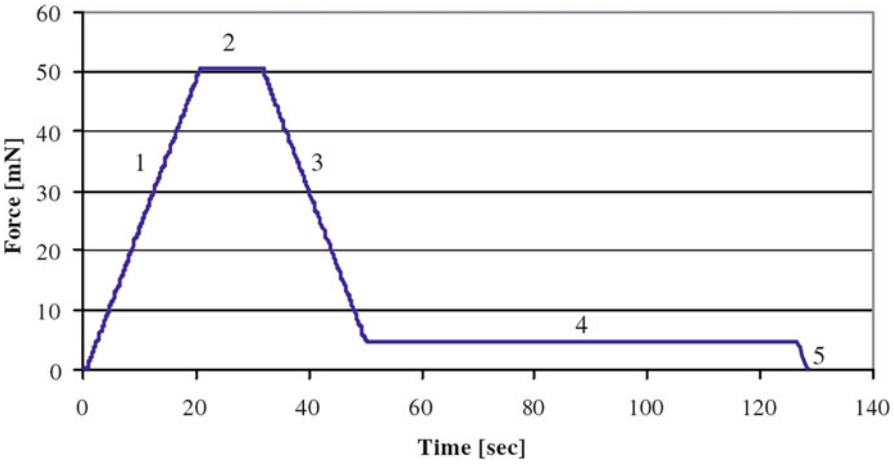

Fig. 5 Force–time diagram for instrumented indentation test (Brice et al. 2003b)

As a consequence, the formulations in the standard must take all characteristics of the nano range, the micro range, and the macro range into account. In addition, the four geometries of the indenters (Vickers pyramid, Berkovich pyramid, sphere, and cube edge) must be determined (ISO 6506-3 2014). For this reason, the standard is comprehensive and contains many explanatory notes. The required large measurement ranges of test force, indentation depth, and initial unloading slope are demonstrated in Table 12 on four materials. To investigate polymer layers 3 µm in thickness, the test force must, for example, amount to less than 100 µN. Adhesion forces to the surface as well as the condition of the surface can obviously influence the force-displacement curve before the contact takes place. The test forces up to 30 kN included in the standard, however, generate indentation depths of approximately 1 mm in metals. If the range of the expected elastic modulus is taken into account, it is also necessary to measure the initial unloading slope of 0.003 to 1400 N/µm. Whereas knowledge of the real geometry of the indenter is important for the results in the nano range (h <200 nm), the type of displacement measurement is important in the macro range (F > 2 N) with regard to the compliance of the machine and of the indenter. The field of application of the standard (Herrmann et al. 2004a) relates to all material types and composite materials, including metallic and nonmetallic layers. Because of their great importance, the particularities for determination of the mechanical properties of thin layers are dealt with separately in Part 4 of the standard.

Test Cycle

It is the main objective of each standard to obtain comparable results by the specification of test conditions, independent of test machines and test laboratories. This is why some influential factors and the specified tolerances are presented because most of the material parameters are time-dependent; the development of force and displacement with time plays an important role. The standard (Herrmann et al. 2004a) requires that all test cycle phases must be completely described in the test report. Figure 6 shows an example of a test cycle in force control, with linear progressive application of the test force up to a phase of constant force at F. This

Table 12 Martens hardness and indentation modulus for selected materials (Properties of engineering materials 2004)

Material	Martens hardness N/mm2	Indentation modulus N/mm2	Test force 100 µN		Test force 2 N		Test force 30 kN	
			h mm	$\frac{dF}{dh}$ N/µm	h mm	$\frac{dF}{dh}$ N/µm	h mm	$\frac{dF}{dh}$ N/µm
	50	1100	0.28	0.003	39	0.5	4770	60
	60	70.000	0.08	0.06	11	8	1380	980
	2000	200,000	0.04	0.08	6	11	750	1370
	15,000	400,000	0.02	0.05	2	7	280	860

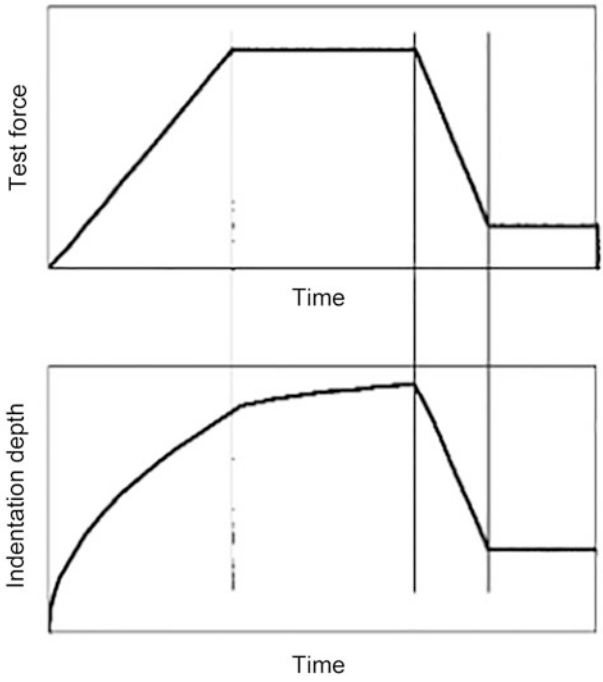

Fig. 6 Test cycle in force control (ISO 6506-3 2014)

increase is followed by a linear force drop with increased force rate up to 0.1 F_{max} followed by another phase of constant force. The test cycle ends with the rapid removal of the force (ISO 6506-3 2014).

An example of a test cycle in indentation control is shown in Fig. 7. Depending on the case, a change from force control to depth control and vice versa between the phases of the test cycle can be advantageous. When material testing machines are used in the macro range, test cycle phases with controlled traverse displacement may occur. Owing to the compliance of the machine, such phases can realize neither a linear increase in force nor a linear increase in indentation. What is decisive is the complete description in the test report. Although the comparability of the results is ensured by such complete information, the determination of the indentation modulus as closely as possible to the elastic modulus imposes an additional requirement regarding the duration of the holding period and the velocity of force removal.

During the beginning of the removal of force, creep of the material may lead to an additional increase in the indentation depth. To limit the potential deviation during the determination of the initial unloading slope, S, it is prescribed in Part 4 of the standard that the velocity of force removal (in N/s) must be at least ten times the product from initial unloading slope (in N/µm) and creep rate of the 30 last data points of the holding period (in µm/s).

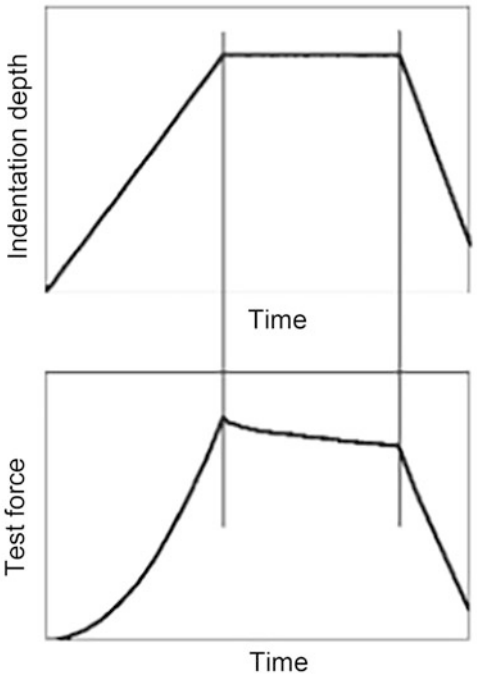

Fig. 7 Test cycle in indentation depth control (ISO 6506-3 2014)

Measurement Uncertainty

Calculating Measurement Uncertainty of the Material Parameters from Results Obtained on Reference Samples The current version of the standard on the instrumented indentation test (Brice et al. 2003b) does not contain any detailed instructions for determining the measurement uncertainty the next time the standard is revised; a procedure analogous to those for conventional hardness tests will presumably be introduced. According to these standards, the results of the indirect test carried out on the reference samples calibrated for this particular materials parameter are used in test laboratories to determine the measurement uncertainty of that parameter. Contrary to conventional hardness tests, not only does the test result consist of only a single hardness value, but several material parameters can require that the associated measurement uncertainty be explicitly stated. For this reason, differently calibrated reference samples, RM_x, must be available. The combined measurement uncertainty, U_x, is calculated as (ISO 6506-2 2014; ISO 6508-2 2016; ES-5178-1 2016; ES-5179-1 2016).

$$U_x = k.\sqrt{U^2{}_{RMx} + U^2{}_{PMx} + U^2{}_{Lmsx} + U^2{}_{bx}} \tag{14}$$

where:

K is the coverage factor of the expanded measurement uncertainty (k = 2).
URM_x is the standard uncertainty of the materials parameter, x, for which the reference sample has been calibrated.
UPM_x is the standard uncertainty of the testing machine when measuring the materials parameter, x, on the reference sample.
U_x is the standard uncertainty when measuring a test sample.
U_{msx} is the standard uncertainty due to the resolution of the measuring systems.
U_{bx} is the standard uncertainty when determining the correction bx.

In the GUM, it is recommended that the correction bx be used in order to compensate for systematic effects. The measurement result of the materials parameter, x, is then given by

$$\overline{x}_{corr} = \left(\overline{x} + \overline{b}_x\right) \pm U_x \tag{15}$$

Dynamic Hardness

An impact device as shown in Fig. 8 released an impact body with a permanent magnet and the very hard indenter sphere itself to the surface of the tested material. The velocity of the impact body is recorded in three main test phases (Maier-Kiener and Schuh 2017; ISO 16859-1 2015; ISO 16859-2 2015; ISO 16859-3 2015; ASTM A956 / A956M 2017):

1. The pre-impact phase: the impact body is accelerated by spring force to the surface of the tested material.
2. The impact phase: where the impact body is in contact with the tested material. The tested material deforms elastically and plastically. After the impact body is fully stopped, elastic recovery of the test material and the impact body takes place and causes the rebound of the impact body.
3. Rebound phase: where the impact body leaves the test piece with residual energy, not consumed during the impact phase.

Leeb-number or Leeb hardness (HL) is determined by the ratio of the rebound velocity (vr) and impact velocity (vi), multiplied by 1000:

$$\frac{V_r}{V_i} \times 1000$$

When the rebound (vr = vi) would cause L = 1000, all energy is elastically recovered and there is no plastic or permanent deformation. The L is decreased with decreasing material hardness.

Abstract

Torque is one of the most important physical quantities which are used for the development of various industries. Torque is defined as the moment of force, also called the rotational force or the turning effect of force. The authors here introduce precise torque realizing method, torque standard machines, torque calibration machines, torque measuring devices, and so on. We also describe the present status of inter-laboratories comparisons of torque. Moreover, the chapter also introduces the SI traceability system of torque, including the description of each traceability component, such as torque testing machines, torque

wrench testers, and hand torque tools. Finally, the authors mention the recent activities concerned with the multi-component force/torque measurement and the dynamic torque measurement techniques.

Introduction

"Torque" is one of the most important physical quantities used in various industries. Torque is measured in multiple scenes for rotational driving equipment such as engines in automobiles (Judge 2012), electrical motors (Bakshi and Bakshi 2020), machining tools (Lacalle and Mentxaka 2008), as well as fastening control tools such as power-driven and hand torque tools (HTT) (Bickford 1998). It's easy to imagine that a truck couldn't climb an upslope without the required torque and that a wheel with loosened screws would cause tires to fall off, leading to a severe accident, for example.

The authors would like to introduce how the precise value of torque confirmed its reliability and how people use the reliable torque in this chapter. First, we define the torque value and then explain how the precise torque is realized (or generated). Second, we introduce how to measure the torque precisely realized, confirming the traceability of measurement in the industrial field from a national torque standard in a country/economy. Next, some typical inter-laboratories comparisons of torque standards are introduced, which contribute to how to confirm the equality of national torque standards. Finally, we also describe the present situation of research activities such as multicomponent force/torque measurement and dynamic torque measurement techniques.

Definition of Torque

Torque is defined as the moment of force, also called the rotational force or the turning effect of force. It's expressed by the cross-product of distance and force. The definition of torque is shown in Fig. 1.

Torque $\boldsymbol{T}$ is defined with the following equations:

$$\boldsymbol{T} = \boldsymbol{r} \times \boldsymbol{F}, \tag{1}$$

$$|\boldsymbol{T}| = |\boldsymbol{r} \times \boldsymbol{F}| = |\boldsymbol{r}|\,|\boldsymbol{F}| \sin\theta, \tag{2}$$

where $\boldsymbol{r}$ is the distance vector from the axis of rotation to the loading point, $\boldsymbol{F}$ is the force vector, and θ is the angle between $\boldsymbol{r}$ and $\boldsymbol{F}$ vectors.

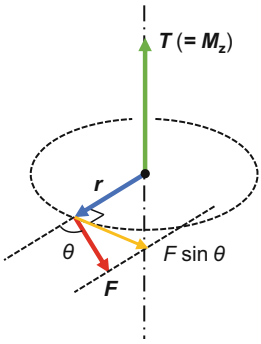

Fig. 1 Definition of torque

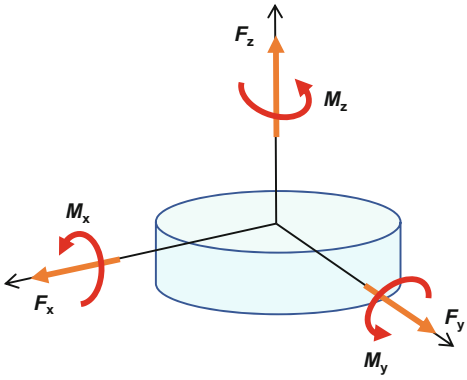

Fig. 2 Six components of force and moment on the Cartesian coordinate system

On the other hand, torque T can be expressed by the following equation when a rigid body having the mass moment of inertia I rotates with the angular acceleration α:

$$T = I\alpha, \tag{3}$$

where T is a scholar value in the case. Equation (3) is utilized for the rotational dynamics.

The unit of torque shall be expressed by "N·m" or "N m." A middle-dot point or a space is required between the unit of force, Newton, and the unit of length, meter, according to the International System of Units, known as the international abbreviation "SI" (BIPM 2019). Torque is distinguished from the unit of energy, Joule, expressed by "J." The expressions such as "Nm," "N-m," or "N.m" are all wrong. Incidentally, space between a numerical value and a unit is also necessary, like "20 N·m." The expression of "20N·m" is false too.

There exist six components of force, including torque, in the natural world. The forces acted on a body are exactly expressed by the forces $\boldsymbol{F}$ and moments $\boldsymbol{M}$ acting on x, y, and z directions on the Cartesian coordinate system as shown in Fig. 2.

Twisting moment $\boldsymbol{M_z}$ generally expresses torque $\boldsymbol{T}$. In contrast, $\boldsymbol{M_x}$ and $\boldsymbol{M_y}$ typically represent the bending moments.

Traceability of Torque Measurement

Generally, the end users use low accuracy but usable measuring devices in the industry. The torque values indicated on such measuring devices ensure the traceability of measurement, finally making the calibration chain to the national torque standards. Such intrinsic torque standard is typically realized by the combination of weights with a known mass, local gravity, and arms with a known length.

Figure 3 shows an example of a typical SI traceability system of torque developed in Japan. The authors believe other countries/economies have established or are establishing similar traceability systems.

First, the National Metrology Institute (NMI) has developed and maintained torque standard machines (TSMs), which realize precise torque (typically, 0.002 % to 0.010 % of relative expanded uncertainty). NMIs have assembled the torque values by themselves from the basic units of mass, length, and time, as explained later.

There are two main flows in torque traceability. One is the "pure torque flow," as shown on the left side of Fig. 3. We try to realize and measure only the M_z

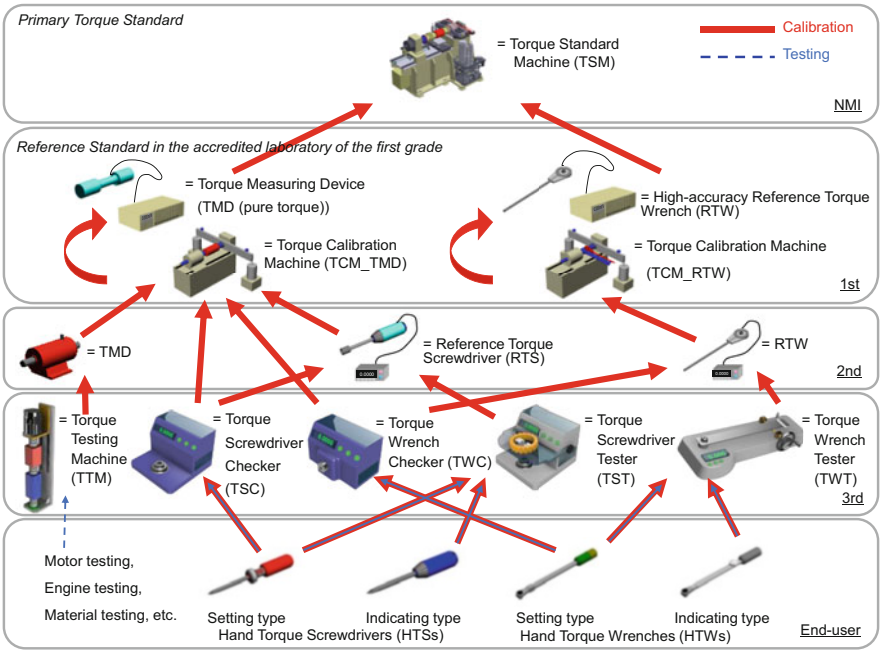

Fig. 3 SI torque traceability system in Japan

component without other components in the pure torque loading. The other is the "torque wrench flow," as shown on the right side of Fig. 3. In the torque wrench loading, bending moments (M_x, M_y) and transverse forces (F_x, F_y) are necessarily and parasitically accompanied when generating torque.

In the pure torque flow, the accredited laboratories calibrate the torque testing machines (TTMs), such as the electric motor testing machines and twisting fatigue testing machines, using torque measuring devices (for pure torque) (TMDs). TMDs are calibrated using torque calibration machines (TCMs) as well. Various products are tested in the industry, such as motors, engines, power trains, and structural materials, using TTMs. As mentioned later, hand torque screwdrivers (HTSs), which measure pure torque, are also included in the pure torque flow.

In the torque wrench flow, the accredited laboratories calibrate the torque wrench testers (TWTs) using reference torque wrenches (RTWs). As mentioned later, hand torque wrenches (HTWs), which measure torque generated by the torque wrench loading, are undoubtedly included in the torque wrench flow.

Here, somebody says that it would be doubtful whether the calibration result in the case of the torque wrench loading becomes so different from the case of pure torque loading. The National Metrology Institute of Japan (NMIJ) in the National Institute of Advanced Industrial Science and Technology (AIST) had continued successful research and found that the torque wrench loading was necessary, apart from the pure torque loading when the relative expanded uncertainty of less than 0.1 % to 0.2 % is required (Ogushi 2016, 2017, 2018, 2020a).

The following sections explain each traceability component in establishing the SI torque traceability system above.

Torque Realization

A torque standard machine (TSM) is a primary torque calibration equipment that realizes precise torque by itself, constructed from quantities of the basic unit such as mass, length, and time. On the other hand, a torque calibration machine (TCM) is a secondary standard. TCM realizes the torque with a precise TMD as a transfer torque standard calibrated by the TSM. This section introduces typical TSMs and TCMs.

Deadweight Type Torque Standard Machine

The machine of this type generates the precise torque loading deadweights at the tip of the moment-arm. Figure 4 shows a schematic of the deadweight type torque standard machine (DWTSM). The following equation expresses the torque T realized by DWTSM:

$$T = mgL\left(1 - \frac{\rho_a}{\rho_W}\right), \tag{4}$$

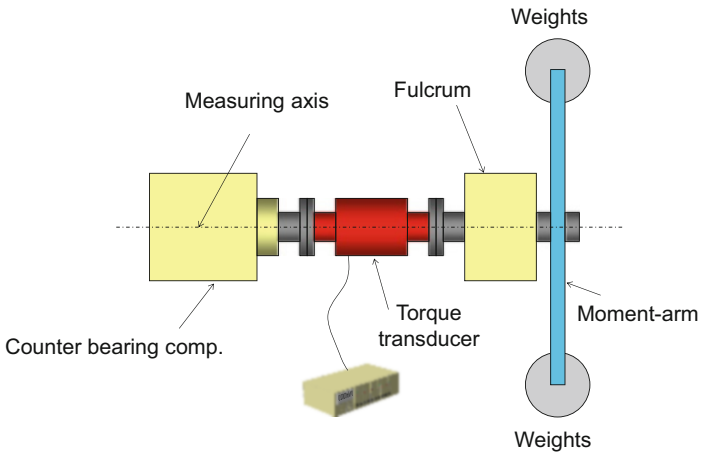

Fig. 4 Schematic of the deadweight type torque standard machine (top view)

where m is the mass of deadweights, g is the local acceleration due to gravity, L is a moment-arm length, ρ_a is the air density, and ρ_W is the density of deadweight material. That is, the influence of air buoyancy is considered.

Many NMIs adopted this type as the national torque standard machine (Adolf et al. 1995; Peschel 1997; Röske 2014a; Ohgushi et al. 2002a, b; Nishino et al. 2010; Gassmann et al. 2000; Carbonell et al. 2006; Park et al. 2007; Averlant and Duflon 2018; Arksonnarong et al. 2019). In order to maintain the torque standard in the smaller uncertainty level, it makes sure not only the traceability for the mass of deadweight, length of the moment-arm, and the acceleration due to gravity to each national standard but also the evaluations of the deformation of the moment-arm (Röske 1997; Ohgushi et al. 2003, 2007), the influence of temperature (Ohgushi et al. 2007), the friction at the fulcrum (Nishino et al. 2010, 2014), and so on.

Although DWTSM is able to realize the most precise torque at present, it takes a lot of cost to maintain its performance. This type's relative expanded uncertainty range for torque is approximately 0.002 % to 0.010 %.

For example, a DWTSM with a rated capacity of 1 kN·m is shown in Fig. 5 (Ohgushi et al. 2002b). The deadweight series consists of five stacks of 1 N with 11 pieces, 2 N with 22 pieces, 10 N with 11 pieces, 20 N with 22 pieces, and 100 N with 22 pieces. They are one inner linkage weight type. The double arm type was adopted for the moment-arm part. The nominal length of one side is 500 mm. Therefore, this DWTSM can realize the torque from 500 mN·m to 1.1 kN·m for both directions of clockwise (CW) and counterclockwise (CCW) torques.

Force Transducer Type Torque Standard Machine

The machine of this type generates the torque using hydraulic cylinders and a moment-arm, or an electric motor. The torque is measured by the force transducers and another moment-arm at the opposite side of the calibrated torque transducer.

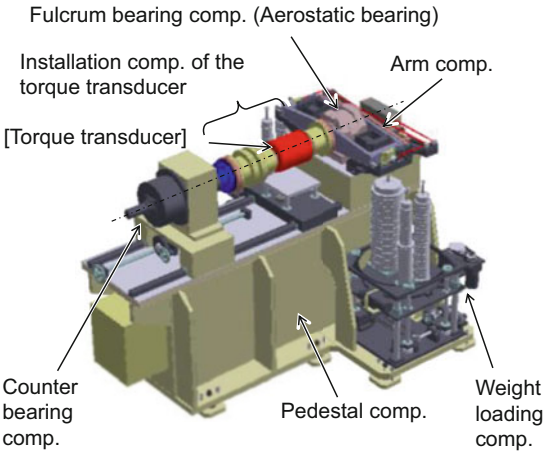

Fig. 5 An example of the deadweight type torque standard machine (1-kN·m-DWTSM at NMIJ)

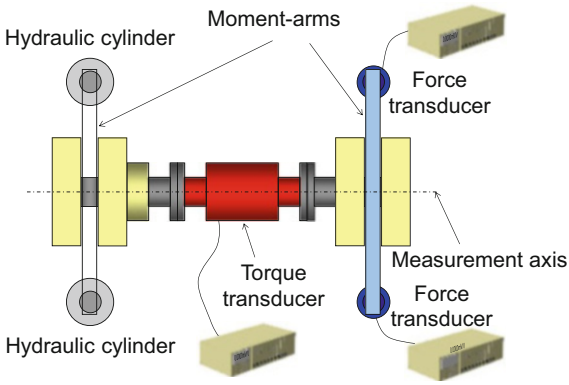

Fig. 6 Schematic of the force transducer type torque standard machine (top view)

Figure 6 shows a schematic of the force transducer type torque standard machine (FTTSM).

The following equation expresses the torque T realized by FTTSM:

$$T = F\,L, \tag{5}$$

where F is the value measured by the force transducers and L is the opposite-side moment-arm length.

The alignment adjustment at the tip of the moment-arm and finding the actual loading point of the force transducer are quite difficult in this type. On the other hand, it's relatively easy to realize the huge torque such as mega-Newton-meter (Kenzler et al. 2002; Peschel et al. 2005). This type's relative expanded uncertainty range for torque is approximately from 0.02 % to 0.10 %.

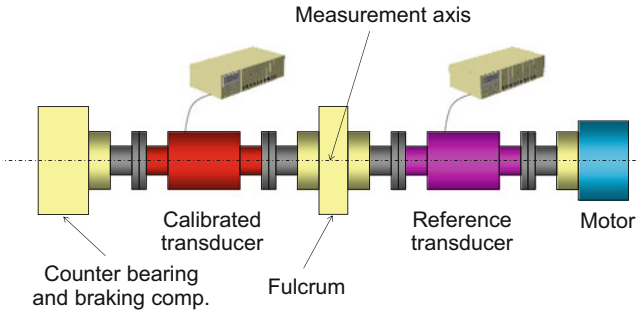

Fig. 7 Schematic of the reference type torque calibration machine

Reference (Comparison) Type Torque Calibration Machine

In a machine of this type, a reference torque transducer and a calibrated one are connected in series. Figure 7 shows a schematic of the reference type torque calibration machine (RTCM). It's also called a comparison type torque calibration machine.

An electric motor generates the torque with the breaking system put on the opposite side. The output from the calibrated transducer is compared with one from the reference transducer. This equipment is easily constructed, although it cannot be a primary torque standard, which means TSM (Peschel 1996; Brüge 2015; Kiuchi et al. 2020). The reference torque transducer is to be calibrated by a superior TSM. It's also advantageous to shorten the total calibration time by executing the continuous calibration, but not the step-by-step one (Saenkhum and Sanponpute 2017).

Figure 8 expresses an example of RTCM at NMIJ (Kiuchi et al. 2020). The calibration range can be set from 100 mN·m to 10 N·m by exchanging the rated capacity of the reference torque transducer.

This type's relative expanded uncertainty range for torque is approximately from 0.040 % to 0.20 %. The calibration and measurement capability (CMC) mainly depends on the long-term instability of the reference torque transducer inside.

Electromagnetic Force Type Torque Standard Machine

In the machine of this type, the torque is realized by electrical quantities applying the principle of Kibble balance, which was invented by Kibble et al. (1990) for the new definition of the kilogram. Nishino et al. utilized the principle for generating the precise small torque and developed the first electromagnetic force type torque standard machine (EMTSM) (Nishino et al. 2016; Nishino and Fujii 2019). Figure 9 shows a schematic of the EMTSM.

The principle of torque realization can be explained using Figs. 10a and 10b. A rectangular coil is placed in a homogeneous magnetic field. A Lorentz force F is

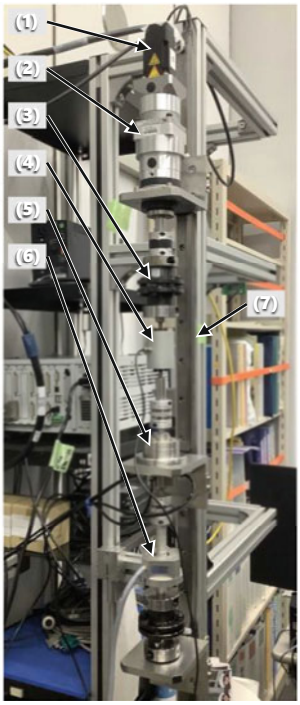

Fig. 8 An example of the reference type torque calibration machine (10-N·m-RTCM at NMIJ), with (1) a servo motor, (2) a reduction gear, (3) couplings, (4) a reference torque transducer, (5) an aerostatic bearing, (6) a calibrated torque transducer, (7) a linear motion guide

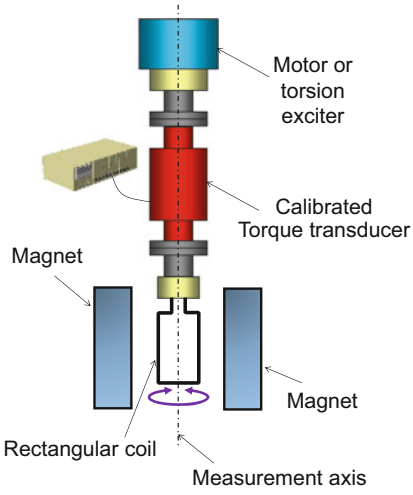

Fig. 9 Schematic of the electromagnetic force type torque standard machine

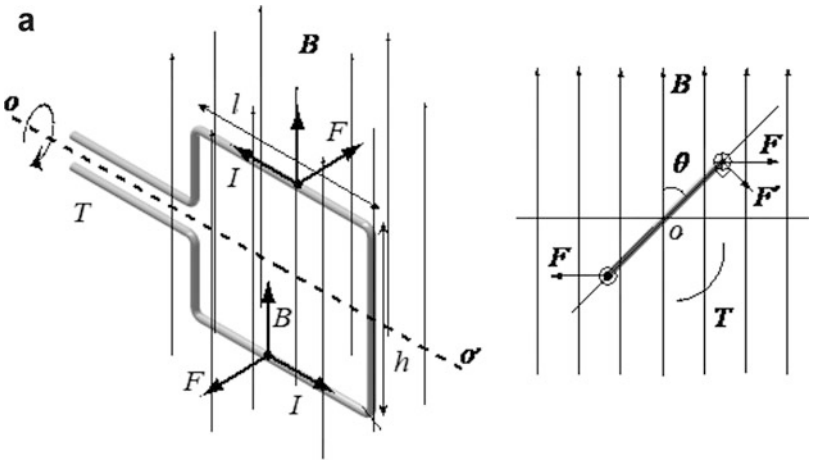

Fig. 10a The principle of torque generation with EMTSM (torque generation mode)

generated when the electric current I flows into the coil, as shown in Fig. 10a, by the following equation:

$$F = IBl \text{ or } F = -IBl, \tag{6}$$

where l is the length of the rectangular coil parallel to the rotation axis O–O′. These two forces are a couple, so the torque T is expressed by

$$T = NABI \cos\theta. \tag{7}$$

where A (= hl) is the cross-sectional area of the rectangular coil, N is the number of turns of the rectangular coil, B is the magnetic flux density, and their product NAB is a kind of eigenvalue in the apparatus.

Next, the rectangular coil is rotated at a constant angular velocity ω, as shown in Fig. 10b. An induced electromotive force (voltage) V is generated as expressed by the following equation:

$$V = NAB\omega \sin\omega t. \tag{8}$$

V reaches its maximum value $V_{\max}$ when the value of sin ωt equals unity like as

$$V_{\max} = NAB\omega. \tag{9}$$

T reaches its maximum value $T_{\max}$ when cosθ equals unity like as

$$T_{\max} = NABI. \tag{10}$$

Therefore, $T_{\max}$ is calculated from Eqs. (9) and (10) as the following equation:

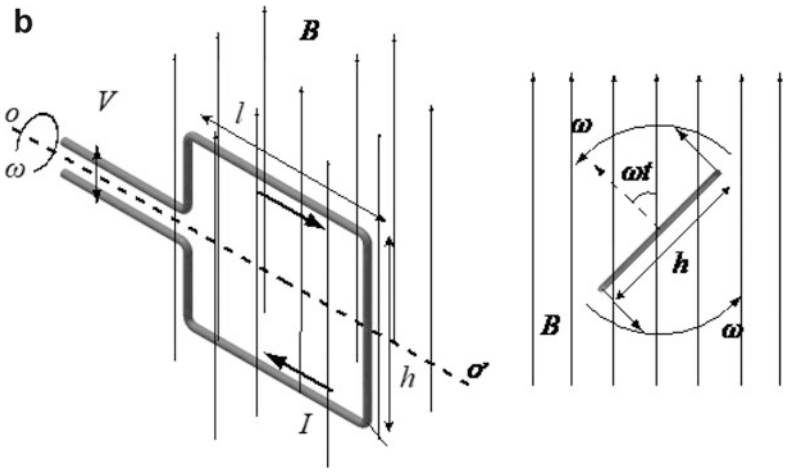

Fig. 10b The principle of torque generation with EMTSM (induced electromotive force generation mode)

$$T_{\max} = \frac{V_{\max}}{\omega} I. \tag{11}$$

By measuring V, ω, and I in each mode, $T_{\max}$ can be obtained without evaluating N, A, and B, respectively. The EMTSM can realize the torque by electric quantities without using mass and gravity.

The realization of precise torque with this method is still tricky mainly because of the nonuniformity of the magnetic field and the unstableness of the angular velocity. The influence of the heat generation also pretends the precise and large torque measurement. This method's range of torque realization is approximately from nano- to tens of milli-Newton-meter. The relative expanded uncertainty level is approximately from 0.1 % to 0.5 %. Figure 11 shows the prototype of the EMTSM developed at NMIJ (Nishino et al. 2016). The torque-generating machine using electromagnetic force is also being developed at the Korea Research Institute of Standards and Science (KRISS) (Kim 2021).

Torque Measuring Devices

The torque standard can be effectively disseminated to the industry when the triple combination of "equipment" realizing precise torque, "a device" measuring the torque precisely, and "a method" calibrating the torque correctly, is prepared. We have already discussed the torque realization in section "Torque Realization." We describe the torque measuring devices (TMDs) in this section.

A torque measuring device is defined as a complete set of a torque transducer, a cable, and an indicating device (with amplification), where the torque transducer

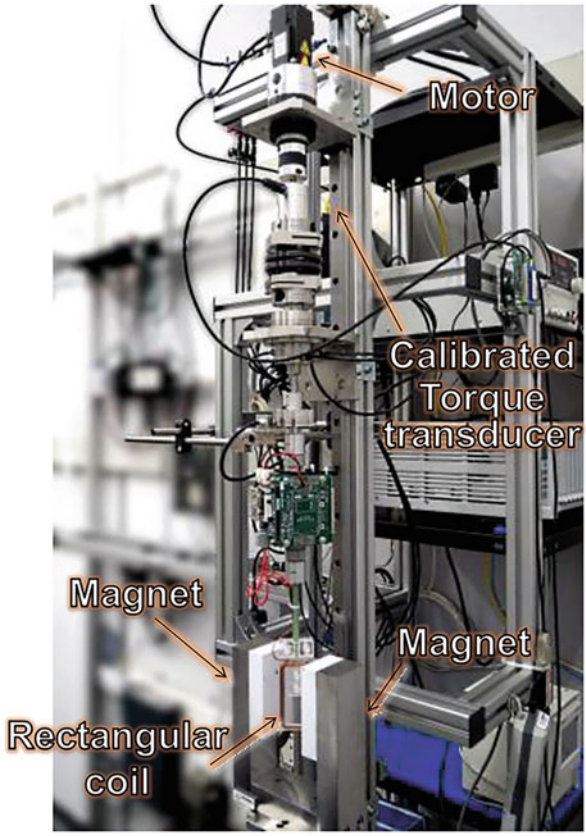

Fig. 11 The EMTSM developed at NMIJ

exchanges the change of torque value into the ones of other quantities such as displacement, voltage, and electrostatic capacity.

The TMD is the device that generally measures the torque with the pure torque loading (DIN 2005; EURAMET 2011; JMIF 2004). On the other hand, the reference torque wrench (RTW) is the device that measures the torque entailing the bending moments and transverse forces, as mentioned in section "Traceability of Torque Measurement."

The TMDs are categorized in strain gauge type, magnetostrictive type, phase difference type, electrostatic capacity type, piezoelectric type, and so on according to their transducing principles.

The strain gauge type measures the torque with an electroresistive strain gauge that is adhered to a spring element or a torque transmission shaft when it's twisted, and the strain occurs. This type is used mainly for torque measurement in the industry (Hannah and Reed 1992). The type has a small drift and is suitable for high-precision measurement. Still, its relatively low natural frequency limits itself to

the measurement with high-speed rotating bodies and high-frequency torsional vibration.

The magnetostrictive type measures the torque with a magnetic bridge circuit. It utilizes a phenomenon that the magnetization state changes (permeability changes) when a ferromagnet such as iron or nickel deforms. When the initial magnetization strength is sufficiently large, the change in magnetic flux caused by torque is measured, and then the torque can be calculated. This type has the feature that torque can be detected without contact in principle (Du 2014).

In the phase difference type, two soft iron disks with the same number of teeth are attached to the transmission shaft with the twisted shaft in between. When a pickup coil is installed with a slight gap between the teeth of each disk, a magnetic flux change occurs when the teeth of the disk pass through the magnetic field generated by this pickup coil, and an alternating voltage is induced. Since the output voltage of both pickup coils has a phase difference due to the twist of the shaft, the torque can be obtained from this phase difference (Sydenham 1985). This type can make high sensitivity, whereas the measurement system becomes expensive.

In the electrostatic capacity type, there are two types, one that uses the change in the gap between the opposing plates and the other that uses the change in the area of the plates. The measurement can be performed without contact with the shaft. When two cylinders dug a groove at regular intervals along the generatrix direction face each other so that their central axes coincide, the capacitance formed between the two electrodes becomes the relative angular displacement between the two cylinders. This change in capacitance is measured to obtain the torque (Beeby 2004). In this method, the key to improving accuracy is how to keep the variation in electric capacity small.

In the piezoelectric type, piezoelectric materials are substances that generate an electric charge when subjected to mechanical stress. The charge obtained is proportional to the mechanical stress applied, and the charge amplifier converts this charge into a measurable, for example, 0 V–10 V signal. The output voltage is proportional to the mechanical stress. By an appropriate arrangement of several piezoelectric force sensors sensitive to shear forces, it would be possible to measure torques. Piezoelectric sensors have a fast response, but have a large drift. Therefore, they are suitable for measuring quasi-static and dynamic torque (Rupitsch 2018).

The torque transducer has rotary and non-rotary styles as a structure. In the rotary type, it's necessary to convert the amount of torsional strain in any of the above types and then transmit a signal from the rotor to the stator. The method includes slip ring/brush, rotary transformer, optical transmission, telemeter types, etc.

There are shaft, flange, and disk shape torque transducers. Most torque transducers that measure pure torque M_z are axisymmetric.

Figure 12 shows a typical TMD consisting of a nonrotating style, a shaft shape, and a strain gauge type torque transducer with an amplifier/indicator.

As a traveling device for an international comparison between NMIs, a TMD that can be expected to have relative stability and repeatability of about 10^{-6} is required. On the other hand, as an industrial application, a system for mass production of

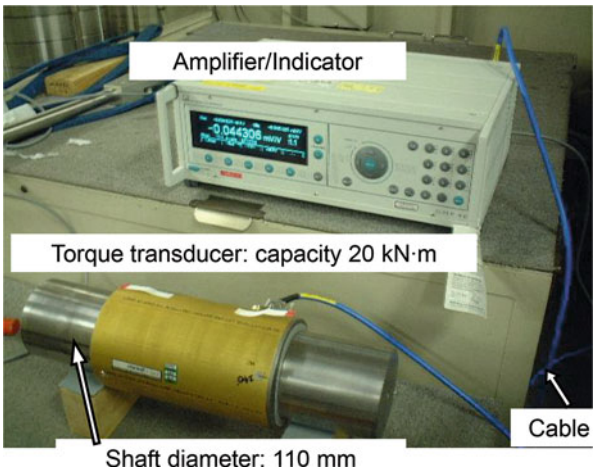

Fig. 12 Typical TMD

torque measuring equipment that can measure with a relative expanded uncertainty of equal to or less than 0.1 % is desired in a specific severe condition. Still, it has not reached that level yet.

Intercomparisons of Torque

Each NMI insists on its calibration and measurement capabilities (CMCs), the smallest uncertainty for the calibration results when the NMI calibrates the almost ideal TMD through the daily calibration procedure. International comparisons are usually carried out to verify the validity of those CMCs.

The Working Group of Force and Torque (WGFT), in the Consultative Committee for Mass and Related Quantities (CCM), in the International Committee of Weights and Measures (CIPM), is conducting related international key comparisons of force and torque for the Mutual Recognition Arrangement (CIPM_MRA). In the field of torque, CCM.T-K1 was completed in 2004 and CCM.T-K2 in 2008, respectively.

In the scheme of CCM.T-K1, two torque transducers with a rated capacity of 1 kN·m were used as traveling devices. The torque steps of 500 N·m and 1 kN·m were compared then. Eight NMIs participated in this comparison. The final report said that all measurement results matched within their CMCs range. Therefore, the international equivalence of measurement standards was confirmed (Röske 2009).

In the scheme of CCM.T-K2, two torque transducers with a rated capacity of 20 kN·m were used as traveling devices. The torque steps of 10 kN·m and 20 kN·m were compared then. Four NMIs participated in this comparison. The final report said that all measurement results matched within CMCs. Consequently, the international equivalence of measurement standards was confirmed too (Röske and Ogushi 2016).

After the above key comparisons, CCM.T-K1.1 through CCM.T-K1.4, additional comparisons of the above key comparisons were also performed. In addition, each Regional Metrology Organization (RMO) has conducted many key comparisons and supplementary comparisons, ensuring the international equivalence of the measurement standard for torque worldwide. The website of the International Bureau of Weights and Measures (BIPM) can be visited for more detailed information on the Key Comparison Database (KCDB) (BIPM 2022).

Reference Torque Wrenches

A reference torque wrench (RTW) is defined as a complete set of a torque transducer with a form of hand torque wrench, a cable, and an indicating device (with amplification). RTW is also called a torque transfer wrench (TTW). Currently, only the strain gauge type transducer for RTW is on the market.

The measuring side of the transducer is a square drive form, whereas the reacting side is a lever form. The lever receives a reaction force within a predetermined lever length range at the point of effort. The RTW would be the best reference standard for calibrating the torque wrench tester (TWT) or torque wrench calibration device (TWCD). Figure 13 shows a typical RTW, in which the square drive size is 10 mm, and the effective lever length range is from 300 mm to 500 mm. The rated capacity is 100 N·m.

Generally, the relative expanded uncertainty for RTWs is from 0.01 % to 0.2 %, depending on the performances of both the RTW itself and the superior calibration equipment.

Torque Testing Machines

Most torque testing machines (TTMs) have built-in torque transducers as the reference standards. In the TTM, torque is generated by a drive assembly such as a motor, and torque is applied to the test object.

Figure 14 shows an example of a material torsion testing machine, which is one of TTM. A motor generates torque. Torque and angle are measured by a built-in torque transducer and a rotary encoder. The shear strength and other mechanical characteristics of the material are evaluated.

Other examples included in TTMs are an engine test stand, a motor testing machine, a driveshaft testing machine, etc. The relative expanded uncertainty of the calibration required for TTMs is approximately 0.1 % to 1 %.

Hand Torque Tools

The hand torque tool (HTT), defined in ISO 6789-1 (ISO 2017), is an essential tool required in the assembly process in the industry as well as a precision measuring instrument.

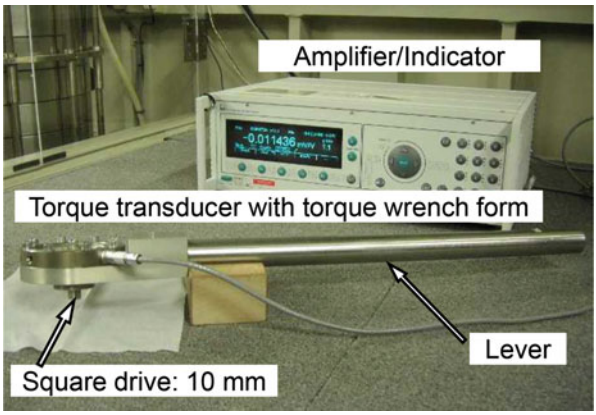

Fig. 13 Typical RTW

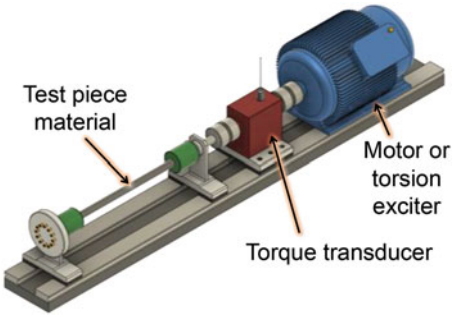

Fig. 14 Typical TTM

HTTs are classified in detail as follows, as defined by ISO 6789-1.

(a) Indicating torque tools (Type I):
   1. Class A: HTW, torsion or flexion bar.
   2. Class B: HTW, rigid housing, with scale or dial or display.
   3. Class C: HTW, rigid housing, and electronic measurement.
   4. Class D: HTS, with scale or dial or display.
   5. Class E: HTS, with electronic measurement.

(b) Setting torque tools (Type II):
   1. Class A: HTW, adjustable, graduated, or with display.
   2. Class B: HTW, fixed adjustment.
   3. Class C: HTW, adjustable, non-graduated.
   4. Class D: HTS, adjustable, graduated, or with display.
   5. Class E: HTS, fixed adjustment.
   6. Class F: HTS, adjustable, non-graduated.
   7. Class G: HTW, flexion bar, adjustable, graduated.

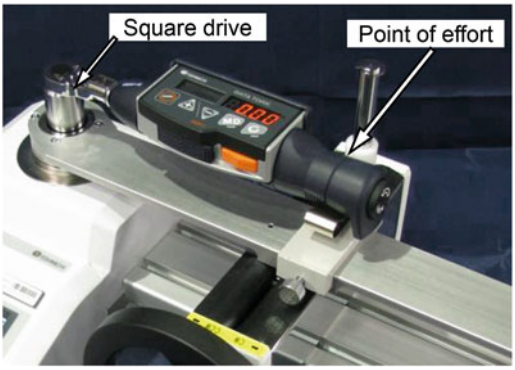

Fig. 15 An example of an HTT (digital torque wrench) installed on a TWT

Figure 15 expresses a typical HTT, a Type I, Class C, indicating torque wrench with an electric measurement (so-called digital torque wrench).

The hand torque wrench (HTW) is calibrated (or tested) by the torque wrench tester (TWT) or the torque wrench checker (TWC). In contrast, the hand torque screwdriver (HTS) is calibrated (or tested) by the torque screwdriver tester (TST) or the torque screwdriver checker (TSC), as shown in Fig. 3. Here, TWT and TST have a loading mechanism then can keep loading stably. They can calibrate both the indicating and setting types of HTTs. On the other hand, TWC and TSC have no loading mechanism, so that they can accept only hand-loading by a human. They can calibrate only setting types of HTTs. The TST is also included in a kind of the TTM.

ISO 6789-1 stipulates 4 % or 6 % as the maximum permissible deviation of HTTs, which varies depending on the type and rated capacity.

Various research has been conducted to improve the calibration or test method for HTWs. Röske proposed the evaluation method of measurement uncertainty for the HTWs calibrated according to ISO 6789:2003 (Röske 2014b). Brüge investigated the measurement uncertainty of setting type HTWs when they were used as transfer devices for comparisons or proficiency tests (Brüge 2014). Bangi et al. showed a simple uncertainty evaluation method for the calibration results of HTWs in action (Bangi et al. 2014). Khaled et al. proposed a new calibration procedure for setting type HTWs to reduce the measurement uncertainty differentiating from ISO 6789-1 (Khaled and Osman 2017). Ogushi researched test results of various digital torque wrenches using the same TWT (Ogushi 2020b).

The research concerning the reliability of torque values indicated or pre-set by HTS might be less discussed. Ogushi et al. have investigated the influence of reference standards on the calibration results of TST (Ogushi et al. 2012), the perfect traceability of HTS to the national torque standard (Ogushi 2016), and the testing method of setting type (Ogushi 2019) and digital HTSs (Ogushi 2021).

Compared with HTTs, there are also hydraulic, pneumatic, and electric driving torque tools. However, there are no international standards and no international agreement on the traceability of measurement. It would be considered difficult to

uniformly determine the permissible deviation, etc., due to the dynamic control of the fastening torque.

Multicomponent Measurement

As shown in Fig. 2, natural forces are represented by six components of force and torque. A six-component force balance is required to measure all three forces and moments that determine an aircraft's motion in a wind tunnel (Smith et al. 2001). Multicomponent measurement is also necessary for six-component force control at a joint of a robot (Siciliano and Villani 1999). There is much research on developing multicomponent force sensors (e.g., Joo et al. 2002; Park et al. 2008).

On the other hand, the development of multicomponent calibration systems has been less reported because of the system complexity. In addition, the rated capacity of each component would be limited, and then multicomponent transducers, which a specific calibration system can calibrate, would also be limited. Merlo and Röske proposed a transducer-based six-component calibration system where six reference force transducers were put in position, and six components could be measured (Merlo and Röske 2000). Röske developed a system to generate and measure the arbitrarily directed forces and moments (Röske 2003). Both driving and measuring units were realized as hexapod structures with the same geometry but mirrored arrangement.

Baumgarten et al. developed a precise F_z-M_z two-component calibration system based on a 1 MN deadweight type force standard machine at Physikalisch-Technische Bundesanstalt (PTB) (Baumgarten et al. 2016). It can calibrate a two-component transducer which is used for the calibration of the screw tightening evaluation system.

The multicomponent calibration systems are generally quite costable. Therefore, a more reasonable and universal calibration method is required in this field.

Dynamic Torque Measurement

In the above sections, we have described a static torque calibration method that takes sufficient time to stabilize torque. However, there is a need in the industry to measure the torque that changes with time accurately.

For example, measuring the fluctuation torque in automobile engines and motors is essential for energy saving (e.g., Liu et al. 2016). The torsional fatigue test of the drive shaft measures the amplitude and phase of sinusoidal torque with high accuracy (e.g., Mayer et al. 2015).

As shown in Eq. (3), the dynamic torque is expressed by the product of the mass moment of inertia and the angular acceleration. It becomes extremely costly and technically challenging to apply a dynamic torque loading to a torque transducer to be evaluated, with a larger moment of inertia at a higher frequency.

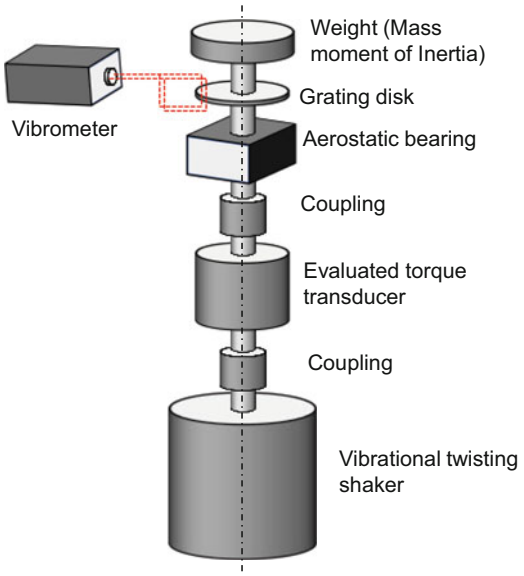

Fig. 16 Dynamic torque standard machine at PTB

Bruns and Klaus et al. are developing a dynamic torque standard machine (Bruns 2003; Klaus et al. 2015). Figure 16 shows a schematic diagram of the machine developed by them. In this machine, a torque transducer is mounted coaxially with the torsional shaker, and the change in angular velocity when torsionally vibrated by the torsional shaker is measured by a laser Doppler vibrometer through a grating disk. The torque can be calculated together with the model parameters (moment of inertia, spring constant, and damping viscosity coefficient) of all the machine elements obtained experimentally. Calibration is performed by comparing the torque calculated by Eq. (3) (but more complicated) with the output torque from the torque transducer.

Oliveira et al. tried to obtain the dynamic torque from an apparatus in rotation, consisting of a motor, a torque transducer, an encoder, two bearings, and different configurations of mass moment of inertia. They made the acceleration pulse between two angular speed steps. They also tried to evaluate the uncertainty of dynamic torque measurement (Oliveira et al. 2019).

Hamaji et al. tried to evaluate a dynamic response of a torque transducer based on the principle of Kibble balance, where the torque was generated with an electromagnetic force, as shown in Fig. 11 (Hamaji et al. 2022). Figure 17 shows a photograph of the electromagnetic force type dynamic torque evaluation equipment developed at NMIJ. Dynamic torque with an amplitude of 0.5 N·m and a frequency of up to 10 Hz has been realized.

We expect a high-reliable evaluation method for the dynamic torque is established and accepted worldwide in the future.

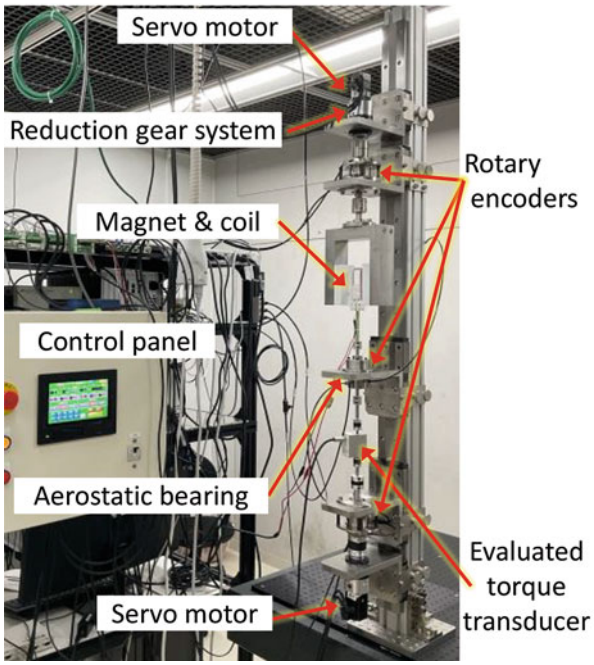

Fig. 17 Electromagnetic force type dynamic torque evaluation equipment at NMIJ

Summary

In this chapter, the authors briefly introduced torque metrology, including how to realize, disseminate, and maintain the national torque standards in each country/economy. First, we define the torque value and then explain how the precise torque is realized (or generated). Second, we also described how to confirm the traceability of measurement in the industrial field. Some inter-laboratories comparisons of torque standards were mentioned too. Finally, we described the present situation of research activities such as multicomponent force/torque measurement and dynamic torque measurement techniques.

There is also a simple method of directly calibrating a torque wrench tester or a torque screwdriver tester using a weight and bar system, although the authors didn't mention it here. We would like to mainly explain the calibration methods that directly ensure the traceability of the torque by torque in the SI unit.

We hope this review paper will be helpful as an introductory text for students or young engineers to learn about torque metrology.

Acknowledgments The author appreciates Ms. Misaki HAMAJI, a researcher in NMIJ, for her contribution to the drawing figures; Mr. Michio NOTE, technical staff in NMIJ; and Mr. Hiroshi MAEJIMA, senior staff in NMIJ, for their assistance in data acquiring, photographing, and processing.

Abstract

Ultrasonic technology is growing rapidly with a promise of having tremendous potential. A range of diverse applications using ultrasonic sensors have been witnessed recently in several areas ranging from healthcare, food sector, non-destructive testing, level measurement, etc. In industry, it is used for processes including cutting, forming, cleaning, and welding of metals and plastics. New hybrid forms of ultrasonics are also finding latest interest and attraction owing to the improved resolution and penetration depth for medical imaging. The present chapter explores the basics of ultrasonics along with a wide range of applications. Improvements in ultrasonic sensors have now resulted in low-cost, user-friendly, and compact devices. Being a radiation-free alternative, ultrasound has become ubiquitous attracting a wide range of interest resulting in the growing customer market. In retrospect, it should not have been so astonishing that ultrasound is soon to be covering the day-to-day field of importance areas widely.

Ultrasonics: An Introduction

The last few decades have witnessed phenomenal growth in the field of ultrasonics and associated areas. At present, it is hard to find any area where ultrasonic application has not entered. Some of the state-of-the-art ultrasonic-based applications are given as follows:

(i) Industrial cleaning (removing dirt even from inaccessible portions and from delicate components), cutting and drilling brittle materials, plastic welding, sintering, non-destructive testing (metal, concrete, polymer), surveying.
(ii) Chemistry and biotechnology emulsification (to disperse one liquid phase into small droplets in a second phase), homogenizer (to reduce small particles in a liquid to improve uniformity and stability), degassing, sonication, trans-esterification (increases the yield of the trans-esterification of oil into biodiesel), nanoparticle preparation.
(iii) Oceanography sonar (submarine detection, surveillance, sea-bed mapping), fish tracking, acoustic release, tomography.
(iv) Medical diagnostics, blind aid, therapy (pain reliever), nebulizer (asthma management), phacoemulsion (cataract removal), lithotripter (calculi disintegrator), cancer hyperthermia.
(v) Material characterization, elastic moduli, residual stress, intermolecular interaction, grain size, dimension analysis, concentration (quality check). Among all these areas, ultrasonic metrology (non-destructive testing, surveying, characterization, etc.) has made its own niche as one of the important branches of scientific research and development.

This chapter specifically deals with the development of new measurement methods based on ultrasonic principles that are useful for scientific laboratories as well as for industries. The unique capability of ultrasonic techniques in comparison to other techniques is its versatility, as it can be applied to systems even if they are optically non-transparent. Besides, rapid, precise, and non-destructive characterization along with the scope of fully automated operations places ultrasonics at the elevated place. The NDE embraces various analytical techniques to determine several properties associated with materials, components, or systems without causing significant change to its physical and chemical properties.

Sound waves above 20 kHz are termed as ultrasonic waves. The physical principles of classical acoustics, however, hold equally good for the audible as well as ultrasonics regime (White 1963; Birnbaum and White 1984; Hutchins 1988; Edwards et al. 1990; Cedrone and Curran 1954). As mentioned in an excellent

compilation by M S Srinivasan in his book entitled, *Physics for Engineers* (Srinivasan 1998), mechanical vibrations above human audible range were achieved more than a century ago by Rudolph Koenig. But ultrasonics as a technology was born during the First World War (1918). It began with the construction of a high power ultrasonic generator by Paul Langevin using quartz crystal. Next important development was in 1927, when Wood and Loomis generated ultrasonic waves in the frequency range 100–700 kHz by exciting quartz disks at about 5 kV. Application of ultrasonics for flaw detection in various substances was first suggested by Sokolov in 1929. This was the beginning of non-destructive testing (NDT) by ultrasonics. During 1945–1946, Firestone in the USA and Sprout in the UK independently developed pulse echo test unit. Developments in the field of transducer technology have played a significant role in the development of ultrasonic test machines. The introduction of polarized ceramic (barium titanate—a piezoelectric material) in 1947 has revolutionized industrial applications of ultrasonics. This has led to generation of higher acoustic power and lowered the cost of ultrasonic machines. The use of computers in ultrasonics in recent years is another important advancement in this area.

Physical Properties of Ultrasonic Waves

Ultrasonic waves are capable of propagating in all the media except vacuum. The ultrasonic waves propagate through the material as stress or strain waves. Elastic properties of the medium govern the propagation of ultrasonic waves. These waves obey laws of reflection, refraction, and diffraction as in the case of optics. The ultrasonic waves are classified as longitudinal waves, transverse waves, Rayleigh waves, and Lamb waves depending on the particle displacement of the media. The longitudinal waves are also known as compression waves. They are commonly used in the ultrasonic inspection of materials. The waves travel through the material media as a series of alternate compression and rarefaction, in which particles vibrate back and forth in the direction of the wave travel. Fluids support only longitudinal wave propagation.

When the particles of the medium vibrate up and down in a plane perpendicular to the direction of motion, the wave propagation is termed as shear or transverse waves. These waves are more often related for solids. The surface waves or Rayleigh waves propagate in elliptical orbits along flat or curved surface of thick solids without influencing the bulk of the medium below the surface. The depth to these waves propagating below the medium surface with effective intensity is of the order of a wavelength only. These waves are abundantly used to detect flaws or cracks on or near the surface of test objects. Lamb waves or flexural waves are also known as plate waves and are produced in thin metal whose thickness is comparable to wavelength.

The ultrasonic waves obey laws of reflection, refraction, diffraction, interference, and dispersion like light waves. Another important parameter for material characterization is the acoustic impedance, which is extensively used for intermolecular

interaction studies in liquids. For plane harmonic waves, acoustic impedance is determined as ρc where ρ is the density of the medium and c is the velocity of the ultrasonic waves. Acoustic impedance decides the fraction of ultrasonic waves reflected or transmitted at an interface. The ultrasonic attenuation is the loss of energy in an ultrasonic wave propagating through a material and can be attributed to scattering and absorption due to heat conduction, viscosity, and elastic hysteresis (Myers et al. 1959; Papadakis 1967, 1976).

The ultrasonic waves travel in liquid with a velocity dependent on compressibility and density. In a lossless medium, it does not show any change with frequency. However, in some medium, the ultrasonic velocity changes with frequency. This is called dispersion, like that in light. In a dispersive medium, velocity is categorized in two types: (i) group velocity and (ii) phase velocity. The group velocity is the velocity of the wave packet. In a non-dispersive medium, the ultrasonic velocity is the group velocity. The phase velocity is the velocity of individual frequency component in a medium, more significant for dispersive medium.

Generation and Reception of Ultrasonic Waves

Piezoelectric Method

The piezoelectric effect was discovered by Curie brothers in 1880 (Aindow and Chivers 1982), who found that certain crystals like quartz, tourmaline, and Rochelle salt develop electric charges across their faces when a mechanical pressure is applied. The converse piezoelectric effect is also observed, i.e., when the electric field is applied across the crystal, a change in the crystal dimension is observed. The direct piezoelectric effect is used to detect the ultrasound while its reciprocal effect is used to generate ultrasound.

Laser Method

Compared to contact piezoelectric transducers, a laser can generate orders of magnitude higher ultrasonic signals. Fast laser pulses generate high frequency broadband (wide frequency range in one pulse) ultrasonic signals. The frequency of generated waves depends upon the choice of laser and material properties. Pulsed lasers with rise times of the range of nanoseconds up to picoseconds have also been used to generate ultrasound in a range of samples. It is generally described in terms of two extreme regimes, the ablative regime and the thermoelastic regime (Rogez and Bader 1984; Ernst et al. 1992; Horváth-Szabó et al. 1994). In the ablative regime, the laser energy is focused onto the surface of the sample which will form plasma at sufficiently high energy densities. On the other hand, in the thermoelastic regime, the laser energy having a sufficiently low energy density is directed onto the surface of the sample to avoid ablation. The laser energy is absorbed within the skin depth of the sample and rapidly heats the exposed volume of the sample. While there may be no superficial damage to the sample, there may be subsurface damage due to the absorption of laser energy, being a major drawback.

Electromagnetic Acoustic Transducer (EMAT)

The electromagnetic acoustic transducers (EMATs) are electrical devices that can transmit and receive ultrasonic waves in an electrically conducting material, without contacting the material being inspected and emerging as a mainstream non-destructive evaluation (NDE) technique. The EMATs offer several distinct advantages over traditional piezoelectric transducers. These advantages include contactless, no need of a coupling fluid, high temperature operation, and the ability to utilize shear horizontal waves. The EMATs are also ideally suited for launching and receiving Rayleigh waves, Lamb waves, and shear horizontal plate waves.

The principle of EMAT is given as follows:

> When, near the surface of an electrically conducting object, a coil of wire is placed and driven by an alternating current at arbitrary ultrasonic frequency, it produces a time varying magnetic field. This field induces eddy currents in the material under test. If a static magnetic field is present, the interaction of these eddy currents with the static magnetic field results in a magnetic volume force whose direction and intensity is determined by the vector eq. $F = J \times B$, where F is Lorentz force, B is magnetic field induction, H is magnetic field, and J is induced eddy current. This magnetic volume force is called the Lorentz force, and this force results in the generation of a wave that propagates within the specimen.

Ultrasonic Non-destructive Testing (NDT) Methods

Basically, two methods of ultrasonic testing, (i) contact method and (ii) immersion method, are commonly used (Fig. 1).

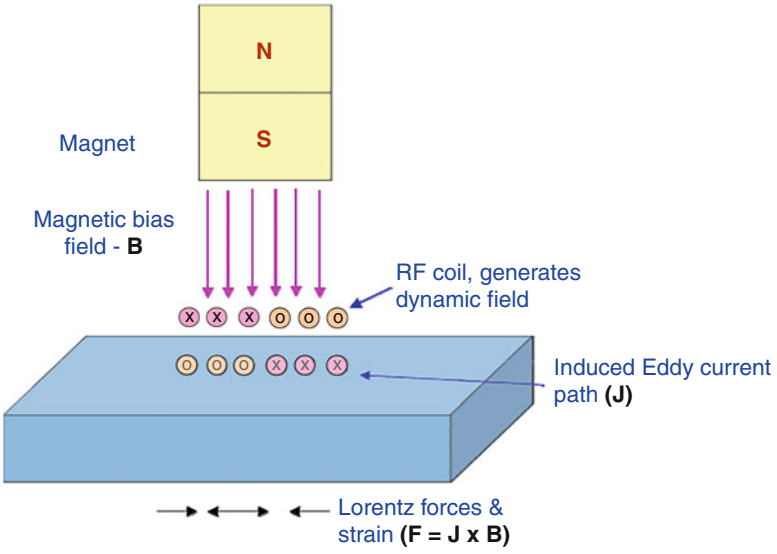

Fig. 1 Working principle of EMATs

Contact Method

In this method, the transducer is brought in contact with the test specimen using a suitable couplant like water, oil, grease, etc. In the absence of couplant, air bubbles are formed between the material under test and the transducer. The amplitude of the reflected pulse is affected by the type of couplant, its thickness, and uniformity of the couplant thickness. For this reason, contact method may not be the right choice where amplitude of echo is important mainly for attenuation measurement as it is often difficult to maintain the uniform pressure. However, this method allows quick testing of surfaces.

Immersion Method

In this method, the test specimen and the special-type immersion transducer are immersed in a liquid, usually water. The liquid acts as a couplant in the transfer of sound energy from the transducer to the test specimen. In this method transducer can be moved under water to introduce the sound beam at any desired angle, thus provides testing flexibility. It also provides constant path length of couplant (water) between the transducer and the material under test. This ensures uniform pulse height throughout the experimental measurements.

Techniques of Ultrasonic NDT

There are three basic ultrasonic test systems that are commonly used in industries. They are pulse echo, through transmission, and resonance system.

Pulse Echo System

Here the ultrasonic waves are not transmitted into the material continuously but in pulses. The pulse is reflected back from the boundaries of the material or discontinuity. The reflected pulse or echo is analyzed for evaluation of material properties.

(a) **Spike Excitation**

In this method, the short duration high amplitude pulses coming from the transmitter are given to the transducer. The transducer converts the spike into a broad band short duration pulse which is radiated into the test piece via a coupling medium. If it encounters a flaw in its path, the flaw reflects an echo wave, a portion of which depending on its form and size reaches the receiver. Echo of flaw indicates transit time from transmitter to flaw and to receiver which gives distance of flaw. A transducer acts both as a transmitter and a receiver. Both the transit time and intensity of ultrasound are measured in this method.

(b) **Tone Burst Excitation**

In high power ultrasonic applications, tone burst generators are often used. In this method, a single frequency pulse, usually matching with the transducer's resonant frequency, is generated. Low-voltage signals are taken and then converted into high-

power pulse trains for the most power-demanding applications. Tone burst capability is mostly useful to work with difficult, highly attenuative materials.

Through Transmission System

In this method two transducers are required; one is used as a transmitter and the other one as a receiver. Short duration ultrasonic pulses are transmitted into the material. The receiver is aligned with the transmitter on the opposite side to pick up the sound waves passing through the material. The quality of the material is determined by change in the pulse shape as it transverses the material. A marked reduction in the amplitude of the received energy indicates a discontinuity.

Resonance System

This system makes use of the resonance phenomenon to detect flaws. Here continuous longitudinal waves are transmitted into the material. The frequency of the waves is varied till the standing waves are setup within the specimen causing the specimen to vibrate or resonate at greater amplitude. Resonance is then sensed by a device. A change in the resonant frequency cannot be traced to a change in the material thickness, but it is usually an indication of a discontinuity in ultrasonic non-destructive testing (NDT).

Techniques for Velocity Measurement (Review of Literature)

Ultrasonic velocity has become an important tool for the study of physical properties of matter. These measurements offer a rapid and non-destructive method for the characterization of materials. During the process control of manufacturing procedures and also in routine monitoring of quality changes of viscoelastic products during and after manufacturing processes, they are often employed. Sound velocity is a favorable parameter for such applications because of its remarkable sensitivity to liquid states.

Basic Pulse Echo Methods

An ultrasonic transducer converts a pulsed radio frequency (r.f.) signal of given frequency into pulsed ultrasonic wave of the same frequency. Pulse echo methods are the most simple and widely used techniques for measuring sound velocities in liquids. Extensive literature survey reveals velocity methods utilizing plane wave sound propagation (Hosoda et al. 2005; Crawford 1968; Carstensen 1954; Cerf et al. 1970; Kaatze et al. 1988; Kaatze et al. 1993; Tong and Povey 2002; Bakkali et al. 2001; Taifi et al. 2006; Sachse and Pao 1978; Kline 1984). This group of pulse measurements is referred as "narrow-band pulse techniques." A sinusoidal signal is not a single frequency. In addition to the carrier frequency, there are side bands, resulting in an effective bandwidth (Goodenough et al. 2005). This bandwidth has to be taken into account for phase velocity measurement. Methods of determining directly the difference between the sound velocities in the sample and in a reference liquid (Cedrone and Curran 1954; Greenspan and Tschiegg 1957) use nearly single-frequency signals. The output of the receiver transducer is added to a reference signal

from the harmonic signal generator, to measure the phase of the signal transmitted through the specimen cell. The sound velocities can also be obtained as a derivative from pulse-modulated attenuation measurements (Myers et al. 1959; Aindow and Chivers 1982).

The other group employs sharp pulses (Tardajos et al. 1994; Hosoda et al. 2005; Crawford 1968; Ernst et al. 1992; Forgacs 1960; Van Venrooij 1971; Papadakis 1973; Bilaniuk and Wong 1993; Høgseth et al. 2000) referred here as wideband techniques having wider frequency spectrum with sharp pulses required to make broadband transducer systems. A single sharp pulse is applied to the transmitting transducer, containing a wide range of frequency components. Pulse propagates through a known distance in the liquid medium and reflects back as received signal. The frequency components of the received signal are extracted using a Fourier transformation of the received signal. Time of flight measurements are crucial for sound velocity determination. The velocity is determined from distance divided by time of flight. One more method for velocity measurements employs pulses propagating through the sample and echoes reflected back and forth (Carstensen 1954; Benedetto et al. 2005). Pulse echo methods are employed for narrow-band signals as well as for sharp pulses. The broad frequency spectrum of sharp pulses allows to determine group and phase velocities and the attenuation coefficient in a considerable frequency range (Kaatze et al. 1988; Meier and Kabelac 2006; Letang et al. 2001; Papadakis 1967; Papadakis 1976; Horváth-Szabó et al. 1994). The broadband technique is based on a Fourier analysis of a primarily sharp pulse. The principle of three main techniques used for ultrasonic velocity measurement is presented briefly in the following section.

(a) **Sing Around Method**

In this method a transducer placed at the end of the sample opposite the transmitting transducer acts as a receiver. Trigger is acquired by the received signal for the pulse generator thereby generating a succession of pulses. Since pulse repetition rate of sequence depends on time of flight in the sample, the velocity may be determined by measuring the repetition rate (Kaatze et al. 1988; Tong and Povey 2002; Papadakis 1976; Horváth-Szabó et al. 1994; Tardajos et al. 1994).

(b) **Pulse Echo Superposition Method**

A series of radio frequency pulses from a pulse generator is transmitted into the sample, and their repetition rate, controlled by frequency of continuous wave oscillator, is adjusted to correlate approximate multiple of an acoustic round trip transit time in the sample. The time delay between superimposed phase pulses is the reciprocal of the continuous wave oscillator frequency.

(c) **Pulse Echo Overlap Method**

As described with the above method, series of r.f. pulse are introduced in the sample with controlled pulse repetition rate. During the acoustic time measurement

oscilloscope is switched to an X-Y mode in which continuous wave oscillator provides sweep. CRT intensity is reduced and two amplified echoes are visible. The echo can be made to overlap cycle for cycle. This method is useful to measure group velocity as well as phase velocity. Ultrasonic velocity can be measured both in liquids and solids, thus making this method versatile and accurate.

Continuous Wave Method

Two transducers, one operated as a transmitter and the other one as a receiver, are used for velocity measurement (McSkimin 1961; Mitaku and Sakanishi 1997; McClements and Fairly 1991; Elias and Garcia-Moliner 1968; Pearson et al. 2002; Nolting 1999; Hubbard 1931; Eggers 1967/68; Pethrick 1972; Dev et al. 1973; Sarvazyan 1982). The transmitting transducer is excited at constant amplitude and at fixed frequency resulting continuous wave propagation in the medium. The ultrasonic wave after interaction with the medium is received by the other transducer. From values of frequency and wavelength, the velocity is calculated. Current techniques employ interferometers, in which the path length of interactions of the ultrasonic waves with the sample is increased by multiple reflections giving high sensitivity of measurements.

Optical Method

When a sound wave passes through a transparent material (solid and liquids), periodic variation in refractive index occurs. A diffraction grating is formed due to maxima at compression and minima at rarefaction. The diffraction grating has spacing equal to half the ultrasound wavelength. A monochromatic light beam is passed through a slit, and further a convex lens is used to make them as parallel rays through the medium. The velocity is determined using Bragg relation. Bragg scattering (Kaatze et al. 1987) and Brillouin scattering (Eggers 1992) are challenging for required applications. Improved signal-to-noise ratios, however, are reached in Bragg reflection as well as in stimulated (Nakajima and Arakawa 1993; Eggers 1994) and forced (Eggers 1997) Brillouin scattering techniques.

All the techniques discussed so far have their own merits and demerits. Most of the techniques are laboratory methods and hence cannot be used for online purposes. Temperature stability is also one additional crucial parameter. New techniques have been designed and developed by the author to overcome the limitations of existing methods (Joshi et al. 2009, 2014). The present chapter manifests current state-of-the-art regarding recent trends and diversity in emerging areas of ultrasonics.

Motivation

It is apparent from the aforesaid sections that during the last few decades, ultrasonic technology has emerged as one of the important branches of scientific research and product development. We also see that one of the established applications of ultrasonics is in non-destructive evaluation (NDE), which embraces various analytical techniques to determine several properties associated with materials,

components, or systems without causing significant change to its physical and chemical properties. The present chapter specifically deals with the development of new measurement methods based on ultrasonic studies which are useful for laboratories and industry.

Ultrasonic non-destructive testing (NDT) provides one of the larger markets for industrial equipments. However, it is only one of many areas in which low-intensity ultrasonic energy is applied. The development of metrology applications of ultrasound has occurred in parallel with the development of medical applications using high as well as low intensity ultrasound. Ultrasound equipment over the last few decades has gotten physically smaller, generates less heat, and has become more power efficient. These upgrades, along with vast enhancements in image quality, have pushed point-of-care ultrasound to widely popularize in emergency rooms and obstetric clinical practices. Availability of instant real-time diagnostic data has consequently helped reduce overall healthcare costs by replacing more expensive diagnostic exams comparatively.

Recent years have witnessed promising growth within the multidisciplinary field that encompasses ultrasonics in diverse applications from medical imaging to several industries. The speed, efficacy, low cost, and non-invasive nature of ultrasound imaging are some of the key attributes that have given this technology an edge over the other medical imaging modalities. In addition, ultrasound equipment is economical compared to other systems; even the most advanced ultrasound systems cost only about one-fifth of the price for a low-end magnetic resonance imaging (MRI) system. Similar technological evolution has been experienced by the ultrasound imaging. Device miniaturization and Windows PC-based architecture have made it possible to pack increasing amounts of processing units into smaller and smaller medical devices.

Diversity in Ultrasonics and Emerging Trends

To assess the performance and safety of medical ultrasonic equipment, ultrasonic power measurement is essential. The power generated from medical transducer can be used to bring about irreversible changes in tissue, being several watts for physiotherapy applications. This characteristic of ultrasound to whether be used for diagnostic or for therapy applications prompts a grave need for accurate knowledge of the intensities of what the patient is being exposed for safety. During the design and optimization of an ultrasonic equipment, acoustic output needs to be determined essentially, as it plays an important role in the performance level optimally. Ultrasonic sensors reliably detect transparent and other demanding objects where optical technologies do not suffice.

The acoustic impedance is basically the opposition exerted by the medium to the displacement of medium's particle by sound energy. Ultrasonic waves on passing through an interface of two media are reflected and transmitted, based on the acoustic impedance of the two media. The acoustic impedance of any medium is governed by inertial and elastic properties of the medium; hence its determination serves as an

important parameter to study the material characteristics of different substances. The greater difference in acoustic impedance will lead to greater reflection of sound energy. The acoustic impedance directly using piezoelectric resonator has also been measured (Bhatnagar et al. 2010). Joshi et al. (Joshi et al. 2013) also measured the acoustic impedance of solid salol directly by measuring successive echo amplitudes. Later Kumar et al. (Kumar et al. 1997) introduced a unique method of evaluation of the acoustic impedance measurement in thin samples like a membrane which was considered to be an unattainable task. In general, relation of acoustic properties with equilibrium constants is a major advantage of sound velocity technique in addition to being non-destructive and cost-effective. More often measurement of ultrasonic velocity and density is carried out by researchers to study the undergoing interactions. It was observed that non-linear variation of the ultrasonic velocity with concentration is the signature of complex formation between unlike molecules. For a particular value of concentration, the maximum echo height also signifies the maximum interaction at that particular value of concentration. In addition to this, density is also one of the basic parameters to act as a probe for intermolecular interaction. The accurate determination of density is rather very critical and generally carried out in a long procedure using a pyknometer. The ultrasonic velocity measurement is usually performed by interferometer method where the accuracy is mainly a function of degree of parallelism between the quartz disc and reflector. All these analyses essentially require measurement of ultrasonic velocity and density, separately, at different time using individual set-up. This usually enhances the chances of error in the measurements because in two different experiments of velocity and density, there is always a possibility of different temperatures in the vicinity of two experimental set-ups. Such temperature difference can further lead to remarkable change in the derived parameters. Also employment of two different set-ups for velocity and density measurements may change concentration due to volatile property of organic liquids, further causing error in the measurements. The relatively small impedance mismatch between soft tissues allows for the ultrasonic waves to propagate across several interfaces providing imaging capability up to large depths. The ultrasonic transducer design plays an important role in determining the quality of images. For an efficient transfer of acoustic energy from the body to the transducer and electrical energy between the system and transducer, the acoustic and electrical impedance matching has to be optimized. Significant technological advances employed in commercial systems have amplified scope and the range of applications of ultrasound in the last few decades. This chapter includes discussion of many of these advances and improvements. Many of the advances that took place in the field of ultrasonics recently are directly related to developments in electronics, data processing techniques, and market demands.

Applications of Ultrasonic Imaging

The ultrasonic NDT and medical diagnosis are two main technical areas utilizing ultrasonic waves and their interaction to material discontinuities. The two important

quantities for which traceable measurements can be made are the acoustic pressure and the acoustic power. To enable measurements undertaken by different parties to be compared on a meaningful basis, the calibration of the devices must be traceable to a national primary standard. From the perspective of modern automization in road safety, a variety of sensors assist self-driving vehicles in navigation and general operation, helping with blind-spot detection and self-parking. The unique advantages of the ultrasound technologies still do not make it a one-stop shop for every need, leading the emergence of new hybrid form of ultrasound-based technologies.

Emerging Technology

Newer technologies are set to revolutionize ultrasound practice effectively. Some recent industrial applications are packaging industry, electronics industry, and food technology offering wide variety of object geometries and surfaces however with narrow space requirements for sensors providing high safety.

The ultrasonic technology and applications are continuously expanding, and these sensors are steadily gaining recognition as an industry standard.

Current Ultrasound Applications in Health Care

Ultrasound technology is an inseparable part of the health care and is a promising technology with several recent advancements. It is utilized for a variety of diagnostic purposes. However, so far, all an ultrasound could be used for was viewing the inside of the human body. Ultrasounds are typically and traditionally used for imaging, usually in internal medicine and prenatal applications. Several newer applications for ultrasound technology include dental descaling and shock wave lithotripsy. This process is very popular now as an alternative to surgery and utilizes targeted ultrasound waves to break up kidney stones and calcium-based growths in the body that are too large to pass naturally.

Futuristic Promising Technology

To look inside the human body, invasive techniques such as surgery can potentially damage the body. Therefore, non-invasive biomedical imaging modalities, such as projection radiography, x-ray computed tomography (CT), positron emission tomography (PET), single-photon emission computed tomography (SPECT), magnetic resonance imaging (MRI), and ultrasound (US), are widely used in clinics today for the diagnosis and treatment of various diseases. Some of these modalities (projection radiography, x-ray CT, PET, and SPECT) use ionizing radiation, which exposes the human body to harmful radiation. On the other hand, much safer MRI is time consuming, expensive, and cannot be used for patients with metallic implants as it uses high-strength magnetic fields. US imaging offers a cheap, real-time, easier to operate, and safe alternative. However, poor soft tissue contrast and difficulty in imaging through skull/bone limit its use in many body parts. Nonetheless, all these

imaging modalities are capable of imaging deeper (∼20 cm inside soft tissues in the case of US imaging), which is a major advantage for clinical applications.

Conventional optical microscopy provides images with high spatial resolution and rich optical contrast, making it possible to visualize cellular and subcellular structures. However, due to light scattering in biological tissue, imaging depth is limited to not more than ∼1 mm. Therefore, even though optical microscopy is a gold standard in pathology, it is not suitable for in vivo human imaging. Another high-resolution purely optical imaging modality, known as optical coherence tomography (OCT), can image tissue with high resolution (∼1 μm) and at an imaging depth of up to ∼2 mm. However, OCT also has limited application to eye retinal imaging to date. Therefore, researchers are trying to come up with various techniques to overcome these depth limitations of optical imaging. Diffuse optical tomography provides imaging depth up to a few centimeters deep inside tissue, but the spatial resolution is relatively low—one-third of the imaging depth. Therefore, high-spatial-resolution images at deeper imaging depths are always a challenge for purely optical imaging techniques.

Ultrasound Mediated Optical Tomograpghy (UOT)

Noninvasive diagnostic imaging technologies to detect diseases such as cancer and others come in a wide variety. Most of these technologies include sophisticated techniques such as MRI and X-ray, but they lack optical contrast which is beneficial for detection of small lesions without using the contrast agents or ionizing radiation. Famous techniques such as optical coherence tomography (OCT) and diffuse optical tomography (DOT), which are optical ion nature show good contrast but the resultant depth and resolution, respectively, are limited by the strong light scattering from the tissue. It is quite challenging to measure with high resolution at penetration depths larger than millimeter order due to the high optical scattering which results in a strong dampening of ballistic photons. In contrast to X-ray these optical techniques are non-invasive and use non-ionizing radiation. The absorption coefficient of light is wavelength dependent making spectroscopy possible, which can be used to determine blood oxygenation levels. On the other hand, the ultrasound in the few MHz range has a scattering coefficient less than light, which allows for superior penetration depth while retaining spatial resolution. There is however a drawback in which ultrasound lacks the benefits of optical contrast. Recently emerging imaging techniques which interplay sound and light are hybrid forms as acousto-optics imaging (AOI) or ultrasound modulated optical tomography (UOT) and photo-acoustics imaging (PAI). These two techniques combine the high resolution of ultrasound with strong contrast obtained with optical techniques. Development of an ultrasonic modulated optical tomography system (Fig. 2) couples ultrasounds and light in order to reveal the local optical contrast of absorbing and/or scattering objects embedded within thick and highly scattering media such as biological tissue and human breast tissue. Thus, ultrasound would be focused into the tissue/sample under test causing periodic compression and rarefaction. In parallel, if the tissue would be illuminated with a laser light source of sufficiently long coherence length, then the intensity distribution at the output will be laser speckle pattern consisting of

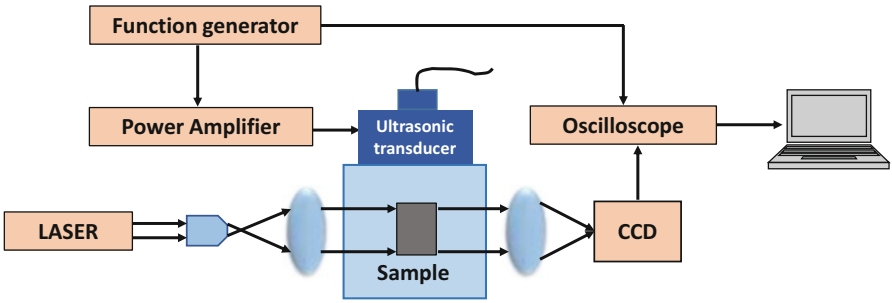

Fig. 2 Schematic setup for ultrasonic mediated optical tomography

distribution of bright and dark speckle grains. The optical effect of ultrasound would result in modification of local refractive index and modification of the position of the optical scattering sites. The combination of light and ultrasound to measure local optical properties through thick and highly scattering media is a tantalizing approach for breast cancer detection. Speckle reduction minimizes the scattering noise and thus increases both the resolution and optical contrast in the biomedical imaging.

Photoacoustic Tomography (PAT)

Hybrid imaging techniques utilizing couplings of physical modalities have attracted considerable attention in recent years. Optical imaging of biological tissue is able to provide structural and functional information, which potentially enables early detection of abnormalities such as tumors and detection of tissue oxygenation. However, one disadvantage of such technique is the difficulty to image objects at depth. By comparison, ultrasound imaging is able to provide good image resolution at depth and is an established clinical imaging modality. However, ultrasound imaging is based on the detection of the mechanical properties in tissues which is not as sensitive as optical techniques in, e.g., detecting tumors. Several efforts have been made in the recent years to develop new imaging modalities which lie visible and near infrared regions and are based on the optical properties of soft biological tissues. At these wavelengths, radiation is nonionizing, and the optical properties of biological tissues are related to the molecular structure, offering potential for the detection of functions and abnormalities. With the growing application of photoacoustic imaging in medical fields, there is a need to make them more compact, portable, and affordable. Besides, medical imaging is a challenging and most needful issue currently. Depending on the organ to be inspected, different waves (X-ray, ultrasound) are used. Tissues are highly scattering media. When using light only, like in diffuse optical tomography, the resolution of a breast tissue image is usually around 10 mm so that doctors can hardly detect an emerging tumor. Use of radiography also could not be much efficient. The ultrasonic waves scatter much less than light waves and thus provide better localization; however it suffers from contrast problem.

It is the need of the hour to get the millimeter resolution, which compelled researchers to associate ultrasonics with optics and thus named as photoacoustic

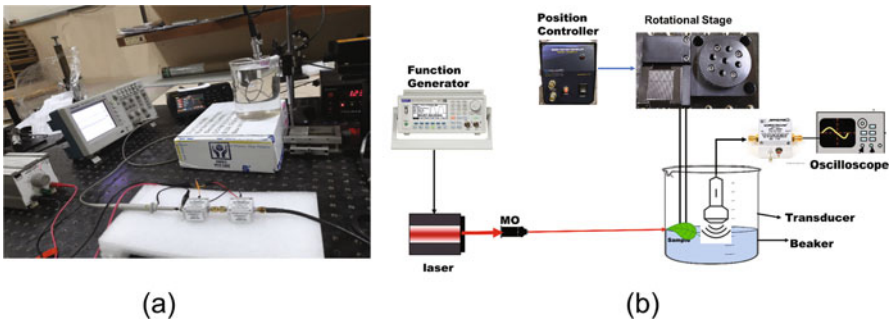

Fig. 3 (**a**) Laboratory set-up of the laser-based PAT system to study biological tissues. (**b**) Modified photoacoustic instrumentation with 360-degree rotational stage

tomography (PAT). In PAT, an image is formed through detection ultrasound waves induced by laser beam. Pulsed lasers with nanosecond time duration having relatively high energies (milli joules)—including Q-switched Ti: Sapphire laser, optical parametric oscillator (OPO), Nd: YAG laser, and dye laser—which are most commonly used excitation sources in PAT systems. However, their high cost, bulky sizes, and strict maintenance requirements significantly limit their practical use in the biomedical applications. Pulsed laser diodes (PLDs) were proposed to address some of these drawbacks because PLDs are relatively simple, compact, inexpensive, and highly power efficient. Design of a very low-cost PAT system is shown in Fig. 3, by replacing the expensive and sophisticated laser with a low-energy pulsed laser diode. It has been shown by several researchers that using PLD, the biological tissue can be imaged with adequate signal-to-noise ratio (SNR) and spatial resolution. Furthermore, since PLDs can operate at a high repetition frequency (up to megahertz), it provides significant advantage for real-time imaging applications. To have a complete information of the sample, 3D images can be built up by moving the focused ultrasonic beam. Interplay of strong optical contrast with high ultrasonic spatial resolution can thus be advantageous for medical imaging. In PAT, due to the conversion of absorbed optical energy into a temperature rise, a corresponding pressure change generates an acoustic signal that can be detected by the ultrasonic receiver, and a high resolution image of optical absorption can be reconstructed revealing the internal structure and functioning. With the growing application of photoacoustic tomography in medical fields, there is a need to make them more compact, portable, and affordable.

Conclusion

Several recent developments in the field of ultrasonics have proved it as a promising tool for medical imaging and non-destructive testing with a promising future full of opportunities. One of its prime attributes is the ability to obtain real-time imaging compared to MRI at a comparably low cost, and ease of operation has also made

impact in daily crucial fields like food safety, medical emergency, and a lot of applications. The past few years have witnessed unprecedented growth in ultrasonic devices in terms of portable size and cost-effectiveness resulting in increased popularity. The financial benefit alone is compelling. In the near future, ultrasonic-based sensors are believed to have a significant role in much wider range of applications.

Abstract

Accurate avalanche forecasting is imperative for the safety of man-machine and habitations and operations including snow removal, road clearance, etc. in higher Himalayas and later use of the road for safe passage. In common parlance, avalanche forecasting means the daily assessment of the avalanche hazard for a given region. Real-time snow and meteorological data are important parameters for the study of snow and avalanche forecasting. The timing and size of an avalanche depend on the amount of snow in the formation zone area, the stability of the snow as well as the triggering factors. Therefore, snow and meteorological data from the avalanche formation zone are the most useful input in avalanche forecasting. The data is measured using the snow and meteorological sensors, and it is of paramount importance as this is the basic input for providing avalanche forecasts at various strategic locations in the snow-bound region of the Indian Himalayas. Therefore, periodical calibration of these sensors/instruments is foremost important for ensuring good quality of snow and meteorological data. All electronic devices are sensitive to changes in their working environment, the same applies to sensors. Changes in the working environment and aging of the sensors may result in erroneous and undesired output due to malfunctioning of the internal elements of the sensor. Therefore, sensor calibration is a very crucial aspect that needs to be addressed to maintain the accepted performance level and reliability of sensor measurement. It becomes evident from the above facts that calibration proves instrumental in improving the performance of the sensors and accuracy of measurement which in turn can help to improve the forecast precision.

Snow · Avalanche · Sensor · Calibration · AWS · Traceability · Uncertainty

Introduction

This chapter will cover the need for snow and meteorological sensors in snow-bound regions of the Indian Himalayas. What are the different kinds of sensors used for the study of snow and avalanche forecasting? What is the need for sensor calibration from a snow and avalanche forecasting perspective? Along with a brief insight into the workings of the avalanche forecasting system. It may be noted that wet snow avalanches are a complex process that has not been completely understood and are quite difficult to forecast; water is a prime ingredient in the snow cover, to forecast wet snow avalanches, it is extremely important to get a fair idea of the liquid water content of the snow cover. Evaluation of wet snow instability by field measurements

and experiments is quite difficult, and generally, physical models are used to estimate the liquid water content in the snow cover utilizing metrological input. It may thereby be understood the paramount importance of calibration for the sensors which read these data, for example, the liquid water content in the snow cover. Any minuscule error can cause inaccurate measurement with disastrous consequences.

Avalanche Forecasting

Avalanches are set in motion due to certain peculiar topographical and snowpack conditions, in most cases, the formation zones are generally having slope angles of 30–45°, accelerated by barren hills with scanty forest/vegetation cover.

The main aim of avalanche forecasting is to provide valuable and crucial information for enhancing the mobility of man and machine in snowbound avalanche-prone areas by evaluating snow and avalanche hazards. The information disseminated is a result of analysis of snow and meteorological data using highly complex mathematical algorithms running on high computation machines/supercomputers. The snow and meteorological data are mostly gathered from Automatic Weather Stations (AWS), and also manually from various observatories installed at specific places of interest in the snow-bound regions.

Avalanche forecasting had been defined by McClung (2000) as "The prediction of current and future snow instability in space and time relative to a given triggering level." The temporal and spatial variability of snow cover is unstable, along with snow and weather condition changes, variability in human perception, and estimation which make forecasting a difficult task and can be seen with skepticism.

The validation of avalanche forecasting is closely associated with the spatial scale that forecasting is designed for; McClung and Schaerer (1993) categorized the scales into three categories, i.e., synoptic, meso, and micro. Synoptic scales are in the order of 10,000 km^2 (e.g., mountain ranges); meso scales are in the order of 100 km^2 and used for terrain features of independent actions like ski runs.

Some institutes in the world are working in the field of avalanche forecast and mitigation strategies. Few of the most renowned institutes in the field of avalanche forecasting are:

- American Avalanche Association & US Forest Service National Avalanche Center in collaboration with US Avalanche Centres, United States (Bridgeport Avalanche Center, Chugach NF Avalanche Center, Colorado Avalanche Information Center, etc.).
- Avalanche Canada, is a nongovernment, non-profit organization dedicated to public avalanche rescue and safety. Avalanche Canada issues daily avalanche forecasts all-round the winter for major avalanche-prone mountainous regions of Canada.
- WSL Institute for Snow and Avalanche Research SLF, Switzerland.

- Defence Geo-Informatics Research Establishment (DGRE), DRDO India. Erstwhile Snow & Avalanche Study Establishment (SASE).

This list is not limited to the above entries but is exhaustive as there are many regional players which have developed methods and algorithms for providing avalanche forecasts for specific areas, especially for the skiers who are at high risk in avalanche-prone areas.

As elaborated above there are several institutes and centers which are operationally committed to the safety of human lives and infrastructure deployed in various snow-bound areas of the world. In the Indian context Jammu, Kashmir, Ladakh, Himachal Pradesh, Uttarakhand, and the higher reaches of Sikkim and Arunachal Pradesh are among the most vulnerable regions from the avalanche threat perspective.

As detailed by LaChapelle, conventional level entry forecasting consists of the following characteristics:

- A well-built element of determinism formed by the interaction of physical process in the snow cover with the weather, coupled with a non-determinate still decision concerning the actual forecast.
- Reliance on redundant & diverse sources of information about weather, snow, terrain, and avalanche occurrence.
- A high level of human skill which is developed through experience & field learning.

Needs and Types of Snow and Meteorological Sensors

Avalanche forecasting is the science of prediction of avalanche occurrence based on results obtained from complex mathematical algorithms and expert opinions. To have both algorithms and expert opinion work on snow and meteorological data from the snow-bound regions is of utmost importance. The accuracy of algorithms will depend upon the accuracy and reliability of data from the snow-bound locations. To measure and disseminate snow and meteorological data from a network of observatories (automatic/manned) is deployed over the area of interest. The snow and meteorological data from these observatories is passed over to a central location twice a day or on an hourly basis where it is fed into various algorithms and provided to experts for opinions which finally provides the avalanche forecast.

Sensors are imperative to the chain of avalanche forecasting since they form the first block in the chain (Fig. 1).

Various weather variables are used to express meteorological and snow, e.g., temperature, wind speed, precipitation, wind direction, pressure, solar radiation, snow depth, and snow surface temperature. In the case of sensors, special attention has to be given to their accuracy and long service life. Especially in the case of sensors for snow data where they have to be exposed to sub-zero temperature conditions with high thermal changes and extreme weather conditions.

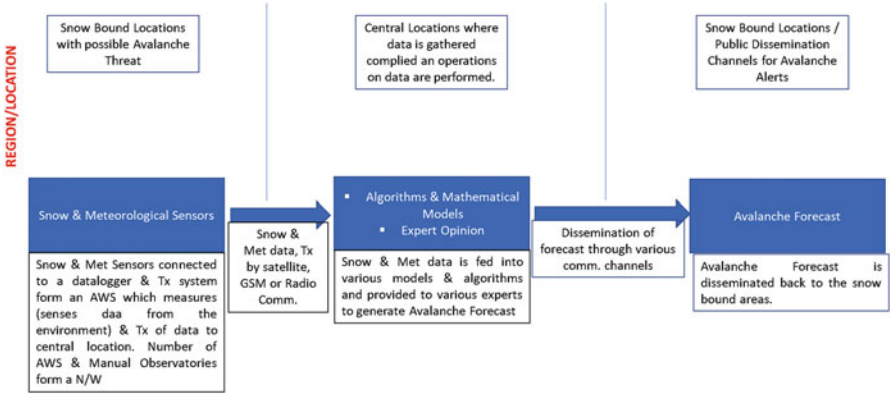

Fig. 1 Avalanche forecasting chain

Automatic Weather Station

Conventionally, data had been collected with manual efforts which suffer from various inherent drawbacks, viz. delay in data reception, exposure of humans to severe weather conditions, measurement errors, and sparse intervals of recording. To obviate these problems and eliminate the risk to human life, automatic data collection with the help of the Automatic Weather Station (AWS) has been adopted worldwide. Sensors form the ears and eyes of the AWS which sense and measure various snow and meteorological parameters for recording these parameters at fixed intervals and disseminating.

The AWS system will primarily consist of Snow and meteorological Sensors, a Datalogger, Data Transmitter with Antenna, a Power supply (Battery, Charger, and Solar Panel), and a Mounting tower. The Datalogger, Data transmitter, and Battery with charger will be housed inside the NEMA-4X enclosure. The lightning arrestor, Antenna, Solar Panel, Sensors, and NEMA-4X enclosure will be mounted on the AWS tower. The advantage with the AWS is that they can be installed even in the formation zones of an avalanche site before the onset of winter. Since the data observation is completely software-guided, it is free from any human error (Fig. 2).

Prolonged, unattended operations of the Automatic Weather Stations are achieved by utilizing low power consumption electronic modules, batteries and solar panels, wireless data transmission, and substantial onboard data storage capacity. AWS reports nonstop, i.e., all meteorological and snow conditions are reported 24 h a day, 365 days a year. They are fitted with custom snow condition sensors or snow depth sensors. Barometric Pressure sensor, Snow Surface Temperature, Ambient Temperature, Water Temperature, Precipitation, Solar Radiation, Wind Speed & Direction, Snow Depth, Relative Humidity, Soil Temperature, etc. are the most common sensors attached to the AWS.

Fig. 2 AWS in snow-bound area

In a typical satellite transmission-based, AWS, the snow and meteorological data is received at Earth Receiving Station (ERS) from the remote AWS for further utilization in the study of snow and avalanche forecasting. The ERS consists of a Dish antenna, Low Noise Amplifier (LNA), frequency Down Converter, Demodulator, Data Management Computer, and Server (Fig. 3).

Typically, the sensors utilized in the AWS for measuring the snow and meteorological data specific to avalanche forecasting are:

(i) Ambient Temperature Sensor
(ii) Relative Humidity Sensor
(iii) Atmospheric Pressure Sensor
(iv) Wind speed and Wind Direction Sensor
(v) Radiation Sensors (Albedometer and Pyrgeometer)
(vi) Precipitation Gauge
(vii) Snow Surface Temperature Sensor
(viii) Snow Depth Sensor

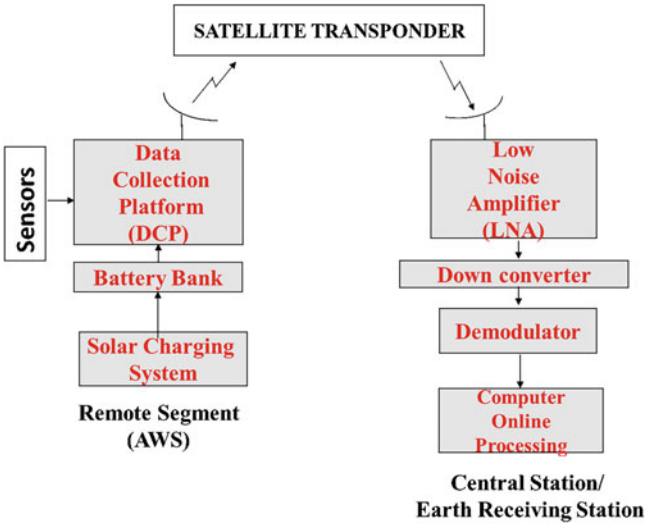

Fig. 3 Block diagram AWS and ERS setup

The parameters and specifications of sensors are given in Table 1 below. The specification of sensors is defined as per the typical installations that exist worldwide for avalanche forecasting purposes.

Grímsdóttir and Ingólfsson (2019) worked on data usage from automatic snow sensors in forecasting avalanches in Iceland. They had relied on snow depth data from different types of snow depth sensors installed in the avalanche starting zone for over 20 years. They measured the output temperature profile based on which an algorithm was developed to calculate snow depth in real-time. The temperature profile also shows the value for avalanche forecasting, since the metamorphism of snow crystals depends on the temperature gradient.

Similarly, Herwijnen and Schweizer (2011) used a seismic sensor to monitor avalanche activity. Rockfalls, landslides, avalanches, etc. are considered hazardous mass movement and are detected remotely by seismic sensors. Avalanche detection through seismic sensors was shown first time by St Lawrence and Williams (1976). Biescas et al. (2003) used runout distance to compare signals between wet snow and dry snow avalanches. They showed that the former generates larger signals than the latter, which can be attributed to the higher mass density of the former.

While avalanche forecasting is being done by both meteorological and snow data, however, it is not simple to predict the influence of meteorological conditions on avalanching. Heightened minimum temperature and change in snow affects the above-average avalanche activity mostly. A combination of prolonged snowfall and mean air temperature near freezing points generally increases the avalanche activity. Furthermore, days with high main wind speed frequently coincide with avalanching. Thereby, it is clear that the period of increased avalanche is related to abovementioned two different processes (Schweizer and Jamieson, 2003).

Table 1 Make and models of various sensors

S. no.	Sensor name	Make	Model no.(s)
1.	Ambient temperature and relative humidity sensor	Rotronic	Hygro Clip HC2A-S3, HC2A-SM, and MPA 101A
		Lufft	WS300
2.	Barometric pressure sensor	Sutron	5600-0120-1S
		Vaisala	PTB210
		RM Young	61,032 V
3.	Wind speed and direction sensor	RM Young	05103 V, and 05108-45
4.	Albedometer	Kipp and Zonen	SMP6
		Deltaohm	LP PYRA 06
5.	Pyrgeometer	Kipp and Zonen	CGR3
6.	Snow precipitation gauge	OTT HydroMet	Pluvio^2
		Belfort Instrument	5915 series
7.	Standard field view infra-red radiometer	Apogee	SI-111-SS, and SI-411-SS
		Everest Interscience, Inc.	Snow-Therm
8.	Ultrasonic snow depth sensor	Campbell Sci	SR-50A-L, and SR-50
		Max Botix, Inc.	MB7374
		Judd Communication	–

A schematic of the operational avalanche forecasting for Western Himalayas is shown in Fig. 4 (Ganju and Singh, 2004).

The following tables give the details of various make and models of the sensor, which are used in AWS specifically deployed for data collection for avalanche forecasting.

Examples of a Few Sensors with the Source of Error

Snow Precipitation Gauge

The density of new snow coupled with the amount and rate of loading of the snowpack provides the precipitation data. It may also be noted that the variation in these quantities is affected by the interaction of wind with the topography. To accurately determine the snow load to trigger an avalanche needs data from both the sensor and the avalanche-prone site. Thereby, it's imperative to measure data from a sufficiently protected site and snow data independent of wind speed or direction (Marriott 1984). For water equivalent measurements, the most used sensors are gauge sensors; however, these sensors also suffer several errors, including missed catch, capping, and evaporation.

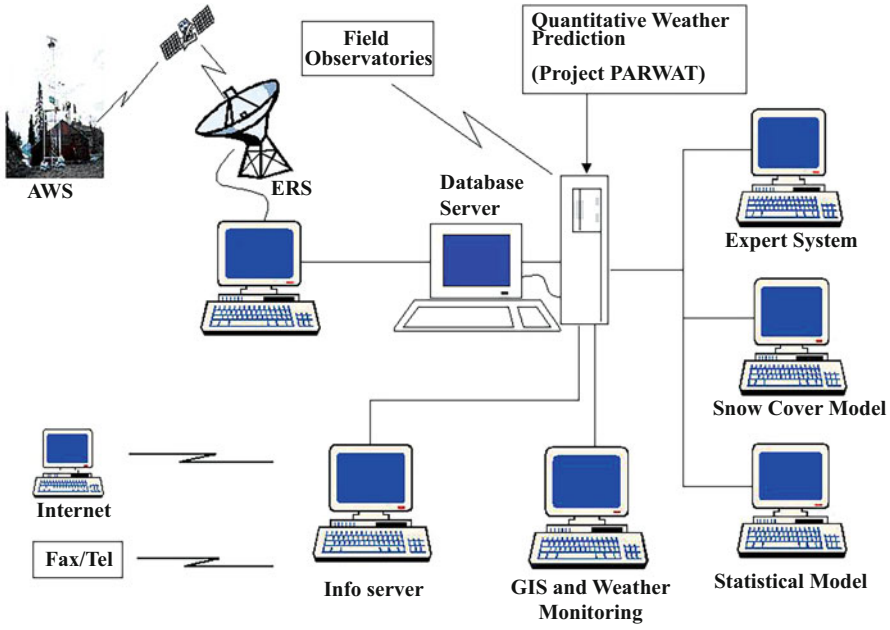

Fig. 4 Schematic of forecasting

Missed catch highlights the wind effect on measuring sites, which may introduce serious errors. Worth by Larson and Peck (1974) shows that wind effects can introduce substantial error engage measurement. The magnitude is related to three factors windspeed, vein speed, and vertical profile, and the obstruction to the airflow presented by the gauge. However, it is possible to develop, a calibration-based correction factor for the lost catch.

Gauge capping indicates the accumulation of snow along the rim of the collection cylinder of in during moderate to heavy snowfalls. This accumulation leads to a decrease in the effective orifice size, thereby reducing the measured data of precipitation. Also, sometimes the eventual melting of the accumulated snow result in an overestimate of the current precipitation.

Evaporation occurs inside a heated gauge, and it appears in the zone of dry snow at a low snowfall rate.

Wind Sensor

Snow stability forecasting involves the estimation of the degree and nature of snow deposits over the topography; both these factors are in turn related to wind information. Variation in local winds is created by both terrain orientation and the synoptic scale veins interacting with the mountain topography. This problem is often further

complicated by veins driven by Mesa scale pressure difference across a mountain range, small-scale channeling effects, or drainage wind.

For wind sensors, site selection for wind measurements is of supreme importance, which requires evaluation of all the potential effects of all the Lanes on the Avalanche starting zones of interest. Choosing a location for measuring veins involves identifying a site that can give sufficient wind information that can be used to infer the starting zone winds. The main error with wind sensors occurred during periods of rime formation. Taylor and Kuyatt (1994) described the process to minimize riming of the instrument by locating the anemometer downwind over the Terrain feature; this process removes most of the supercooled water droplets causing riming.

Air Temperature Sensor

Forecasting of snow stability includes many factors such as crystal types, surface melt, rainfall occurrence, the density of snowfall, snowpack metamorphism, etc., and all these factors are intricately related to the air temperature and subsequently to the snowpack strength. Temperature fluctuations in large mountain areas are dependent on air freezing levels or diurnal variations or the free air circulation. Sometimes minor effects like localized terrain-induced factors can also cause temperature fluctuation.

Topographic effects may cause variation in temperature from the scale of a few meters, to up to a scale of hundreds of kilometers. The biggest contributor to an error in air temperature measurement is the lack of shielding from heat and radiation sources. Locating sensors close to heated buildings or direct sunlight without proper radiation shielding may produce errors in measurement, making observation difficult to interpret and correct.

All these errors categorically signify the need for precise functioning of the sensor by proper maintenance and periodic calibration, to circumvent the errors and produce realistic and reliable data. In those instances where sensor data alone must be relied upon, the best solution appears to be several measuring sites with several types of sensors at each site. This type of input often helps to resolve potential ambiguities produced by individual sites or sensors. Similarly, an increase in the number of measuring sites can overcome deficiencies at individual sites and provide information on mesoscale weather features.

Need for Sensor Calibration from a Snow Avalanche Perspective

The classic technique for assessing avalanche hazards is as described by Lachapelle (1980). The technique uses daily weather, snow, and snow cover data observed and measured at selected locations for a given area. The data are acquired through sensors, which are then evaluated by human expertise, which in turn is strictly dependent on the accuracy of the sensor for that specific region (Fig. 5).

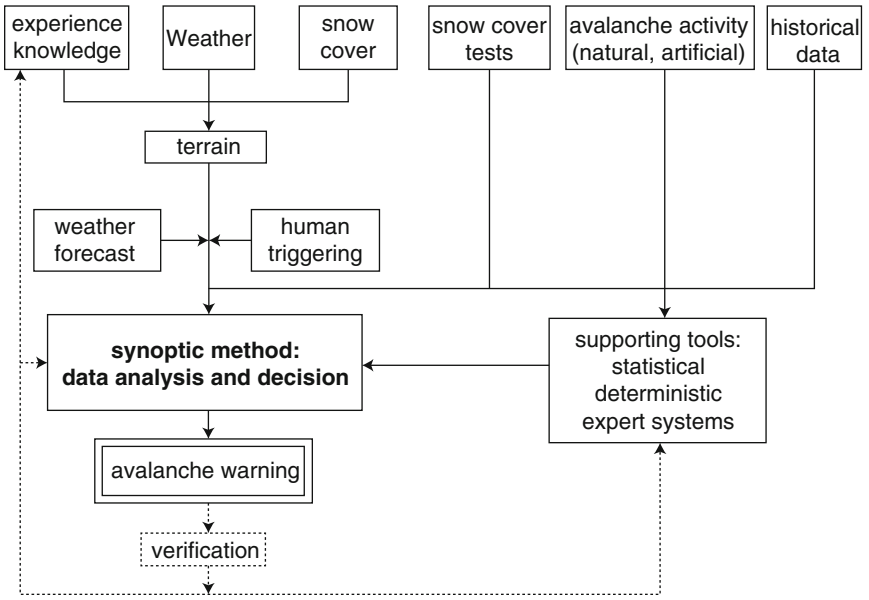

Fig. 5 The classical conventional method to forecast avalanches on a regional scale (Schweizer and Fohn, 1996)

The accuracy of avalanche forecasting heavily depends on the quality of data received from various sensors installed on AWS and various other portable scientific instruments located in observatories/field locations. The data recorded by the sensors is of paramount importance as this is the basic input for providing avalanche forecasts for high-altitude locations in snow-bound regions. Therefore, for ensuring a good quality of data from these sensors/instruments, periodical calibration of these sensors is foremost important. The calibrated sensors will provide more accurate and reliable data, which in turn will help in providing better avalanche warning and weather forecasting to the inhabitants and personnel deployed in snow-bound areas. This will enhance the safety of mankind and infrastructure in snow-bound areas which is of paramount importance.

Snow and weather conditions over a large area can be inferred from the snow and weather parameters, both these parameters aren't necessary for avalanche forecasting, and for this purpose, the point measurement of the factors is needed to analyze snow stability. The human experience is the main tool for inferring and interpreting these data in the mountain environment, as the process is a very complex or qualitative correlation between the measured point letter and the variation in the conditions of the two basic parameters needed generally.

There can be two major errors in the avalanche forecasting system. The first error is associated with the site chosen for measurement, i.e., the topography and environmental conditions, which may vary over short distances and are often hard to predict. For example, the temperature may vary by complications of mesoscale or

synoptic scale weather conditions. This makes it undetectable from a valley site. Thereby, multiple measurements need to be taken to remove ambiguity.

There are a wide variety of sensors available for measurement of each parameter, and generally, these cause the second source of error. All sensors have the individual type of responses for the same environmental conditions, thereby there can be very different readings at the same location but from different instruments. An accurate and systematic calibration of the sensors to remove anomalies/data ambiguities are of paramount importance.

Calibration Methods

Specialist knowledge is required to determine the frequency at which instruments should be calibrated. For example, an instrument can have a margin of 2% inaccuracy, in that case, certain performance degradation can be allowed if after recalibration the inaccuracy becomes 1%. The pattern of performance degradation is quantifiable, thereby before reducing accuracy to the defined limit, the instrument can be recalibrated.

There are three standard calibration methods used for sensors as follows:

1. One-point calibration
2. Two-point calibration
3. Multipoint curve fitting

1. This type is for linear sensors and correcting sensor errors of a single level measurement accuracy. This is the fastest calibration method out of the three and uses a zero-point adjustment. One-point calibration is typically done in the lower 20% of the sensor range. The single point-based calculation is done to differentiate the instrument reading and the reference value, and finally, this produces an offset correction factor.

   In the case of gauge transducers, this method is as simple as venting the device's both input and reference ports to the atmosphere. An absolute transducer may require the instrument to be brought down in the vacuum range for zeroing. This depends on the full span pressure of the DUT.

   This method is generally ideal for transducers that possess a constant offset value since the adjustment applies to all the points across the complete range. For example, temperature sensors are usually one-point calibrated.
2. This type is for correcting both offset errors and the slope, the usual process being zero and span adjustment. This type of calibration works on instruments with linear drift throughout the range and having a zero error. This method is different from the one-point method as it requires the instrument to be pressurized to the top 20% of the range for getting the second point reading or the span. The span adjustment is used to create a multiplier that is factored in at every point within

the measured pressure. Additionally in this type, sensors output has to be reasonably linear over arrange and with two reference values, i.e., high and low.

3. This type is for nonlinear sensors, which also require some adjustment to get an accurate measurement. Transducers generally have a zero shift or span drift and at times it will be inconsistent linearity throughout the range. Sometimes the zero or span point doesn't produce offset values, but it may still produce errors throughout the range. For instruments with this type of behavior, it will need a multipoint adjustment.

   In this method, the calibrator can use a minimum of three to a maximum of 11 reference points for adjustment, where each point set can be treated as two-point calibration. Though it takes more time, the multipoint method gets the best result. This type of calibration is typically referred to as performing a "linearization" of the device. For example, this is usually done for thermocouples, which are used in extremely hot or extremely cold conditions.

   In the case of snow and meteorological sensors specifically required for avalanche forecasting purposes, the calibration has to be done in the sub-zero range as the sensor is exposed to such temperatures during most of the period which is of interest to the forecaster. The calibration systems designed and in use for sensors utilized in avalanche forecasting should have at least two points in 0 °C and below ranges preferably the lowest measuring point of the sensor or the lowest temperature which the sensor is expected to encounter in such environments.

Principles of Calibration

When the output of any instrument or sensor getting tested for the first time, it is always compared against the output of an instrument that has an accuracy level known to the testers this method is called calibration; however, both the instruments should receive the same input for the calibration process the input can be out of a various range which covers the whole measurement range of the sensor and the calibration process ensures that the accuracy of all the instruments in questions for measuring purpose is known over the whole measurement range but one factor has to be considered that is the environmental condition should be same for all the instruments and sensors that are being calibrated.

It is a well-known factor that over time characteristics or specifications of any instrument or sensors can change, thereby the calibration process has to always be repeated mostly at previously predefined intervals to set the sensors updated. The sensors have changes in their specification or output or characteristics do too many external factors which even include dirt dust chemicals and even temperature changes in the environment and additionally the mechanical wear.

In the process of calibration, both the frequency of calibration and the system used for calibration are to be established properly, and thereby it is very important that the system always remains efficient and up to date by periodical review. However, sometimes cost efficiency is a matter because repeated calibration can

be expensive, and thereby alternative system can be adopted which may be less expensive but there shouldn't be any compromise for the effectiveness of the calibration. When a review of calibration is done primary basis becomes the previous history of the calibration of the sensor, thereby our instrument can be calibrated frequently because either it is an old instrument that the aging factors are taking into consideration or because the operating environment has changed. The environmental changes and the repeated use or frequent use of any instrument sensors can affect the sensor both adversely or positively, though there is always a possibility that the calibration interval can be decreased or can be increased as per the situation in need.

The international standard ISO 900 is the quality control function used for any calibration process to any measurement; previously the British quality standard BS5750 was used. Taking consideration of the human factor of human error or manual error 9000 plus always made it very specific that the person dealing with the calibration equipment needs to be properly trained. They are not various national standard organizations that can monitor both the mechanical testing laboratories and the calibration of instruments. Minerally different countries have their separate mechanisms for the maintenance of standards but always the frameworks have to be equivalent in the effect of ensuring the requirement of ISO/IEC 17025 standards. This helps to retain a global standard for the goods and services that are cross boundaries and also properly calibrated.

Whenever the instrument gets calibrated, it is termed as the device under test (DUT). To be calibrated the duty configuration should have known shell input stimuli for the sensors, and this process helps to determine actual errors in the measurement.

The calibration process helps us to determine the following results:

- No error noted on the DUT.
- An error is noted and no adjustment is made.
- Adjustment meant is made to remove the error and the error is corrected to the desired level.

Control processes are adjusted by monitoring the control system and for that sensor calibration is necessary. Automatic systems also apply sensor calibration to get error-free results.

Traceability

Calibration acts like a chain reaction whereby each successive instrument is calibrated for accuracy concerning this previous or higher-up model in the chain. Thereby to trace the measurement standard for the instrument which lies at the bottom of the chains, all the aspects of all elements of the calibration chains must be known beforehand. Traceability is thereby known as the knowledge of the full complete chain of instruments involved in the total calibration procedure, it is also mandatory for having an ISO 9000 standard.

An unbroken chain of calibration always contributes to the measurement of uncertainty, and when this gets documented, the result can be referred to and it becomes a property of the measurement and the property is called metrological traceability. Data validation needs both the measurement data and the traceability of the test.

Traceability is characterized by six essential elements.

i. The fixed reference point can be either a national or international standard, and to reach this point an unbroken chain of comparisons is needed.
ii. Uncertainty of measurement: This needs to be calculated for each step in the chain, and this then culminates in the whole chain's overall uncertainty.
iii. Documentation: All steps must be performed properly as per well documented procedures and the results must be recorded.
iv. Competence: There should always be recorded evidence of technical computer competence of the laboratory performing the steps.
v. Difference to SI units: The chain of comparisons must, where possible, end at primary standards for the realization of the SI units.
vi. Calibration intervals: There should be repeat calibrations with appropriate intervals; however, the intervals can depend on several variables, for example, uncertainty, frequency of use, way of use, etc.

ISO/IEC 17025 Standards always stress the accuracy or validity of the results from all equipment used for tests and or calibrations, including equipment for subsidiary measurements. Traceability to SI units is maintained by calibrating all the equipment. However, standards include other mechanisms as well, other than traceability.

ISO15189 standards use either natural constant or SI units or any stated reference, both the trueness verification and calibration have to be traceable to any of those three standards. Most of the time, laboratories need to design specific programs for this purpose.

All the calibration and medical laboratories have to get checked for the requirements and acceptable traceability while testing. This task is being overseen by the national accreditation board for testing and calibration laboratories (NABL, 2012). All laboratories, therefore, need to have a set calibration program and traceability to SI units (national or international standards). Calibrations of equipment are performed from:

i. National Physical Laboratory, India, or a national metrology institute that is a signatory to the CIPM Mutual recognition agreement (MRA).
ii. Accredited calibration laboratories: When the MRA covers calibration activities. Calibration, certificate bearing accreditation, body symbol, or a special reference to the accreditation status by a recognized accreditation body shall only be considered for valid traceability.

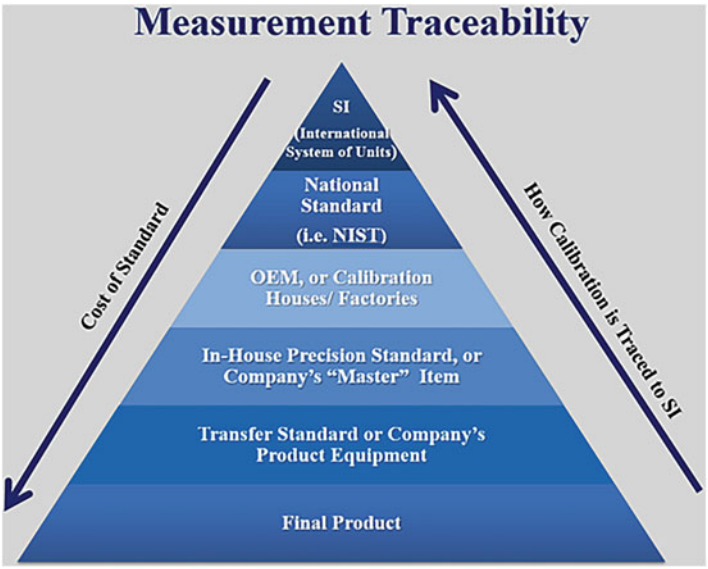

Fig. 6 The concept of measurement traceability

Sometimes there are cases when such traceability as indicated above is not possible and reasonable. In that case, the following options can be taken:

i. Certified reference material is needed for a reliable chemical or physical characterization, and traceability is a demonstration of such performance.
ii. Specific methods and or consensus standards are also recognized by NABL, which are multipartite and acceptable to all. The laboratory involved must participate in proficiency and performance testing, then only it can provide satisfactory evidence of correlation of results.

With all the procedures detailed above, NABL thus maintains a policy on traceability of measurement results (Fig. 6).

Uncertainties in Calibration and/or Measurement

Measurement Uncertainty

Higher accuracy is the most demanded component in the manufacturing process; however, in any measurement or calibration, such factors are always uncertain pump and thereby measurement uncertainty is the natural parameter which defines all these uncertain factors in the measurement. Various industries produce more or less similar measurement equipment, and often the uncertainties can be estimated by the better equipment. The intent of the industries depends on the competitive advantage of the

fact that uncertainty is inversely proportional to the quality, and thereby the equipment's effectiveness and accuracy can be predicted within the range of its performance. However, uncertainty is a complex procedure and there may be a situation where actual accuracy is lower than the predicted performance level accuracy.

Generally, an instrument is evaluated by the errors found during the operation however error can also occur because of improper uses of the instrument and also incomplete knowledge of the test artifact. This instrument's unrelated contributors to the errors give rise to the test uncertainty.

A measurement system only becomes acceptable when it produces accurate measurement results and also the verification of the expected quality output. Any measurement result can only be complete when it is added with a statement of its uncertainty which considers all possible measurement errors at each level of handling.

The quantity subject to measurement is called measurand (ISO, 1993), and measurement uncertainty is thereby defined as the parameter, associated with the result of a measurement that characterizes the dispersion of the values that could reasonably be attributed to the measurand.

During measurement, there can be two factors that influence the process: one is the expected accuracy of the output and the other the factors influencing the measurement process, measure, and the specific quantity subject to the measurement (Fig. 7). A few examples are as follows:

i. Temperature is a prime factor while dealing with metal items, thereby temperature actors are better when micro-level accuracy is needed in measuring metal tools.
ii. The length of a row acts as a measurement during measurement as the length is always affected by the tension in the road.

A Fishbone diagram can be used to depict the contribution of various sources of measurement errors and uncertainty in the final measurement output. It is also called

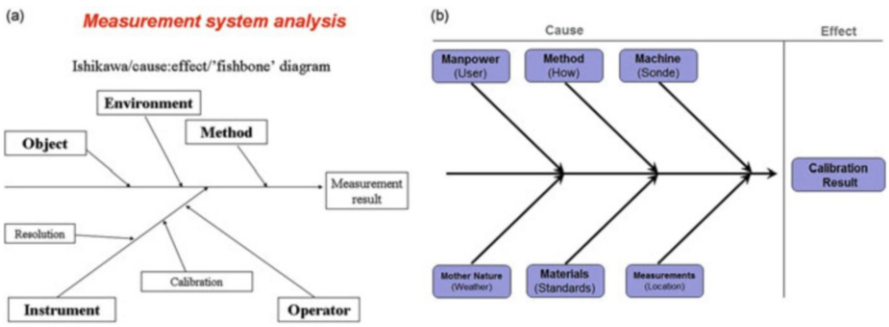

Fig. 7 (**a**) Fishbone diagram of measurement uncertainty. (**b**) Fishbone diagram of measurement uncertainty

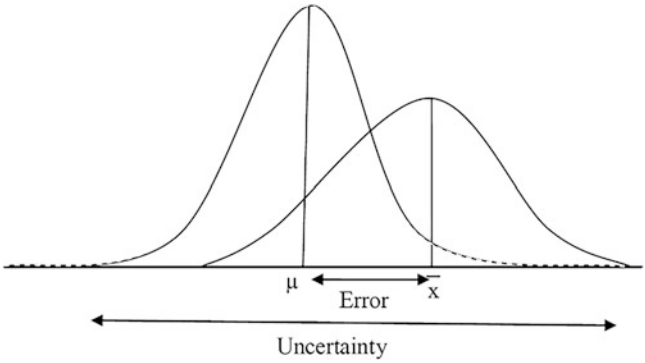

Fig. 8 Difference between error and uncertainty

as Ishikawa diagram, simply it's a hierarchical representation of cause and effects as stated above.

There is the general depiction of 6 Ms (manpower, mother nature, material, measurement, method, and machine), which are the different categories of causes. These 6 Ms can in turn impact calibration uncertainty by influencing the sources of uncertainty, i.e., instrument, standards, location, weather, how, and the user (Figs. 8 and 9).

Uncertainty Budget

Uncertainty has many sources that require identification, quantification, and characterization, a list of which items all components contribute to the uncertainty is called an uncertainty budget.

This tool is used by engineers, physicists, and meteorologists globally for uncertainty analysis while doing the quality measurement. This budget provides the laboratory with a formal record of the uncertainty analysis process which can be shared with other professionals who can validate the results.

How Uncertainty Budgets Improve Measurement Quality

There are several ways uncertainty budgets can help improve measurement quality. Here is a list of common benefits associated with these budgets:

1. Have ISO 17025 standards
2. Obtain or maintain ISO 17025 accreditation
3. Estimate the CMC uncertainty expressed in the Scope of Accreditation
4. Less time and effort are needed for measurement uncertainty calculation
5. Provide objective evidence that an uncertainty analysis was performed

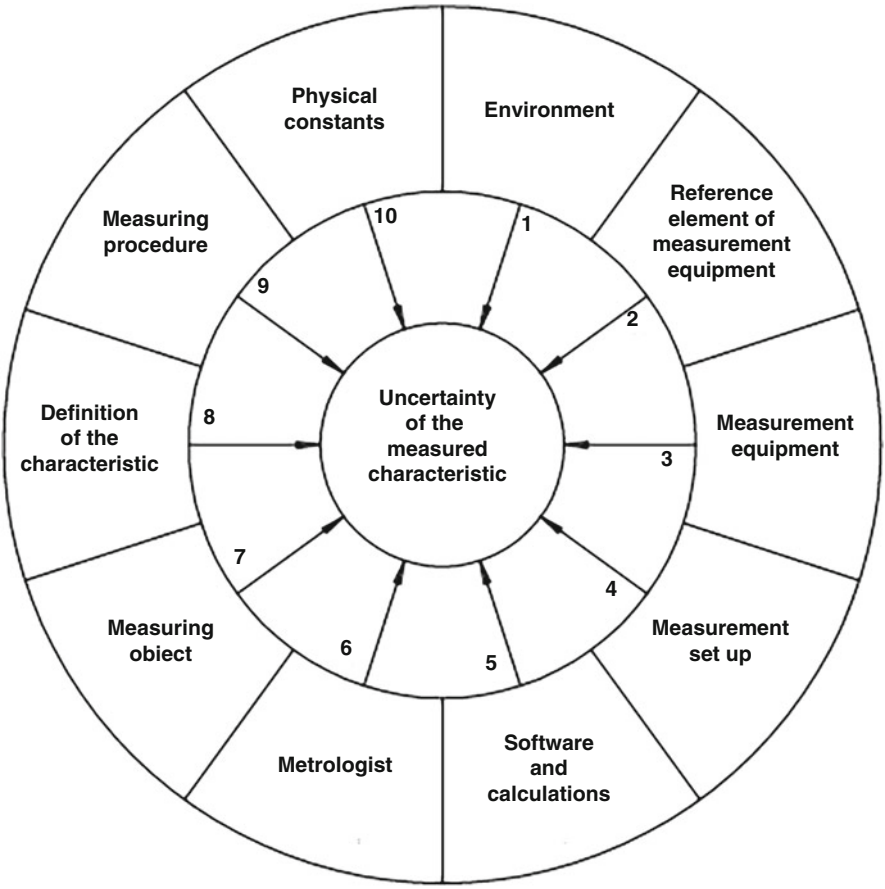

Fig. 9 Uncertainty contributor to measurement

6. Quality improves as uncertainty contributors are evaluated (i.e., find the greatest contributors and identify where reductions can be made)
7. Decision makers have more confidence
8. Errors in measurement results are reduced or prevented completely
9. Less measurement risk (e.g., Statements of Conformity and Decision Rules)
10. Increase customer satisfaction and improve customer service

Example of the Uncertainty Budget

An example is shown below, which also clarifies the several principles of uncertainty analysis. The reported value for a test item is the average of N short-term measurements where the temporal components of uncertainty were estimated from a three-level nested design with J short-term repetitions over K days.

Table 2 Example of error budget for type A and type B uncertainties

Type A components	Sensitivity coefficient	Standard deviation	Degrees freedom
1. Repeatability	$a_1 = 0$	s_1	$J - 1$
2. Reproducibility	$a_2 = \sqrt{(K-1)/K}$	s_2	$K - 1$
3. Stability	$a_3 = 1$	s_3	$L - 1$
4. Instrument bias	$a_4 = 1$	s_4	$Q - 1$

The number of measurements made on the test item is the same as the number of short-term measurements in the design, i.e., N = J. Because there were no repetitions over days or runs on the test item, M = 1; P = 1. The sensitivity coefficients for this design are shown on the foregoing page.

This example also shows the effective use of bias correction, when the sample instrument is biased with regard to other instruments. The sensitivity coefficient, given that the bias correction is based on measurements of Q artifacts, is defined as $a4 = 1$, and the standard deviation, s4, is the standard deviation of the correction (Table 2).

a. *Standard Uncertainty (UI)*
   It is the representation of each component of uncertainty that contributes to the uncertainty of measurement, by an estimated standard deviation.
b. *Combined Standard Uncertainty (UC)*
   It is the combination of all the standard uncertainties, which represents the standard deviation of the result. It is usually the square root of the sum of the squares of the individual standard uncertainties.
c. *Expanded Uncertainty (U)*
   It is the combined standard uncertainty times the coverage factor. The expanded uncertainty forms a boundary about the measurement result y within which the measure Y lies.

$$\mathrm{y} - \mathrm{U} \leq \mathrm{Y} \leq \mathrm{y} + \mathrm{U} \,\mathrm{or}\, \mathrm{Y} = \mathrm{y} \pm \mathrm{U}$$

d. *Coverage Factor (k)*
   A number larger than one by which a combined standard measurement uncertainty is multiplied to obtain an expanded measurement uncertainty.
e. *Accuracy*
   Accuracy is the closeness of agreement between a measured quantity value and the true quantity value of a measurand. A measurement is said to be more accurate when it offers a smaller measurement error.
f. *Bias*
   Bias is the difference between the average value of all the measurements (μ) and the true value (μo). Bias is a measure of the amount by which a tool is consistently off target from the true value, and bias can be positive or negative.

$$\mathrm{Bias} = \mu - \mu\mathrm{o}$$

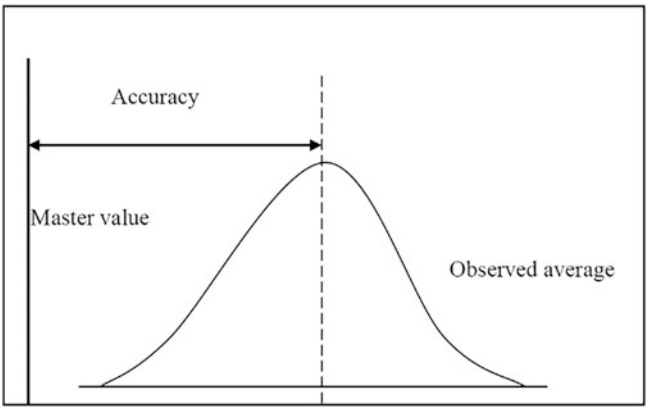

Fig. 10 Accuracy

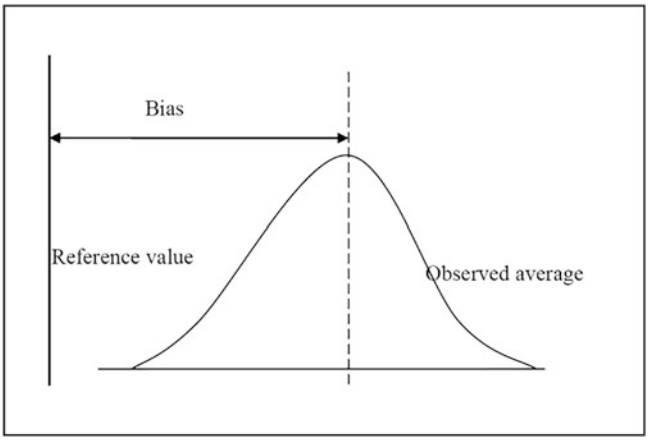

Fig. 11 Bias

g. *Precision*

Precision is the measurement of the extent of variation between different measurements. The standard deviation of the measurement distributes quantify the total variation in the measurement that is the precision. Precision is inversely proportionate to standard deviation, and it is also the degree of closeness of the measured value for each other (Figs. 10 and 11).

Test Uncertainty Ratio (TUR)

Various phases of production process certify the measurement equipment performance. Generally the measurement capability of the equipment has to be perfect and

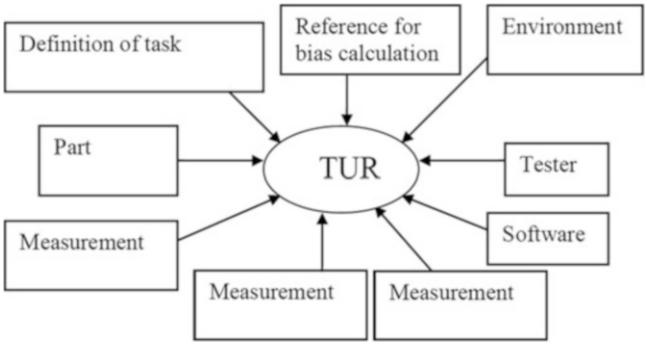

Fig. 12 Contributors to TUR

also the acceptance of the manufactured product has to be reliable. The method to obtain these two is called the test uncertainty ratio. The ratio between the uncertainty in determining the measured value and the tolerance for a specific measurand is the TUR. In the numerator lies the specified tolerance and in the denominator lies the uncertainty former and the higher value of the TUR always indicates a better performance of the test (Fig. 12).

Test Uncertainty

The outcome of any test is always uncertain and this factor is called the uncertainty whenever a new piece of equipment gets tested. During calibration, some permanent sources of calibration errors can be found in the measurement equipment itself. The errors generate due to manual inputs provided by the person handling the equipment, and thereby from all the instruments which produces the reference value. However, during calibration, the instrumental errors are not included in the test uncertainty. The uncertainty is only reflected in the ability of the test to evaluate properly the instrument, thereby it is different from measurement uncertainty and the value is smaller as well. In simple language calibration process verifies the performance of the instrument whereas the measuring instruments are to be calibrated by using the reference to determine the uncertainty.

Calibration Hierarchy

Celebrations can be performed in sequence starting from a reference and ending with the final measuring system, the hierarchy became the outcome of calibration where each of the previous celebrations in turn influences the next calibration. Measurement procedures are operated by measuring systems, and the measurement standards form the elements of the calibration hierarchy. However, in general, a simple comparison between two different standards can also be called calibration, only if

the comparison is useful for correcting the quantity value, and also the uncertainty can be attributed to any one of the standards used.

Sensor-Specific Calibration Systems

The parameters and specifications of various calibration systems for calibration of snow and meteorological sensors are given in Table 3 below.

Wind Speed Sensor Calibration System

To have a calibration system for the wind speed sensor which is to be utilized in sub-zero ranges of temperature, a specially designed wind tunnel is proposed. Brief design characteristics and standard requirements of the tunnel will be discussed in this section.

The wind tunnel design shall be based on a wind tunnel calibration facility that employs all sensors traceable to national/international references and as per guidelines mentioned in ASTM D 5096-02, ISO 17713-1, and IEC 61499-12-1 standards.

The wind sensor calibration system, design envisages having a full-fledged, standalone, and self-sufficient calibration facility for calibrating wind speed and direction sensors/anemometers/wind vanes at different temperatures and wind speeds.

The design will be such that the system would be able to calibrate and test the wind sensors and anemometers with the design proposed for the wind tunnel calibration facility.

Functional Requirements and Specifications for the Wind Speed Sensor Calibration System

- The system must be capable of calibrating all types of phase-shifts (ultrasonic, laser Doppler), Pressure Types (pressure tube, pressure plate, sphere anemometers) and thermoelectric (hot wire and hot plate anemometers), electro-mechanical wind speed sensors, Standard Cup Counter Anemometer within the size of the existing test section as mentioned in the preceding paras.
- Max Wind Speed: 60 m/s with Max Uncertainty 0.1 m/s.
- Closed Circuit – Closed Wall test Section type wind tunnel.
- Min Test Section Dim: The test section should be able to accommodate the sensors intended to be calibrated. The width and height of the test section will be calculated based on the blockage ratio and size of the anemometers to be calibrated. The min test section dimensions should be following the ASTM D 5096-02, ISO 17713-1, and IEC 61499-12-1 standards which define that the Blockage Ratio should be less than 5%. Blockage Ratio calculation will include a summation of Frontal Area of Sensor Under Test (Approximate Calculation of Projected Area/Area Perpendicular to Wind Direction Provided below), Sensor Mounting, Reference Wind Speed Sensor/Pitot Tube, Pressure Sensor,

Table 3 Parameter and specification of various calibration systems

Sl. no.	Calibration systems and parameters	Specification
1.	**Temperature calibration system**	It consists of a dry block calibrator, liquid temperature bath calibrator (for glass thermometers), and platinum resistance thermometer with temperature indicator and data acquisition system for both calibrators
	a) Platinum resistance thermometer (PRT)	
	(i) Temperature range	40 °C to +420 °C
	(ii) Leads	4 Wire
	(iii) RTPW	25.5 ± 0.5 Ω or 100 ± 0.5 Ω,
	(iv) W(Ga)	≥1.11807
	(v) Measurement uncertainty	±0.010 °C or better(−40 °C to 420 °C)
	(vi) Sheath	Inconel/Quartz Glass
	(vii) Diameter	6 ± 1 mm
	(viii) Length	450 ± 50 mm
	(ix) Connection cable	4-wire Measurement Leads compatible with Temperature
	(x) Indicator	Specified below
	(xi) Calibration	NMI Traceable Calibration as per ISO/IEC 17025: 2017
	(xii) Carrying case	To be supplied along with PRT
	b) Temperature indicator with data acquisition system	
	(i) Temperature range	40 °C to +420 °C
	(ii) Temperature resolution	0.001 °C or better, 0.0001 Ω or better
	(iii) Temperature accuracy	±0.008 °C to ±0.020 °C or better in the full range
	(iv) Sensing current	1 mA
	(v) Inputs	Two or more channels (for 4 wire RTD)
	(vi) Display units	°C, Ω
	(vii) Temperature conversation equation	ITS-90, Callendar-Van Dusen, with provision to set new calibration coefficients
	(viii) Communications and data logging	Compatible Communication port to interface with external computer and software for data logging
	(ix) AC power	230 V AC (±10%), 50/60 Hz
	(x) Calibration	NMI Traceable Calibration as per ISO/IEC 17025: 2017
	(xi) Carrying case	Supplied along with indicator
	c) Dry block calibrator	
	(i) Temperature range	40 °C to +140 °C
	(ii) Temperature resolution	0.1 °C or better
	(iii) Immersion depth	150 mm or higher
	(iv) Temperature stability	±0.030 °C or better in the above range
	(v) Temperature axial uniformity	±0.070 °C or better (40 mm) in the above range

(continued)

Table 3 (continued)

Sl. no.	Calibration systems and parameters	Specification
	(vi) Temperature radial uniformity	±0.050 °C or better in the above range
	(vii) Block insert	(i) One – suitable for max. 16 mm diameter sensor probe (ii) One – suitable for various RTDs
	(viii) AC power	230 V AC (±10%), 50/60 Hz
	(ix) Calibration	NMI Traceable Calibration as per ISO/IEC 17025: 2017
	(x) Carrying case	Supplied along with dry block calibrator suitable for field application
	d) Liquid temperature bath calibrator	
	(i) Temperature range	40 °C to +100 °C with single fluid silicone oil
	(ii) Temperature stability	±0.010 °C or better in the above range
	(iii) Temperature uniformity	±0.020 °C or better in the above range
	(iv) Set point resolution	≤0.01 °C
	(v) Display resolution	≤0.01 °C
	(vi) Bath volume	≤45 l
	(vii) Bath access opening	Wide opening
	(viii) Bath immersion depth	≥170 mm
	(ix) Control probe	4 Wire PRT
	(x) AC power	230 V AC (±10%), 50/60 Hz
	(xi) Calibration	NMI Traceable Calibration as per ISO/IEC 17025: 2017
	(xii) Bath liquid	50 l **silicone oil** suitable for above temperature range
2.	**Humidity calibration system**	The proposed humidity generator/calibrator is based on a two-pressure method along with an air supply source to achieve a better accuracy level for calibration of DRDO-SASE humidity probes: 1 Unit
	(i) Relative humidity range	10–95% RH or extended range (at test chamber temperature range)
	(ii) Relative humidity resolution	0.01% RH or better
	(iii) Humidity generation principle	Based on the two-pressure method
	(iv) Flow gas type	Nitrogen or air
	(v) Relative humidity uncertainty	±0.5% or better with above RH range
	(vi) Chamber temperature range	10–70 °C or an extended range
	(vii) Chamber temperature stability	±0.05 °C or better
	(viii) Chamber temperature uniformity	±0.1 °C or better
	(ix) Temperature resolution	0.01 °C or better
	(x) Test chamber pressure	Ambient

(continued)

Table 3 (continued)

Sl. no.	Calibration systems and parameters	Specification
	(xi) Gas flow rate	Adjustable with 0.1 resolution
	(xii) Inlet gas pressure	>150 psi along with air supply source and accessories
	(xiii) Test chamber size	25 × 25 × 25 cm or bigger
	(xiv) AC power	230 V AC (±10%), 50/60 Hz, single phase
	(xv) Data acquisition	Compatible software, data cables, and accessories
	(xvi) Interface port	RS-232/USB/IEEE
	(xvii) Calibration	NMI Traceable Calibration as per ISO/IEC 17025: 2017
3.	**Pressure calibration system**	Proposed barometric pressure calibration is setup which consists pressure/vacuum source, pressure controller, vacuum chamber, secondary standard, and data acquisition system, a completely automatic system
	a) Barometer pressure controller	
	(i) Range	0–2000 mbar (abs)
	(ii) Accuracy	Better than ±0.008% full-scale deflection (FSD)
	(iii) Precision	±0.004% FSD
	(iv) Resolution	Four to six digits
	(v) Panel	Touch Screen Panel for control
	(vi) AC power	230 V AC (±10%), 50/60 Hz, single phase
	b) Vacuum pump	
	(i) Type	Rotary vane type
	(ii) No. of stage	Double stage
	(iii) Pumping speed	16 m^3/h
	(iv) Ultimate vacuum	$\leq 5 \times 10^{-3}$ mbar
	c) Air compressor/nitrogen cylinder	
	(i) Cylinder	Air compressor/nitrogen cylinder
	(ii) Regulator	ISI mark regulator for cylinder
	(iii) Accessories	Accessories to generate pressure less than 2000 mbar with proper safety valve for overpressure and regulated output
	d) Vacuum chamber	
	(i) Dimension	Vacuum chamber dimension with minimum working space inside the chamber 1.5 × 1.5 × 1.5 ft
	(ii) Material	Chamber made of SS 304/metal with a frontside full optical window/vacuum glass door which can easily open to keep the device under test (DUT) inside the chamber
	(iii) Illumination	Provision for illumination for good vision
	(iv) Connection	Suitable connecting vacuum port, and feed-through for input power supply and output voltage/current of at

(continued)

Table 3 (continued)

Sl. no.	Calibration systems and parameters	Specification
		least three devices under test. The vacuum chamber should be leak tested for high vacuum compatibility
	e) Test bench/working table	Calibration test bench with at least three lockable drawers and powder-coated CRC frame, focusing lamp, perforated backplate with one wheelchair
	f) General	The primary requirement is a complete remote-controlled, automated pressure calibration bench in the barometric pressure range from 0 to 2000 mbar. The accuracy of the measuring devices is at least 0.008% of full scale. All the above parts mentioned must be fully compatible with each other. Any hardware, connectors, plugs, software, and any items required to ensure complete compatibility will be provided by the bidder. The pressure and vacuum pump provided should be able to maintain the pressure inside the vacuum chamber from 0 to 2000 mbar. However, if the bidder has an integrated solution as mentioned above, the same will be accepted if it meets the technical specifications
4.	**Infra-red temperature calibration system**	
	a) IR radiation thermometer	
	(i) Temperature range	40 °C to +80 °C
	(ii) Emissivity	≥0.95
	(iii) Spectral response	8–13 μm
	(iv) Resolution	≤0.1 °C or better
	(v) Response time	≤5 s
	(vi) Uncertainty	≤0.5 °C
	(vii) Laser aiming sight	Laser marker or marker through the eyepiece
	(viii) Control interface	RS232/IEEE ports for serial data transfer to an external computer for online data evaluation (USB adapter), software for online data evaluation (Windows version), cables, and necessary accessories
	(ix) Operating temperature	23 ± 3 °C or wider
	(x) Mounting accessories	Suitable mounting accessories (if any)
	(xi) AC power	230 V AC (±10%), 50/60 Hz
	(xii) Calibration certificate	NMI or NMI Traceable Calibration certificate as per ISO/IEC 17025:2017
	b) **Blackbody source with accessories**	
	(i) Temperature range	40 °C to +100 °C
	(ii) Temperature stability	±0.2 °C or better
	(iii) Temperature uniformity	±0.2 °C or better
	(iv) Spectral range	8–14 μm
	(v) Accuracy	±0.5 °C or better

(continued)

Table 3 (continued)

Sl. no.	Calibration systems and parameters	Specification
	(vi) Resolution	0.1 °C
	(vii) Aperture diameter	50 mm diameter or more
	(viii) Emissivity	≥0.95
	(ix) Control probe	4 Wire PRT
	(x) Control interface	Interface with control software, cable, and accessories, real-time data logging software
	(xi) Calibration	Confirmation certificate for stability and uniformity
	(xii) Cooling arrangement	To be provided to achieve 40 °C (coolant to be provided by the supplier)
	(xiii) Anti-frost system	To avoid frosting at low temperature (optional as per requirement)

Temperature Sensor, Relative Humidity Sensor in the test section, and Support Apparatus in the test section (if any).

- Blockage Ratio: Less than 5%.
- Flow Uniformity: Uniform Velocity Profile within 1% variation inside the test section.
- Horizontal Wind Gradient: Less than 2% (Within Test Section).
- Turbulence Intensity: Less than 1% (Within Test Section).
- Air Density Uniformity: Better than 3% (Within Test Section).
- Reference Wind Speed Sensor: Pitot Tube (max uncertainty: 0.1 m/s; traceable to national/international reference standards)
- Parameters to be monitored inside the test section with the following sensors:
  - Temperature Sensor with max uncertainty ±0.5 °C
  - Relative Humidity Sensor with max uncertainty of ±2%
  - Pressure Sensor with max uncertainty ±1 mbar

  All these sensors must be traceable to some reference national/international standards.
- Temp Range Control: –30 °C to +30 °C (in steps of 5 °C). The system must have the capability to maintain the set temperature within a tolerance of ±0.5 °C for a period of 10 min. The max time taken to attain a temp of –40 °C from 30 °C should not exceed 4 h.
- Data Acquisition System Sample Frequency 10 Hz: The system should be able to acquire data from Reference Pitot Tube, Temp Sensor, Relative Humidity Sensor, Pressure Sensor, and anemometer under test inside the Test Section at min 10 Hz sampling frequency. Min resolution of acquiring wind speed should be 0.02 m/s, Temp 0.1 °C, RH 1%, and Pressure 0.5 mbar. The DAQ should have the capability to store the data for at least 72 h and generate a calibration summary for the sensor under test as per the standards mentioned above.

The design criteria should cater to excellent flow quality in space and time, ease of anemometer mounting, and good accessibility to the test section.

Sample Calculation for Approximate Frontal Area of Sensor Under Test and Blockage Ratio

As an example, two sensors have been considered for calculating the frontal area and blockage ratio:

1. RM Young Mechanical Wind Speed Sensor Model No. 05103, 05106, 05305, 09101, 09106, 05108-45. The technical details and specifications can be accessed from http://www.youngusa.com/products/7/. Max Size: 65 × 20 × 40 cm (L × W × H)
   a. Propeller Swept Area: πr^2 (r = 0.2/2) = 0.032 m^2
   b. Approximate Area of Sensor Body Perpendicular to the Flow = 0.02 m^2
      Total Frontal Area: 0.052 m^2
2. Standard Cup Counter Anemometer as per Indian Standards IS 5912:1997. The technical details and specifications can be accessed from https://archive.org/details/gov.in.is.5912.1997.
   Max Size: 39 × 39 × 30 cm (L × W × H)
   a. Cup Swept Area: 0.0488 m^2
   b. Approximate Area of Sensor Body Perpendicular to the Flow = 0.01776 m^2
      Total Frontal Area: 0.06656 m^2
      Format for Calculation of Blockage Ratio:
      Total Projected Area Perpendicular to the Direction of Wind Flow
      i. Frontal Area of Sensor Under Test (Standard Cup Counter Anemometer as per Indian Standards IS 5912:1997): 0.067 m^2
      ii. Frontal Area for Ref Sensor/Pitot Tube: an m^2
      iii. Frontal Area of Mounting for Sensor Under Test: b m^2
      iv. Frontal Area of Temperature Sensor: c m^2
      v. Frontal Area of Relative Humidity Sensor: d m^2
      vi. Frontal Area of Pressure Sensor: e m^2
      vii. Frontal Area of Support Apparatus (if any): f m^2
      Total Blockage Area (x) = (0.067 + a + b + c + d + e + f) m^2
      Height of Test Section: y m
      Width of Test Section: z m
      Area of Test Section (q) = y × z m^2
      Blockage Ratio = $\frac{x}{q}$ (Blockage Ration should not be more than 5%)

Automatic Calibration of Temperature Sensors

Orzylowski et al. (2000) in IEEE Instrumentation and Measurement technology conference in 2000 discussed the essential problems associated with the automatic calibration of industrial thermometric sensors in the temperature range of 200–1300 ° C carried out utilizing the comparison method.

The distance of the resistive sensors, the measurement junctions, and the reference computers are to be located in a uniform temperature field to perform a proper

calibration. For this purpose special furnaces are used in high-temperature ranges and liquid thermostats are used for the low-temperature region, which is up to 200 ° C.

During the calibration procedure, there may be several temperatures at which calibration needs to be done. For this purpose, a uniform and stable temperature failed, and possibly a short setting time is required, for which measurement inserts temperature control is used. Sometimes algorithm is used for accuracy requirements when the automatic calibration is being done at several temperature fields.

The paper discussed that for the calibration of standard thermocouples in the target temperature range, the requirements for the temperature field surrounding the sensor junctions can be defined as below.

i. There cannot be a difference of more than 10 K between the insert temperature mean value and the nominal calibration temperature.
ii. 0.2 K is the optimum value for the differences in temperature between calibrated thermocouple junction and the reference function. However, the value should be less than zero point when the temperature is 2000 ° C.
iii. 0.5 K/cm is the threshold for temperature gradient along a sensor, additionally at least 5 cm of distances are required.
iv. During the calibration measurement, 0.05 K should be the minimum temperature mean value stability.

During automatic calibration, the supervisory PC checks and monitors the stable temperature for several program levels according to the requirements. The accessory to the computer is a heater controller through a serially galvanically insulated interface and also a multi-channel temperature measuring system. The reference insert and the calibrated sensors produce data and the computer uses the data to calculate the signals for the temperature controller, and finally the record values of temperature are obtained in the measurement insert for each level of calibration (Fig. 13).

Digital data processing was used to reduce the measurement noise and to obtain the desired resolution. The supervising microprocessor performed the following functions:

i. Drives the auto-zero switches of the input amplifiers
ii. Controls the switching of gain in the input amplifiers
iii. Provides the timing signals for the A/D converter
iv. Compute the temperature concerning the characteristics of the sensors used
v. Controls the communication with a supervisory computer

The basic problems concerning the design of a system for the calibration of industrial thermometric sensors can be summarized as follows:

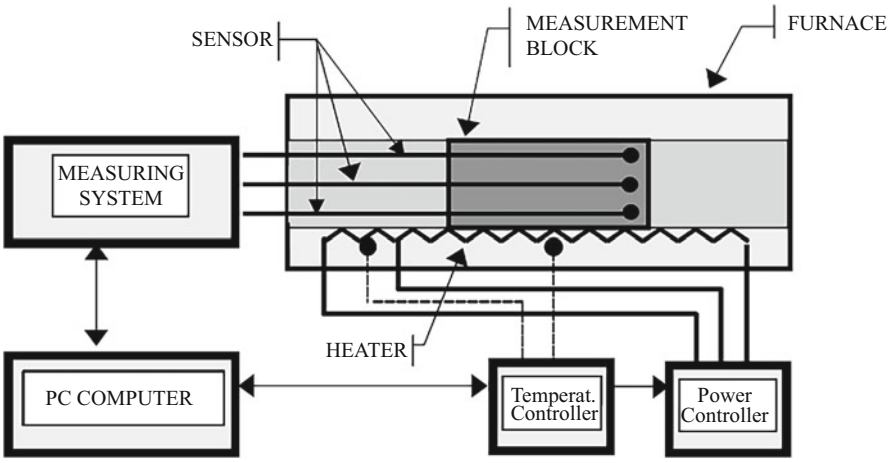

Fig. 13 The scheme of calibrating system

i. A tubular furnace with a multisection heater creates a uniform temperature field in which particular attention was paid to the phenomenon of radiation inside the furnace chamber.
ii. A measurement inserts temperature predictive control, where precise temperature control was obtained within the measurement insert and much-reduced setting time for the necessary conditions of the calibration measurements.
iii. Finding an algorithm for the automatic detection of the fulfillment of the accuracy requirement for the measurement.
iv. Analysis of the measurement error sources and the workout of an accurate multichannel measurement system with insulated channels for measurement of temperature sensor signals.

All the factors together helped in designing a perfect system that fulfills all the requirements of efficient calibration.

Temperature and Relative Humidity Calibration System

Ambient temperature and relative humidity mostly impact the calibration process, thereby both factors are needed to be maintained within a tolerable limit. Uncertainty is caused due to deviation from this limit, thereby disqualifying the complete calibration work. The ambient temperature and relative humidity are always reported on calibration certificates, establishing their importance.

Maintenance of both these factors requires not only an air handling system but also monitoring devices that ensure that the system is operating properly and parameters are within acceptable limits.

Rick Walker and Alan Cordner (2006) have detailed the procedure for temperature and relative humidity calibration system accordingly. Presently there are digital recorders available that are more accurate with remote access functions, which are hardier and can record data for a much longer period. They described a specific digital temperature/relative humidity recorder (Fluke Hart), which can store more than a year of data for two sensors and is accurate to ±0.125 ° C and ±1.5% relative humidity. The recorder of interest has a display unit and dual sensors, the sensors are used for both temperature and relative humidity sensing. The sensors are connected directly to the display unit, thereby simultaneous monitoring of two different locations can be done for both the data.

The sensor units contain analog to digital converters, and digital representation of the measurement is passed from the sensor units to the display unit. The sensor units need not always match the display unit, as the final accuracy of the sensor unit is the requirement, therefore, and only sensors are calibrated. Each sensor unit is calibrated independently as each has its unique characteristics. This uniqueness is stored in the nonvolatile memory of the sensor, thereby the digital parameters are also calibrated along with the sensor (Fig. 14).

A sensor always has non-volatile memory which produce date of the direction and the slope with reference to the judgment parameters; by setting both ways factors measurement errors of the sensors can be corrected. The opposite and slope adjustment parameters are also related to the relative humidity and temperature measurements. Calibration should include points at the extreme of the ranges and the point near the middle. All the relative humidity generally does not affect the temperature measurement but the temperature fluctuation does affect the measurement. Normally at the midpoint of the temperature range, the relative humidity is calibrated, a

Fig. 14 Fluke Hart scientific temperature/relative humidity recorder

specification of selective humidity then also allows for operation in other temperatures but within the specific temperature range.

Once the sensors are installed in the chamber it is expected that the calibration will be automatic. Normally the computer turns all the works while operating the humidity generator and collecting the sensor data, but that computer needs at least one temperature/relative humidity recorded display unit, with which the computer would also be connected. To preserve self-heating conditions, all sensors would have to be powered continuously.

Calibrating one or two temperature/relative humidity sensors at a time in an environmental chamber is common practice. The uncommon issue is the large number of sensors that needed to be calibrated at a time, and the low uncertainty required of the calibration.

Finally, the performance of the system is presented in terms of calibration and certainties, with contributing components as detailed during the procedures.

Icing Cloud Calibration of Icing Wind Tunnel

The icing cloud calibration process needs to be revised because the features of snow clouds are different from small supercooled droplets in terms of size, shape, and density. Then, relevant parameters in the acceptance criteria need to be updated. The basic procedure remains unchanged, including size distribution, water content, and cloud uniformity measurements. But the instrumentation and techniques to be used for the calibration of snow conditions change. As an alternative to tunnel calibration, the tunnel can operate with calibrated instrumentation that is used to measure the actual test conditions being obtained at the test point. This provides the actual conditions for each test point, including the effect of the test article. A wind check test is needed as the main acceptance criteria by testing a model to demonstrate the ability of the test facilities to reproduce snow accretion phenomena. This in turn allows an intercomparison of the test facilities, and assess the impact of any change in the test facility configuration.

Snow Conditions

Snowflakes, also called snow crystals, are aggregates of many single ice crystals. In nature, ice crystals often form in mixed clouds, where ice crystals grow via water vapor deposition at the expense of evaporating supercooled liquid water droplets, once the environment becomes saturated with water. This effect is called the Bergeron Findeisen effect, and it corresponds to the air transport of water vapor from the liquid to the ice phase, where the water vapor transforms directly into solid. Furukawa and Wettaufer (2007) had classified the snow crystal shapes into,

a. Plates and dendrites from zero to –3 °C.
b. Needles, columns, and prisms from –3 °C to –10 °C.
c. Solid, thin, and sectored plates and dendrites from –10 °C to –22 °C.
d. Solid plates and columns below –22 °C.

Finally, snowflake aggregation mostly appears at air temperatures near 0 °C. And this is predominantly affected by the air temperature and the shape of the aggregating ice crystals. Snowflake diameters are mainly between 2 and 5 mm and inversely proportional to the snowflake density, i.e., the larger the flakes, the lower the density (Table 4). This constant of proportionality between snowflake diameter and the density of snowflakes is almost four times larger in wet flakes than in dry flakes (Fig. 15).

Icing/Snow Cloud Parameter

- Total water content (TWC) or ice water content (IWC) are more relevant than liquid water content (LWC) and solid phase content (snow).

Table 4 Performance target and acceptance criteria

Parameters	**Measurement Instrument Maximum Uncertainty**	**Tunnel centerline Temporal stability**	**Spatial Uniformity**	**Limit value**
Aerodynamic parameters				
Airspeed	±1%	±2%	±2%	N/A
Static air temperature <–15 °C	±2 °C	±2 °C	±2 °C	N/A
Static air temperature between –15 °C and + 2 °C	± 0.5 °C	± 0.5 °C	± 1 °C	N/A
Flow angularity	±0.25	N/A	±2°	±3°
Flow turbulence				
Atomization pressure/snow generation system off	±0.25%	±2%	<2%	N/A
Atomization pressure/snow generation system on (maximum)	±0.25%	±2%	<2%	N/A
Pressure altitude	±50 m	±50 m	N/A	N/A
Cloud and cloud uniformity parameters				
Total water content/ice water content/ liquid water content	±15%	±20%	±20%	N/A
Liquid water ratio/wetness of the snow	±20%	±25%	±25%	N/A
Median mass diameter	±10%	±10%	N/A	N/A
Absolute humidity	±3%	N/A	N/A	N/A
Snow particle bulk density/snow bulk density	±15%	±20%	±20%	N/A
Parameters	**Measurement Instrument Maximum Uncertainty**	**Accuracy**		
Real atmospheric conditions representativeness and continuity check				
Snow/no snow accretion	N/A			
Growth rate (mm s^{-1})				

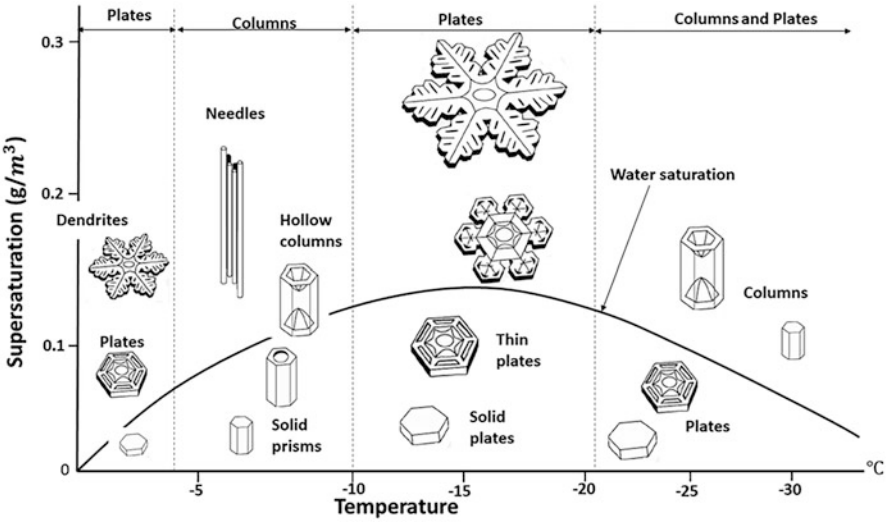

Fig. 15 Snow crystal morphology diagram (Tan et al., 2022)

- Median much diameter (MMD) is used instead of median volume diameter (MVD) for snow because of the variability of the density of the snowflakes.
- Absolute humidity is chosen instead of relative humidity to avoid ambiguity when liquid and solid phases are simultaneously present. Snow, particularly bold density, and snow density are added since they constitute a key parameter to assess the quality and the type of simulated snow and represent it with regard to real snowflakes.
- Liquid water issues, since it is expected to be one of the most important parameters of snow accretion.

The Main Measurement Objectives to Be Made to Ensure Calibration with the Selected Instrumental Payload Are as Follows

- Measurement reliability of large ice particle properties like size-dependent crystal number and mass. Up to 10 mm and beyond if possible.
- Ensure the measurement capabilities of bulk snow water content containing large snow crystals.
- Reasonably good morphological analysis and indicator for dry and wet snow of the snow particles. Along with the use of a high-resolution grayscale imager.
- Ensure cloud homogeneity in the test section.

Few additional adjustments for the most adequate instrument payload are as follows:

- The more the ice particle is at the upper size limit of a corresponding probe, the higher the probability of truncated images that need to be reconstructed.

However, with some uncertainties, in general, the retrieved reconstructed image underestimates the real size and mass when image truncation occurs.

- There is a potential that snow crystal fragmentation in a wind tunnel may produce non-negligible submillimeter crystal mass. That needs to be documented. Thereby 2 T stereo probe is recommended in such cases.
- High-resolution imaging probes are required for the entire snow particle size range and disposing of extremely large sample volumes for good statistics of snow microphysical properties and concentration. High-resolution imaging probes can improve the knowledge of cloud particle morphological information with the potential to create a proxy or an indicator of the presence of liquid water. This new particle thus distinguishes wet and dry snow.
- Bulk ID measurement devices for implementation of reliable snow water content measurement in test facilities.
- Liquid cloud droplets are injected into the test section in addition to the snow-type particles, and there is a clear need for phase discrimination of particles (solid/liquid). In such cases, data from high-resolution imaging probes or cloud droplets spectrometers may be used.
- The possible small ice crystals, contamination, and loss of last snow particles due to ice particle shattering should be avoided. Thereby, artifact minimization is needed during snow particle sampling.

Humidity

Humidity is an important parameter for icing that can be characterized using different values like relative humidity, absolute humidity, or dew point temperature. It is not possible to measure correctly the humidity in the working section of the facilities in icing conditions because the measurement of the sensors is biased by the presence of super cool droplets or/and snow. Therefore, humidity measurement is generally done upstream. The cloud generation system in the still chamber (Table 5).

Particle Size Distribution (PSD)

Snowflake size varies between 2 and 5 mm, ranging up to 15 mm. PSD measurement requires at least the use of two probes to cover the whole size range. The test facility should provide a detailed description of processing methods to account for shattering or out-of-focus verticals. If the instrument is also used for evaluating water content, and mass size relationship, it should be substantiated. In such a case it has to be monitored. Such instrumentation shouldn't be used as a sole basis for water content calibration (Table 6).

Particle Morphology

In addition to imaging probes, spanning the entire snow particle size range and disposing of extremely large sampling volumes for good statistics of snow microphysical properties. High-resolution imaging probes have been effective in considerably improving the knowledge of cloud vertical morphological information. These have the potential to create a proxy or an indicator of the presence of liquid water in the snow particle, thus distinguishing at least dry and wet snow. However, with

Table 5 Acceptable instrumentation for humidity measurement

Instrumentation	Principle
Chilled mirror hygrometer	This device measures the dew-point temperature by controlling the temperature of the mirror to condensate the water vapor of the sampling flow. This technology can measure very low dew-point temperature (–70 °C) but response time and stability could be affected by the sampling flow rate. Sometimes, an error on dew-point temperature is possible due to an uncertainty on the state of water, supercooled water, or ice, over the mirror for negative temperature
Optical sensors	Water vapor has an interesting absorption spectrum with some peaks in the IR and UV wavelengths. Based on this property, some devices measure the extinction of a laser beam crossing a sample of air and calculate the vapor concentration from Beer-Lambert's law. The absorption coefficient of the medium depends also on its pressure and temperature and must be corrected to ensure good accuracy
Capacity hygrometer	This device measures relative humidity and the local temperature. The principle of measurement is based on the change of the permittivity of material with relative humidity. The local temperature is used to calculate the local vapor pressure. This technology cannot operate accurately in very dry or wet conditions

extremely limited sample volume that does not allow quantifying particle statistics with high frequency (Table 7).

The Snow Cloud Uniformity Assessment

The cloud coverage area and concentration uniformity in the test section is another important wind tunnel measurement to support the calibration activity. For liquid clouds, the icing calibration grid is the recommended method, which is based on the rime ice accreted. For the snow clouds, cloud uniformity is measured through the measurement of total water content at a matrix of points across the test section.

Modes of Calibration

- Baseline calibration: It is the full calibration of the facility and includes an error, thermal calibration, and icing in snow cloud calibration. Full calibrations are required on initial commissioning or following any major facility modification that changes the icing/snow cloud.
- Interim calibration: It should be performed on an annual basis for the first 2 years following the baseline calibration, resulting from initial commissioning or a major change to the facility. These should include either confirming that icing/snow cloud uniformity has not changed from that established during the baseline calibration, or confirmation of tunnel axial centerline LWC/IWC measurements. The interim calibration should also include confirmation of the MVD/MMD calibration using a representative sampling from the baseline calibration.
- Check calibration: It should be performed every 6 months, except when it is superseded by a baseline or interim calibration. This consists of measurement of icing/snow cloud uniformity and centerline LWC/IWC measurements, over a representative sampling of uniformity.

Table 6 Instrumentation for PSD measurement

Instrumentation	Principle
Two-dimensional stereo probe (2D-S)	Optical array probe developed by SPEC. A laser beam deflects the cloud particle entering the field of vision which in turn fails in collecting optical and counted at a rate such that the pixel resolution in time is the same as that in the across-array dimension. This forms a digitized shadow image of the particle
Cloud imaging probe (CIP)	Cloud Imaging Probe developed by DMT. A collimated Ledger beam reflects the shadow images of the particles passing through, which had been projected on a 64 photodetectors linear array. A change in the light level of the diode represents each particle. The changes in the photodetectors should be compatible with the pro velocity and the instrument size resolution. Particle images are reconstructed from individual "slices," where a slice is the state of the 64-element linear array at a given moment in time A slice must be stored at each time interval that the particle advances through the beam at a distance equal to the resolution of the probe. Optional grayscale imaging gives three levels of shadow recording on each photodetector, allowing more detailed information on the particles The CIP also contains a Hotwire LWC sensor. This sensor estimates liquid water content using a heated sensing coil. The system maintains the coil at a constant temperature, usually 125 °C, and measures the power necessary to maintain this temperature. More power is needed to maintain the temperature as droplets evaporate on the coil surface and cool the surface and surrounding air. Hence, this power reading can be used to estimate LWC The CIP measures cloud particles in the 25–1600 μm range with a resolution of 25 μm (64 photodiodes)
Precipitation imaging probe (PIP)	Optical array probe developed by DMT. Cloud particles enter the field of view passing through a laser beam. Particle shadow falls on a collecting optical array (normally a photodiode array). This is sampled at a rate such that the pixel resolution in time is the same as that in the across-array dimension. This forms a digitized shadow image of the particle The Precipitation Imaging Probe (PIP) is a state-of-the-art probe that measures particles in the 100–6200 μm range. It is an ideal choice for measuring rain, snow, graupel, and hail
High volume precipitation spectrometer (HVPS)	The HVPS-3 (Version 3), developed by SPEC, combines 2D-S optoelectronics with HVPS optics and probe tips designed to minimize shattering Probe images precipitation sized particles using the 2D-S 128-photodiode array with 150-micron pixel resolution The HVPS probe measures particles in the 150–19,200 μm range. It is an ideal choice for measuring rain, snow, graupel, and hail

Table 7 Acceptable instrumentation for ice particle morphology measurement

Instrumentation	Principle
High speed imager (HSI)	Developed by ARTIUM, the HSI records high-resolution (5 μm) digital images of cloud particles as they pass through the measurement volume of the instrument. It collects the images of the particles on a 2000 by 900 CMOS array with sufficient resolution for obtaining the drop size and shapes over the size range 3–4000 μm, with the images having a resolution of 3 μm. The method of data processing leads to the particle size distribution and calculates the usual microphysical parameters: ice particle concentration, mean particle size, and ice water content. The classification of the shape of the ice particles can also be derived
Cloud particle imager (CPI)	The CPI is a major improvement on existing imaging/shadowing probes such as the PMS classical OAPS. The CPI can image and count particles in the size range of 2.3–2300 μm, with the images having a nominal 2.3 μm resolution. Image analysis and data processing software provided with the probe takes particle size information (including area and volume) and ice crystal habit classification from the images to produce histograms, etc.
Multi-angle snow camera (MASC)	The Multi-Angle Snowflake Camera, or MASC, was developed to address the need for high-resolution multi-angle imaging of hydrometeors in free fall, while simultaneously measuring their fall speed The MASC consists of three cameras, separated by 36 and each pointing at an identical focal point approximately 10 cm away. The focal point itself lies within a ring through which hydrometeors fall. The ring houses a system of near-infrared emitter-detector pairs, arranged in two arrays that are separated vertically by 32 mm. Hydrometeors passing through the lower array simultaneously trigger each of the three cameras as well as a bank of lights aimed at the center of the camera depth of field. Fall speed is calculated from the time it takes

- Continuity check: A model should be tested during or before and after the above calibration test to assess changes or stability of the tunnel's ice/snow accretion characteristics.

Aerothermal Calibration of Icing Wind Tunnel

A dryer air thermal calibration should be conducted to determine the basic airflow qualities of the facility. The flow properties should be as below:

- Airspeed distribution
- Temperature distribution
- Turbulence intensity distribution
- Centerline airspeed correction
- Clean tunnel flow angularity distribution

- Humidity time history
- Altitude time history

References cum Literature Review

Avalanche Hazard forecasting through sensor-acquired data is a regular activity being carried out by all mountainous countries. For example, USGS Scientists from the northern Rocky Mountain Science Centre had been studying snowpack stability and shifting in snowmelt, and runoff for the last 26 years. They particularly focus on wet snow avalanches. Which occurred in the spring when snowmelt weakens the strength of the snowpack? This action may prove crucial to future generations, as wet snow and avalanches are likely to become more common with the prevailing climate change scenario (Clark et. al, 2017).

Eric Trenbeath, an avalanche forecaster for the USFS Utah, had spoken about reading patterns in the snow and how that fits in the Avalanche forecast. In his blog, The Art of Avalanche Forecasting, special emphasis was given to the accuracy of sensors.

Similarly, the importance of calibration for multi-sensor imaging has been described in detail by K. Thome in 2017, at the International Geoscience and Remote Sensing Symposium.

Lachapelle (1980) made the first study on the fundamental process of conventional avalanche forecasting. The forecasting was said to be cumulative integration of a widely diverse body of information, gathered over a specified period. Information about snow conditions is highly diverse. The data readily fall into three categories, viz. meteorology, snow cover structure, and mechanical state of snow on a slope. Every available item, no matter how trivial, uncertain, or seemingly irrelevant, enters the integration.

The Shoda diagram illustrating the chain of causation in an avalanche formation is shown in Fig. 16 (De Quervain et. al, 1973).

The path of data flow in avalanche forecasting is shown in Fig. 17 (De Quervain et. al, 1973).

The forecasting data sequence, meteorologist snow structure mechanics, follows the chain of causation from distant approximate, and also follows a sequence of decreasing number of event classes and especially are decreasing population of elementary events in each class. The supreme importance of removing the uncertainty by identifying the errors in data thereby becomes crucial. And the sensors providing the data to the Algorithm need to be calibrated for perfection.

At World Congress on natural disaster mitigation, a new approach to avalanche forecasting for the western Himalayas was presented (Ganju and Singh 2004). The paper discussed a fresh approach by integrating state-of-the-art technology with conventional tools, thereby paving a way for the future development of sensor-dependent forecasting. It established the fact that communication of field data through modern telemetry systems and remote sensing satellites can overcome the shortcomings of the non-availability of timely data. Thereby, leading to frequent

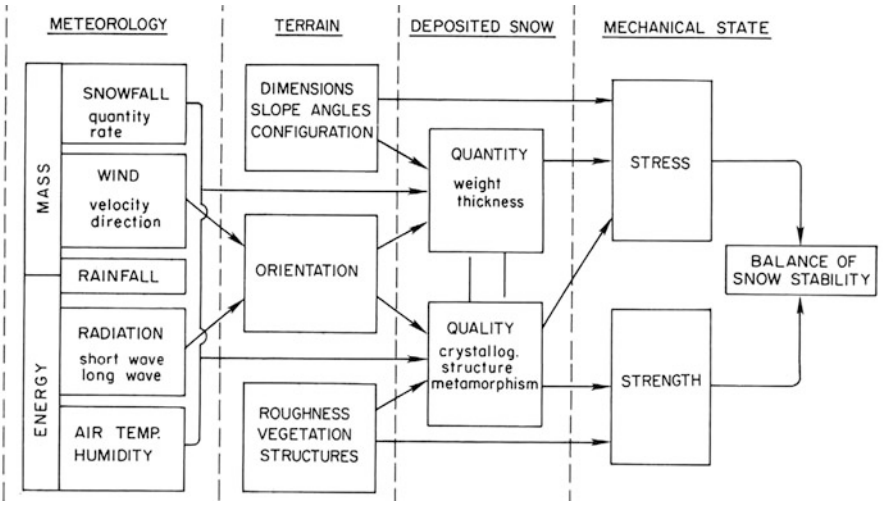

Fig. 16 The Shoda diagram

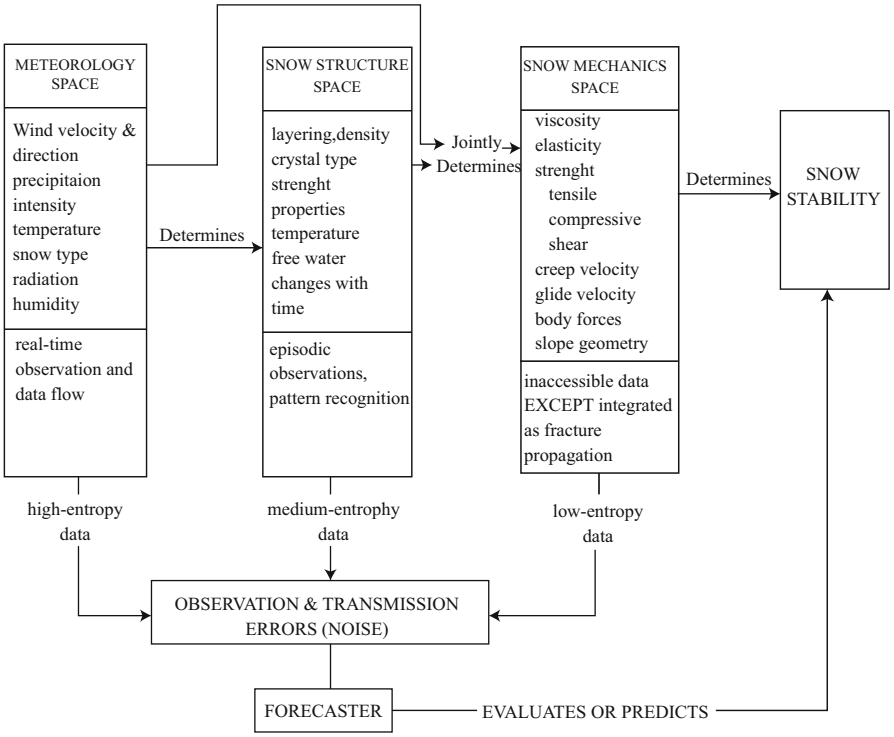

Fig. 17 Avalanche forecasting data flow

disasters. Presumably accurate functioning of the sensors was of paramount importance for the smooth operation of all the AWS, and appropriate functioning of the sensors can only be ensured by accurate calibration.

Studies made by Vilajosana et al. do not show the importance of the sensor location relative to the avalanches. However, to analyze the signals in great detail, sophisticated equipment in a single avalanche path is required. This also signifies the crucial need for proper calibration. Depending on the size of the event, avalanches that occur up to several kilometers away from the sensors can be detected (Leprettre et al. 1998). However, automatic avalanche detection is based on even detection using an amplitude threshold and event classification; single interpretation is relatively limited, and due to the amplitude threshold only larger avalanches are registered in the sensor. Thereby, in the recent past, automatic avalanche monitoring systems were not much widely used, as identification of avalanches remains problematic (Navarre et al. 2009).

In situ calibration of meteorological sensors has been discussed in detail by Merlone et al. It was elaborated that checking the measurement by comparison against reference high-quality instruments is a non-metrological approach. And this can only be overcome by the introduction of systemic periodic calibration that guarantees expressed traceability. The prototype of the Portable Climatic chamber coded EDIEO (Earth Dynamic Investigation Experiment O) was designed in 2010, aiming to promote this modus operandi by allowing in situ calibration of temperature, pressure, and humidity sensor, while evaluating their mutual influences. The relevance of the work lies in providing traceability and metrological quality to mountain atmospheric data, and a complete analysis of any uncertainty source in the calibration process was reported along with the total uncertainty results satisfactory for the application.

In another study by Grykałowska et al. (2015), the basic principles for calibration of meteorological temperature sensors were discussed in detail. The availability of reliable data defines the success of any meteorological and climate observation. The study also detailed the establishment of active cooperation between the World Meteorological Organisation (WMO) and the International Bureau of Weights and Measures (BIPM), to combine the requirement of monitoring climatic conditions, along with the responsible assurance of precise measurements, in short paving the way for accurate calibration. In the study, the calibration of temperature sensors was divided into the following phases.

- Characterization of the parameters of the measurement system used in the experiment (The measurements were carried out in liquid air equipment and a climatic chamber).
- Calibration was carried out using the equipment.
- Study of humidity impact on the readings.
- Calibration in the climatic chamber.
- Comparative in-situ measurements.

It may be noted that the importance of calibration in sensors especially related to snow and avalanche forecasting is not a young field of research. Almost four decades ago Marriott and Moore has explored the errors in measurement and their interpretation, thereby highlighting the requirement of calibration, in one of the first reported studies. They have shown that measurement of weather and snow parameter for forecasting may frequently contain false or misleading information, such errors can be either attributed to poor site selection or inconsistent response of the sensor due to changing weather conditions. It's a combination of sensors and direct human observation to provide a correct forecast. However, proper functioning of the sensors to provide useful information optimal for stability analysis and thereby leading to avalanche forecasting is the most crucial factor. Erroneous data of even a Milli scale of measurement may lead to false predictions associated with a disastrous consequence, thereby once more necessitating the requirement of proper calibration. Calibration is an important process to ensure that the data products meet the requirement of scientific utilization (Freeman 1992). Calibration and data quality evaluation are important aspects of performance of a sensor; the consistency and quality of any sensor data depends on the calibration and quality and worked as parameters to evaluate and monitor the sensor for a long-term regular output.

The calibration methodology for snow test facility has been worked out with funding by European Union. The work has proposed a calibration methodology for snow and mixed face condition. Not even parameters for calibration with their acceptance criteria for measurement accuracy, temporal stability, spatial uniformity, and target values have been defined. The possible instrumentation for particle size distribution and water content measurements are also described.

The National Institute of Standards and Technology (NIST) has also described procedures for calibrating several different types of industrial thermometers. One of the main types they described is a liquid in glass thermometer, which includes both mercury and organic field models. These thermometers covered a temperature range from 20 ° C to 400 ° C (Vaughn and Strouse 2001)

Conclusion

The accuracy and reliability of snow avalanche forecasting heavily depend on the quality of snow and meteorological data received from various sensors. Therefore, for ensuring a good quality of data from these sensors/instruments, periodical calibration of these sensors is foremost important. A summary of various sensors and corresponding calibration systems is given in Table 8 below.

On the Khumbu valley on the Nepal side of Mount Everest, a dedicated facility for calibration of AWS has been established; this is called the Everest pyramid laboratory cum observatory. Such an establishment itself makes it very clear that calibration is having paramount importance in the field of forecasting. This facility represents a fruitful collaboration between environmental science and metrological activities also; this is the highest metrology laboratory in the world. In this time with the climate change issues, climate science needs an intricate collaboration with

Table 8 Summary of various sensors, and corresponding calibration systems

Sr. no.	Sensor name	Range	Accuracy	Supply voltage	Calibration system
1.	Ambient temperature and relative humidity sensor	40 °C to +50 °C	≤±0.2 °C	5 or 12 V DC (typical)	Temperature calibration system, and humidity calibration system
		0–100% RH	≤±2%		
2.	Barometric pressure sensor	500–1100 mbar	≤±0.5 mbar	5 or 12 V DC (typical)	Pressure calibration system
3.	Wind speed and direction sensor	0–60 m/s	≤±1% of reading	5 V or 12 V DC (typical)	Temperature controlled wind tunnel
		0–360° (mechanical)	≤±3°		
		0–355° (electrical)			
4.	Albedometer	0.3–2.8 μm (shortwave)	<2% (nonlinearity)	5 or 12 V DC (typical)	Radiation sensor calibration system
5.	Pyrgeometer	4.5–42 μm (longwave)	<2% (nonlinearity)	5 or 12 V DC (typical)	
6.	Snow precipitation gauge	≥1500 mm	≤±1 mm	5 or 12 V DC (typical)	Snow precipitation gauge calibration system
7.	Standard field view infra-red radiometer	50 °C to +55 °C	≤±0.5 °C	5 or 12 V DC (typical)	Infra-red temperature calibration system
8.	Ultrasonic snow depth sensor	0.5–6 m	≤±0.5% of the distance to the target	5 or 12 V DC (typical)	Snow depth sensor calibration system

metrological activities, which can improve data quality and forecasting activities, for robust incomparable measurement. The same has been achieved in 2010 when World Meteorological Organization (WMO) signed the Mutual Recognition Arrangement (MRA) with International Committee for Weights and Measures (CIPM). The field of climate change also depends on the possibility of measurements, and there is a regular need to test and evaluate the behavior of a calibration system to assess the proper activity and maintenance of sensors and even reporting failures which are otherwise difficult to identify. Evaluation of proper calibration and the associated uncertainty always needs proper calibration. There is an actual objective and need of any project to deliver long-lasting quality data on climate and global warming; all these activities may help to formulate policy based on reliable assessments and deliver an applicable and feasible mitigation strategy (Merlone et al. 2015).

Tell oppression being mostly manual tasks there is always an inherent relationship with the field of psychology and neurophysiology as the human mental attribute dealing with uncertainty needs to be countered.

Garner (1974) demonstrated the role of redundancy in surmounting basic limitations, in perceiving and assimilating information. Normally numerous measurement data are being collected as there are always natural variations or observational errors. Example of forecasting needs some multiple measurements with multiple variables, and the soul importance of calibration can also be highlighted once more.

Abstract

Measurement is the most fundamental idea in science. Measurement of pressure is the next-most measured process parameter after temperature. It is required almost in all process and manufacture industry. A large number of different types of pressure-measuring devices are on hand to fulfil the requirement of industry. In this chapter a glimpse on pressure, pressure units and its conversion, various types of pressure, commonly used pressure-measuring instruments, and pressure sensor's metrological characteristics is described. The basic definitions related to metrology are described. The measuring properties of different pressure gauges are also tabulated. The approved pressure calibration and measuring capabilities (CMCs) of different countries' national metrology institutes (NMIs) are compiled in this chapter. The NMIs have CMCs of different ranges starting from 0 pascal to 1400 MPa.

Introduction

Measurement is maybe one of the most fundamental ideas in science. The word "measurement" is taken from the Greek word "metron," which means "limited proportion." Measurement is a procedure in which properties of an object are determined by comparing them to a standard. Measurement has a great significance not only now but from the start of human civilization. A speedy advancement of new instruments and measurement techniques started in the nineteenth century during the Industrial Revolution to fulfill the requirements of commercial production. Since then, there has been a significant and fast development in measurement technique and instruments. This has been especially visible during the last decades of the twentieth century.

The science of pressure measurement started in the middle of the seventeenth century. The credit of measuring atmospheric pressure goes to Evangelista Torricelli. His discovery was immediately started to be used in a lot of scientific research. After World War II, there was rapid development of pressure measurement devices, vacuum to high pressures. The accuracy of these instruments has major impact on the quality of product manufactured by industries using these instruments.

The accurate measurement of pressure plays an important role in manufacturing and processing industries such as automobiles, aerospace, steel, synthesis of high-strength materials, research, etc. In the industry accurate pressure measurement is important not only due to quality considerations but also to safety requirements. No single instrument can measure the pressure in the entire range of interest with the same accuracy and reproducibility. The instruments may also not be sensitive enough to small changes in pressure and insensitive over a working temperature range. The pressure, velocity, and temperature are the most important properties of fluids. Pressure and temperatures play a major role in the fields of "pipeline constructions," "water supply," "hydraulic lifts," "hydraulic presses," "hydraulic diggers," "hydraulic for irrigation," "thermal power," "hydraulic power," "aviation of flights," human blood, etc. The pressurized fluids can be used to perform work as they exert forces. The pneumatic and hydraulic systems use fluids for their working. These systems are used in most of the industries such as "automobile manufacturing" (brakes), "hoists" found in service stations, "dentist's chair," "aeronautics," "submarines," the "shipping industry," etc. A small pressure applied on a very large area can make a very large force. When any fluid flows over or through an object, it delivers small force pushes on the surface of the object. These forces, over the entire surface, are defined as pressure and can be calculated as force per unit area. The study of physical quantities like pressures, velocity, and temperature is very important to understand the fluid flow. In this chapter, focus will be on describing pressure, its unit, its type, and various pressure-measuring instruments. The basic definitions related to metrology and metrological characteristics of a pressure sensor are also described. Lastly CMCs of various country NMIs including uncertainty and type are also tabulated.

Pressure

In mechanical concept, the pressure on any object can be generated by applying normal force on the surface of the object. The physical quantity pressure is defined as the force applied perpendicular to the surface per unit area. It is a scalar physical quantity. The fundamental mathematical expression for pressure is given in Eq. 1:

$$\text{Pressure (p)} = \frac{\text{Force (F)}}{\text{Area (A)}} = \frac{\text{m g}}{\text{A}} \tag{1}$$

where m is applied mass to generate pressure force and g is acceleration due to gravity.

Any physical state of matter that possesses weight, whether at rest or in motion, exerts a pressure upon the surface in contact.

Units of Pressure

Many units are in use to measure the pressure (https://blog.beamex.com/pressure-units-and-pressure-unit-conversion) depending on the perspective of use. It will not make any sense if we say maintain air pressure of my car's tire at 206843 Pa, rather 30 psi.

SI Unit of Pressure

The unit of pressure in International System of Units (SI system) is pascal (Pa); 1 pascal is the pressure exerted by 1 newton force on area of 1 m^2. It is same as newton per square meter (N/m^2). Pascal is a small unit of measurement, for example, the standard atmospheric pressure is 1.013×10^5 Pa.

Imperial Units

In some countries like the United States and United Kingdom, the mass is being measured commonly in pounds or ounces and area and distance with inches or feet. So, some other pressure units derived from these are pounds per square feet (lbf/ft^2) and pounds per square inch (psi). In the United States, the most common pressure unit is psi. Nearly in all country, we measure the tire pressure in psi.

Liquid Column Units

The older pressure-measuring devices often use liquid in a transparent tube or U-shaped tube. Therefore, pressure is also expressed in terms of height of liquid column in the tube or difference of height of liquid in the two arms of a U-shaped tube. This unit of pressure is still in use. We measure blood pressure in millimeter of mercury (mmHg). We get a long list of pressure units in terms of height, just to mention a few: "centimeter," "inch," "millimeter" (torr) and "micrometer" (mtorr) of mercury, "millimeter," "centimeter," "meter," "inch," and "foot" of water.

Atmospheric Units

The "standard atmosphere" (atm) unit is used for measurement of the atmosphere's absolute pressure. It is approximately equal to typical air pressure at Earth mean sea level and is defined as 101325 Pa. There is another unit to measure the atmosphere's absolute pressure which is a "technical atmosphere" (at) which is close to "atm." The "at" is equal to pressure generated by 1 kilogram force at 1 square centimeter. The torr is another unit to express the atmospheric pressure. It is approximately 1/760 of atm. Torr is not included in the SI system.

Non-SI Unit of Pressure

In the "centimeter-gram-second" (cgs) system, the unit of pressure is "barye" (Ba), which equals to pressure exerted by 1 dyne force on area of 1 square centimeter. The "bar" is a metric unit of pressure, equal to pressure exerted by 1000000 dyne force on area of 1 square centimeter, but not part of the SI system. Units derived from the bar

include the "megabar" (symbol, Mbar), "kilobar" (symbol, kbar), "decibar" (symbol, dbar), "centibar" (symbol, cbar), and "millibar" (symbol, mbar).

A few other units are kilogram force per square meter (symbol, kgf/m^2), gram force per square meter (symbol, gf/m^2), and kilogram force per square centimeter (symbol, kgf/cm^2).

Pressure Unit Conversion Standards

The pressure is measured in various units; some of them have been discussed above. Sometimes there is need to convert pressure expressed in one unit to another pressure unit. Many conversion tables, even online conversion calculators, are available. The one such conversion factor (Rab et al. 2022) is shown in Table 1.

Types of Pressure

In this section of the chapter, various types (Gaßmann 2010) of pressure will be discussed.

Absolute Pressure

The pressure whose reference point of the measurement is zero pressure or an absolute or perfect vacuum is "absolute (abs) pressure." It is denoted by "P_{abs}." The pressure used in perfect gas law is an example of absolute pressure.

Gauge Pressure

The pressure whose reference point of the measurement is ambient pressure is "gauge pressure." Mostly pressure instruments measure gauge pressure since these instruments indicate the pressure relative to atmospheric pressure.

Differential Pressure

Differential pressure reads the difference in pressure of two different points of measurement.

Note that the same instrument can be used for all three types of absolute, gauge, and differential pressure; only the reference is different. Differential pressures are commonly used in industrial process systems. The relation between absolute, gauge, and vacuum pressures is shown in Fig. 1.

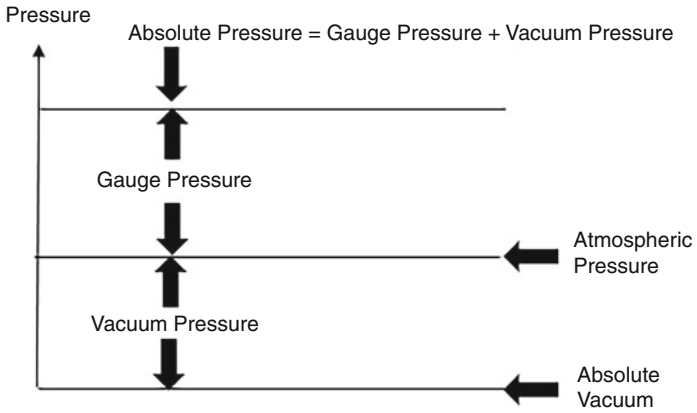

Fig. 1 Relation between absolute, gauge, and vacuum pressures

Hydrostatic Pressure

The pressure exerted by a fluid at any given point is called the "hydrostatic pressure." Pressure exerted by nonmoving (static) fluid on the body of a container is called "static," when the fluid is moving, it is called "dynamic." The principles of fluid dynamics can be used to describe the pressure in closed conditions. Bernoulli's equation given in Eq. 2 can be used to determine the pressure at any point in a fluid:

$$p + \frac{1}{2}\rho v^2 + \rho gh = \text{constant} \tag{2}$$

where p is "pressure"; ρ, "density"; v, "velocity"; g, "acceleration due to gravity"; and h, "elevation."

The applications of hydrostatic pressure are in "hydraulic brakes," "artesian well," "blood pressure," "hydraulic head," "plant cell turgidity," "Pythagorean cup," etc.

Static Pressure

The pressure uniform in all directions is called "static" pressure. If pressures exerted by a fluid at different direction are independent of direction, it will be a static pressure.

Dynamic Pressure

When fluid flows, it applies extra pressure on surfaces which are perpendicular to the fluid flow direction and not much effect on surfaces which are parallel to the flow

direction. This additional pressure in a moving fluid is called "dynamic pressure." Dynamic pressure is referenced to static pressure; therefore, it is a differential pressure.

Stagnation Pressure

The sum of the static and dynamic pressures is called the total pressure or stagnation pressure.

Static pressure and stagnation pressure are related to each other as shown in Eq. 3:

$$p_o = \frac{1}{2}\rho v^2 + p \tag{3}$$

where p_o is "stagnation pressure"; ρ, "density"; v, "flow velocity"; and p, "static pressure."

Explosion Pressure

Pressure generated during ignition of explosive gases, mists, and dust/air suspensions, in free or enclosed spaces, is known as "explosion" or "deflagration pressure."

Negative Pressure

Negative pressure is the situation whereby the pressure of one place is lower than in comparison to another.

Surface Pressure

The pressure in two-dimensional area is known as surface pressure. It is calculated by the lateral perpendicular force applied on a unit length of a line. Surface pressure is denoted by π and can be calculated using Eq. 4:

$$\pi = \frac{\mathrm{F}}{\mathrm{l}} \tag{4}$$

where F is lateral perpendicular force and l, length of line.

Pressure of an Ideal Gas

The pressure exerted by the ideal gas molecules confined within a rigid container is determined using "ideal gas law" given in Eq. 5:

$$\text{Pressure (p)} = \frac{nRT}{V} \tag{5}$$

where n is the "number of gas molecules"; R, "ideal gas constant" (8.314 J mol^{-1} K^{-1}); T, "temperature" of the gas; and V, volume of the container.

Vapor Pressure

When vapor is in a "thermodynamic equilibrium" with its condensed phase (liquid or solid) in a closed system, the pressure exerted by the vapor above the liquid or solid surface is known as "vapor pressure" or "equilibrium vapor pressure." The evaporation rate of a liquid depends upon equilibrium vapor pressure. As temperature of liquid increases, vapor pressure also increases. The vapor pressure is nonlinearly proportional to temperature according to "Clausius-Clapeyron" relation. The total pressure in the system is called "partial vapor" pressure if only vapor pressure of a mixture contributes to total pressure.

Fluid Pressure

The fluid exerts pressure. The pressure exerted by a fluid depends on its depth and density. The pressure of a static fluid can be easily calculated if the density of the fluid is known. P is the pressure on top of fluid as shown in Fig. 2. The absolute pressure at a depth H in a fluid is calculated as given by Eq. 6:

$$P_{abs} = P + (\rho \times g \times H) \tag{6}$$

where ρ is the density of the fluid and g acceleration due to gravity at that place.

Pressure Ranges

Some arbitrary defined pressure ranges (https://www.nist.gov/document/pmc-2pdf) are given in Table 2.

Pressure-Measuring Instruments

The pressure-measuring instruments are called pressure gauges (used to measure pressure above atmospheric pressure) or vacuum gauges (used to measure pressure below atmospheric pressure). Pressure gauges are used in automobiles, aeronautics, oil production, food industry, chemical industry, hydraulics, etc. Many instruments (Morris and Langari 2016; Soloukhin et al. 1991; Bourdon Tube Pressure And Vacuum Gauges 1971; https://www.budenberg.co.uk/store/gauges/pressure;

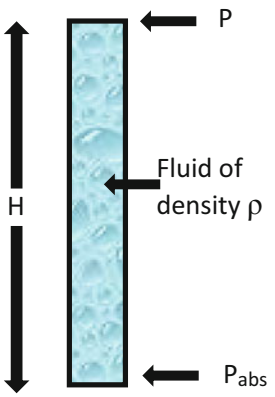

Fig. 2 Pressures exerted by liquid column

Table 2 Pressure ranges, table taken from reference (https://www.nist.gov/document/pmc-2pdf)

Range	Pressure range (Pa)	Pressure (conventional unit)
"Very high pressure"	10^{8}–10^{11}	1–1000 kbar
"High pressure"	10^{5}–10^{8}	15–15000 psi
"Atmospheric pressure"	10^{2}–10^{5}	1 torr–1 atm
"Low vacuum"	10^{-1}–10^{2}	10^{-3}–1 torr
"High vacuum"	10^{-4}–10^{-1}	10^{-6}–10^{-3} torr
"Very high vacuum"	10^{-7}–10^{-4}	10^{-9}–10^{-6} torr
"Ultrahigh vacuum"	10^{-10}–10^{-7}	10^{-12}–10^{-9} torr

Jones n.d.; Brombacher 1970; Cross 1963) have been invented to measure the pressure from 1×10^{-9} Pa to 1×10^{9} Pa till now, having different advantages and disadvantages. The cost of a pressure-measuring instrument depends upon pressure range, sensitivity, and dynamic response of that instrument. The oldest type is the "liquid column manometer" invented by "Evangelista Torricelli" in 1643. The "U-tube manometer" was invented by "Christian Huygens" in 1661. The different types of measuring instruments are shown in Fig. 3.

A "vented gauge pressure transmitter" reads pressure with respect to ambient atmosphere pressure. The main advantage of this gauge is that it reads zero when pressure is not applied, and its pressure measurement is not affected due to change in atmospheric temperature and pressure. At one end of the pressure sensing diaphragm, pressure to be measured is applied, and the other end is exposed to ambient atmospheric pressure via a vented cable or porous surface or a hole on the other side of the device.

A "sealed gauge reference" is very similar to vented gauge except that atmospheric pressure is sealed at another end of the diaphragm. The "sealed gauge" never reads zero as atmospheric pressure changes continuously. The sealed gauge is generally used to measure high pressure. At high pressure, accuracy of the reading is not affected due to change in atmospheric pressure.

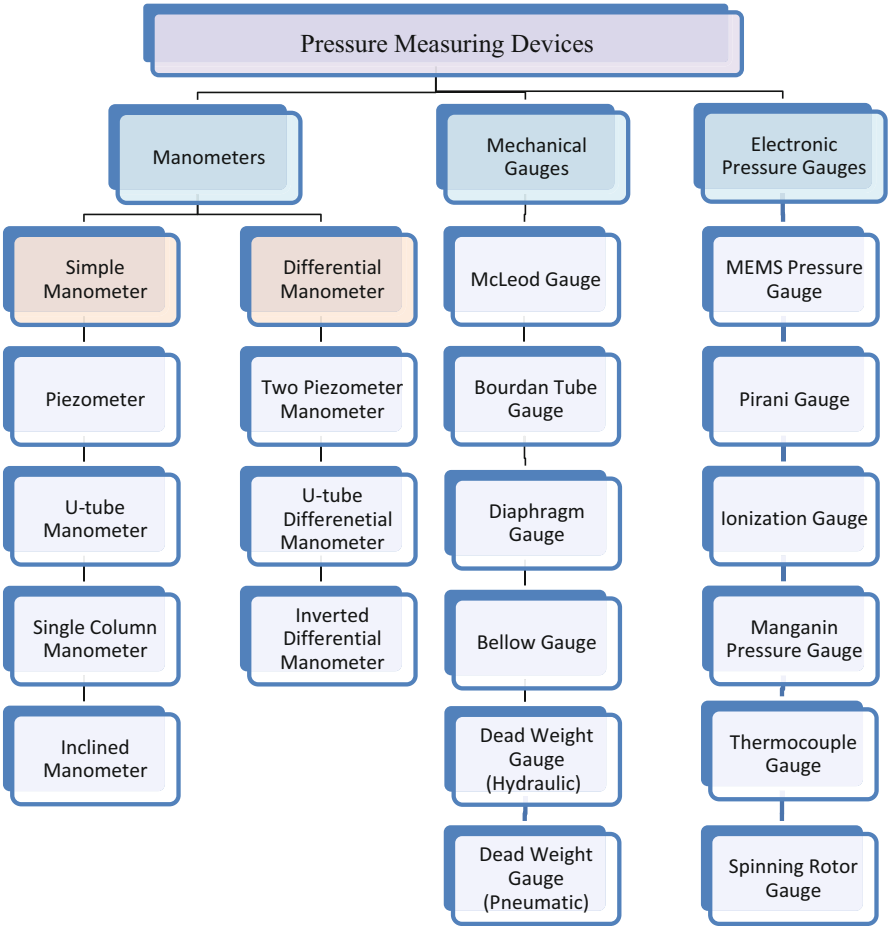

Fig. 3 Type of pressure-measuring instruments, content of figure adopted, and modified from Fig. 3 in reference (Rab et al. 2022)

An "absolute pressure" is pressure measurement whose reference point is zero pressure or absolute vacuum. The barometer reading the absolute pressure is the best example of this pressure.

Liquid Column Gauges

A manometer (https://solutionpharmacy.in/differential-u-tube-manometer/) is an instrument which measures pressure near to atmospheric pressure. These instruments are the cheapest, easy to use, easy to construct, and accurate pressure measurement devices. These instruments are widely used primary standards. It consists of a tube, half filled with the liquid. In a manometer, the weight of liquid

columns is balanced by pressures. It is used for measuring the "static pressure." Manometers inherently measure differential pressure. To determine absolute pressure, the reference side pressure must be known or negligible. Manometer gauges comprise of a vertical column of liquid either in a tube or in a U-shaped tube.

The different types of manometers are as follows:

1. "Simple manometer"
2. "Differential U-tube manometer"
3. "Inverted U-tube manometer"
4. "Inclined manometer"
5. "Small manometer"

The U-tube differential manometer is shown in Fig. 4. The ends A and B of this tube are subjected to different pressures P_1 and P_2. The liquid in columns will rise or fall in accordance with pressures at both ends until the weight of liquid becomes equal to the pressure to be measured. The end A is connected to the region where pressure needs to be measured, while the other end B to the "reference pressure." If we want to measure "absolute pressure" at end "A," the end "B" has to be connected to zero pressure or "absolute vacuum," and for "gauge pressure" measurement, end "B" has to be exposed to the atmosphere. The liquid height difference is directly proportional to the applied pressure. The difference (h) between two levels of liquid is measured by vertical ruler. For precise length measurement, high precision of about 10^{-3} mm micrometeor can be used; this can enhance overall accuracy of the instrument. The acceleration due to gravity (g) at the place of the instrument also required to be measured precisely. If we are taking reference density of fluid, the fluid must be of high purity. The most commonly used purification technique is vacuum distillation. The pressure can be calculated by using Equation "6" excluding the term P. Any fluid can be used in the manometer, but for high accuracy, mercury is preferred due to its high density (13.534 g/cm^3), chemical stability, small temperature coefficient, low vapor pressure, and does not stick to the walls of the tube. Since

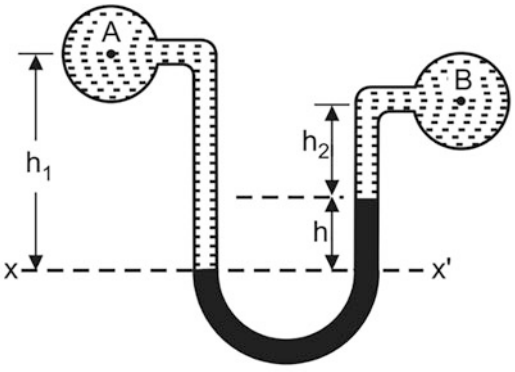

Fig. 4 U-tube differential manometer. Picture has been taken from reference (Song et al. 2020)

mercury expands with temperature and is compressible, its density depends upon temperature and pressure; therefore reference density values are to be specified for a particular temperature and pressure. For low-pressure measurement and to obtain higher resolution, lesser-density oil compared to mercury density can be used. In the "U-tube manometer," there is no fixed reference point as liquid height changes in both limbs of the tube in accordance with pressure. This makes the height difference measurement more difficult in comparison if one surface could be kept at some fixed level. The performance of manometers depends on length measurement, temperature measurement, operator skill, and environment conditions. The magnitude of random errors such as properly locating the liquid surface, measuring the height difference, variations in capillarity effect, and variations in temperature may be evaluated experimentally by repeated observations. The manometers have some drawbacks like small operational range of order of 1 MPa and fragile. The errors in measurement occur due to change in temperature as density of fluids used in manometers changes with temperature. Good commercial manometer using mercury can attain as low as 20–30 ppm of the measured pressure near atmosphere. The manometers are used in gas systems, to construct swimming pools, climate forecasting, for blood pressure measuring, etc.

McLeod Gauge

"McLeod" (https://en.wikipedia.org/wiki/McLeod_gauge) gauges are used to measure absolute pressure at very low pressure range between 10^{-4} torr and 10^{-6} torr. It was invented by Herbert McLeod in the year 1874. McLeod gauge is shown in Fig. 5. It consists of mercury reservoir, piston, reference column, bulb, scale, and measuring capillary. This gauge works on the principle of Boyle's law. It takes some volume of gas from a vacuum chamber whose pressure needs to be measured. After taking the small volume, the instrument is tilted. When the instrument is tilted, the infilling mercury compresses the small volume of taken gas. A mercury manometer is used to measure the pressure of compressed small volume of gas. By knowing the compression ratio, the pressure of the original vacuum can be determined. In this gauge there is linear relation between applied pressure and height. This gauge can be used as reference standard to calibrate other pressure gauges. McLeod gauges cannot give continuous output; therefore it measures only on sampling basis. Nowadays, these gauges are replaced largely by electronic vacuum gauges.

Aneroid Gauges

In "aneroid gauges," the pressure sensing element is made up of elastic metal. The working principle of "aneroid gauges" is the metallic sensing element flexes elastically when the pressure difference is applied across it. Aneroid gauges do not use any fluid for its working. "Aneroid gauges" can be used to measure the pressure of both liquid and gas. Working these gauges does not depend on the type of gas or liquid

Fig. 5 McLeod gauge. Picture has been taken from reference (https://en.wikipedia.org/wiki/McLeod_gauge)

whose pressure is being measured. The pressure sensing element may be a "Bourdon tube," a "diaphragm," a "capsule," or a set of "bellows."

Bourdon Tube Gauge

The "Bourdon tube gauge" is one of the most broadly utilized devices. It was invented in about 1849 by "Eugene Bourdon"; since then its use is increasing day by day. He patented "Bourdon tube pressure gauge" in the year 1849 in France. This gauge can be used for measuring the pressure of all types of liquids and gases including steam, water, and air. It can operate from 60 kPa to nearly 700 MPa. This gauge is useful for measuring static or slow-changing pressures. A Bourdon gauge (https://en.wikipedia.org/wiki/File:WPGaugeFace.jpg) indicator side is shown in Fig. 6, and inner construction is shown in Fig. 7. It uses a coiled tube as an elastic transducer. One end of this tube is connected to pressure to be measured and another end to the pointer through mechanical linkage. When pressure increases in the tube, it uncoiled due to expansion. When tube expands

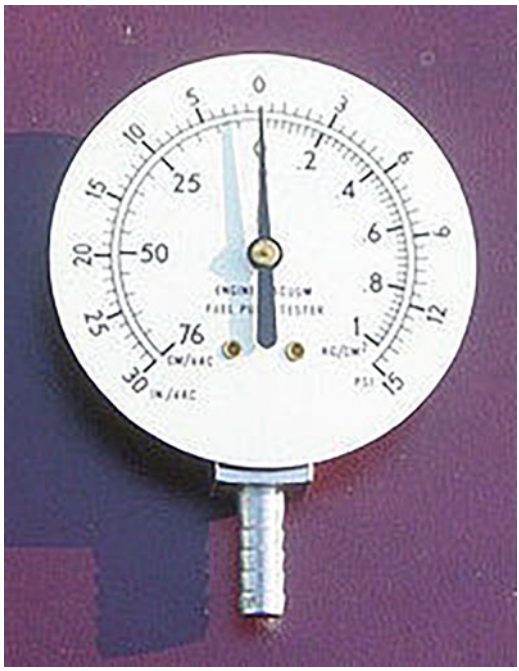

Fig. 6 Indicator side with card and dial Bourdon gauge. Picture has been taken from reference (https://en.wikipedia.org/wiki/File:WPGaugeFace.jpg)

it rotates the pointer connected with the tube via adjustment link, segment leaver, and pinion. When pressure decreases the tube contracts and tends to coil more tightly. This motion is transferred to an indicating needle. The pressure can be read directly with the help of calibrated scale. The performance of these gauges is limited to 0.1%. The precision of measurement is also limited by visual detection. The repeatability of gauge is also limited due to inelastic behavior of the tube material. Temperature changes also affect the reading because of thermal expansion of components. To reduce these problems, electronics can be blended with mechanical components. The mechanical linkage, arm, and pointer can be replaced by optical lever, and deflection of tube can be detected electronically and output displayed digitally.

Diaphragm

Diaphragm pressure gauges (https://en.wikipedia.org/wiki/File:Barograph_03.jpg) have a simple working mechanism. It consists of a thin circular membrane of a corrugated metal sheet called a diaphragm as shown in Fig. 8. The diaphragm can be made using a variety of materials like Inconel, nickel, titanium alloys, stainless steel, fused quartz, silicon, etc. (https://www.nist.gov/document/pmc-2pdf). In diaphragm gauge the flexible membrane defects if there is pressure difference in both sides of the membrane. The deformation of diaphragm is proportional to the pressure difference on two faces of thin flexible membrane. The one face of the membrane is kept at

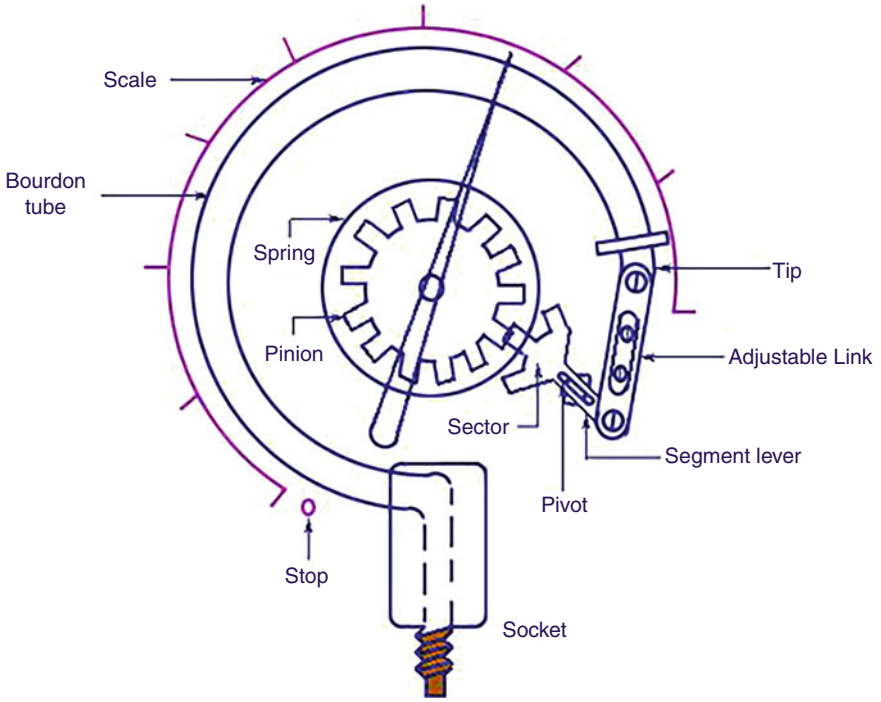

Fig. 7 Inner construction Bourdon gauge. Picture has been taken from reference (Maitra n.d.)

Fig. 8 A pile of pressure capsules with corrugated diaphragms in an aneroid barograph. Picture has been taken from reference (https://en.wikipedia.org/wiki/File:Barograph_03.jpg)

pressure to be measured, and the reference face can be exposed to the atmosphere, at any pressure, or can be sealed according to the type of measurement like gauge pressure, differential pressure, and absolute pressure, respectively. The deformation can be measured using mechanical, optical, or capacitive techniques. This gauge is used for low-pressure measurement from -100 kPa to 40000 kPa (https://tameson.com/pressure-gauge-diaphragm.html) in food and beverage, pharmaceutical, petrochemical, mining industries, etc.

Bellow Gauge

The pressure sensing element of bellow gauge is a bellow (https://instrumentationtools.com/bellows/). These gauges are more compliant than Bourdon gauges and the diaphragm gauges. The bellow is a thin-walled metallic tube which can contract and expand according to pressure variation as shown in Fig. 9. Generally, bellows contain 12 to 24 folds and its diameter ranges from 1.2 to 30 cm. When pressure is applied to the inlet (one end) of the bellow, it will expand or contract according to the applied system or line pressure. Another end of the bellow is connected to a spring and a pointer. As the bellow expands or contracts, either pressure can be read directly on scale, or an electrical signal is generated which can be processed to measure pressure. Within the elastic limit of the material of bellow, the relation between deflection and pressure is linear. The bellow gauge can measure pressure from 0.6 kPa to 100 kPa. The bellow gauge is more sensitive than the Bourdon tube gauge, thus useful for low-pressure applications.

Differential Pressure-Measuring Devices

The "differential pressure-measuring devices" measure the difference of two pressures. The devices which are used for differential pressure measurement have two input ports. The pressures whose difference has to be measured are applied to ports. The instrument output gives the differential pressure. Any pressure-measuring devices described earlier can be used to measure differential pressure in special forms. These devices are suitable for flow measurement, pumping plants, etc.

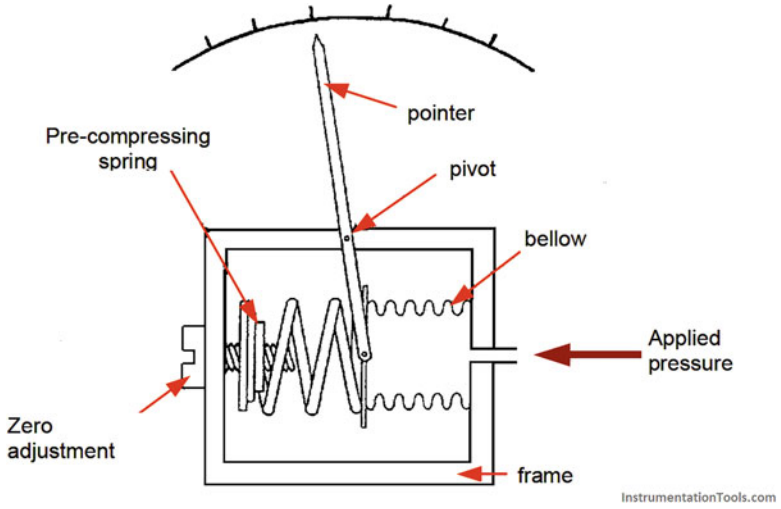

Fig. 9 The bellow gauge. Picture has been taken from reference (https://instrumentationtools.com/bellows/)

Deadweight Piston Gauge

The deadweight piston gauge (de Malherbe and Firth 1970; http://www.calref.it/clrf_eng/manual/Manual%20PDWT-10.pdf) measures the pressure using the fundamental units, mass and length; therefore they are used as a primary standard. Many other names of piston gauges are "deadweight gauges," "deadweight tester" (DWT), "gauge tester," "piston manometer," and "pressure balance." The DWTs are proven primary standards and the most accurate instruments available in the market for the calibration of secondary pressure gauges and sensors. It has therefore been used for years in factory, calibration laboratories, industry, national metrological institutes, and research laboratories. The basic construction of deadweight piston gauge is as illustrated in Fig. 10. The main element to construct these gauges is piston and cylinder assembly. The piston is implanted into a close-fitting cylinder. At one end of the piston, fluid pressure is applied, and weights are loaded at the other end to generate pressure to balance the fluid pressure. The different types of piston gauges have been constructed to accommodate the method of loading and method of rotating the piston and controlling the clearance to reduce friction between piston and cylinder resulting to increase the accuracy of the gauge. Three commonly used designs of cylinder are the simple, the reentrant cylinder, and the controlled clearance cylinder (Rab et al. 2022; Jain et al. 1992). Controlled clearance DWTs contain an external jacket through which hydraulic pressure can be applied to vary the clearance between the piston and the cylinder. Three different design configurations,

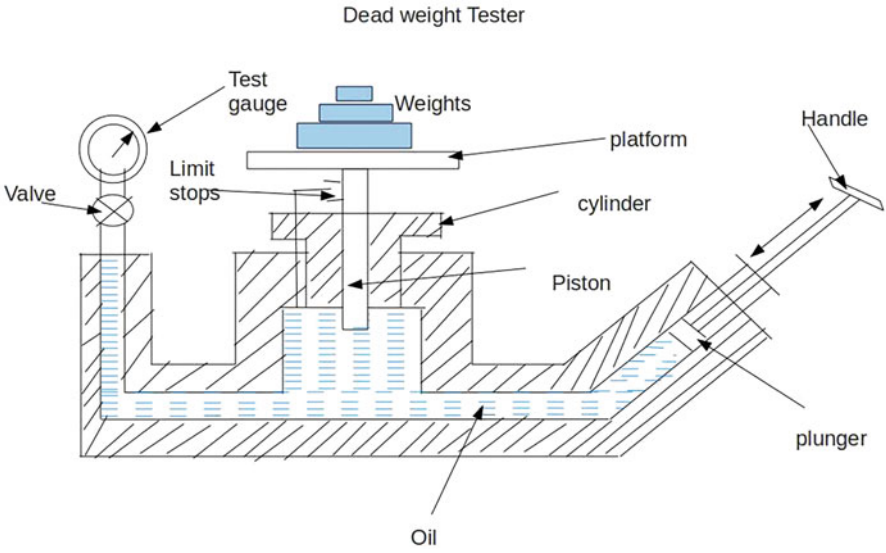

Fig. 10 Component of dead wight tester. Picture has been taken from reference (http://4.bp.blogspot.com/_SEJ_mMmfxvU/TKhjEXQ_mnI/AAAAAAAAAHw/h5qGU3EqnyQ/s1600/dead+weight+tester.jpg)

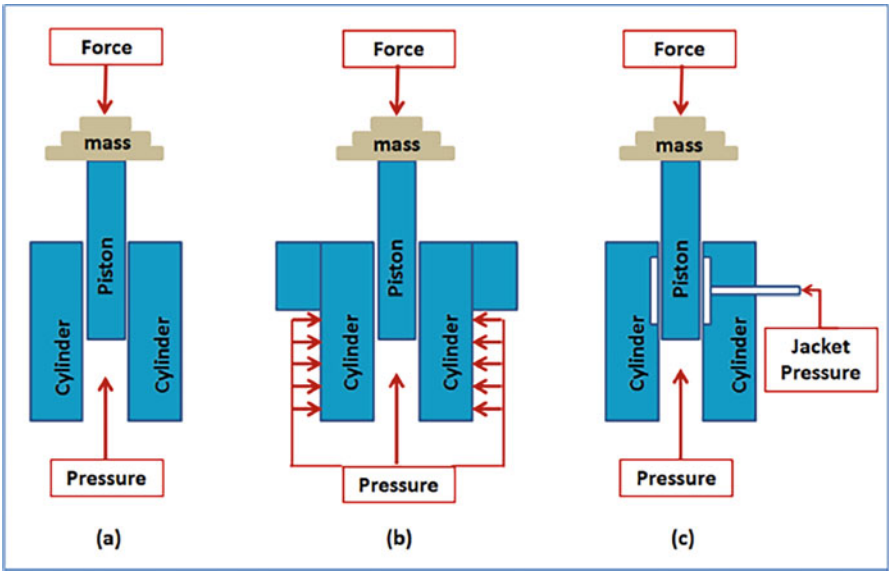

Fig. 11 Different design configurations of piston-cylinder assembly, (**a**) simple-type DWT, (**b**) reentrant-type DWT, and (**c**) controlled clearance-type DWT. Picture has been taken from reference (Rab et al. 2022)

simple, reentrant, and controlled clearance of piston-cylinder assembly (Rab et al. 2022), are shown in Fig. 11. The DWTs can use oil or gas for its operation. Gas can be used for pressure near to atmospheric pressure and lower part of high-pressure range in both gauge and absolute mode. Oil-operated gauges can be used for high and very high pressure in gauge mode. To achieve high accuracy by reducing the friction between piston and cylinder, piston and weight stack are rotated with respect to cylinder. The clearance between piston and cylinder must be small. The uncertainty of the DWTs is calculated by uncertainties of the acceleration due to gravity, mass of the weights, and effective area. In most cases, effective area of piston limits the accuracy of these gauges. The distortions of piston and cylinder introduce additional uncertainties. The piston gauges are very sensitive and stable. Commercial oil-operated gauges are available up to 1.3 GPa, and special purpose gauge have been built for operation up to 2.6 GPa (Thomson and Heydemann 1967; Eremeev 1974; Nishibata et al. 1980).

Pressure can be calculated by knowing the mass applied to piston, area of piston, and acceleration due to gravity at that location using Eq. 1. When pressure is applied to the piston and cylinder assembly, the area of piston gets charges. For accurate pressure calculation, the effective area of piston must be determined, and some other factor must be included. The effective area is determined by cross-floating with a known reference primary standard DWT. With a formula given in Eq. 7 (3rd International Congress on Mechanical Metrology (CIMMEC2014) 2015), the most accurate pressure can be calculated:

$$p = \frac{\left[m_p\left(1-\frac{\rho_a}{\rho_{mp}}\right)+m_r\left(1-\frac{\rho_a}{\rho_{mr}}\right)\right]g_l+\sigma C}{A_{0,T}\left[1+\left(\alpha_c+\alpha_p\right)(\theta-20)\right](1+\lambda p_n)} \pm \rho_{fluid} g_l \Delta h \tag{7}$$

where:

p is "the measured pressure, given in Pa"
m_p is "the mass of the piston, in kg"
ρ_a is "the specific volumetric mass of the air, in kg/m^3"
ρ_{mp} is "the volumetric mass of the piston material, in kg/m^3"
m_r is "the sum of the remaining masses operating on the system, in kg"
ρ_{mr} is "the specific volumetric mass of the remaining masses, in kg/m^3"
g_l is "the acceleration due to the local gravity, in m/s^2"
σ is "the surface tension of the fluid, in N/m"
C is "the length of the circumference of the piston, in m"
$A_{0,\ T}$ is "the area of the piston-cylinder assembly, in m^2"
T is "the reference temperature of the piston, in °C"
$\alpha_c + \alpha_p$ is "the coefficient of the linear thermal expansion of the piston-cylinder assembly, in °C^{-1}"
θ is "the temperature of the piston at the time of the measurement, in °C"
λ is "the distortion coefficient of the piston-cylinder assembly, generally in (10^{-6}) MPa^{-1}"
p_n is "the rated pressure of the measurement given in MPa"
ρ_{fluid} is "the specific volumetric mass of the fluid used, in kg/m^3"
Δh is "the gap between the piston and the cylinder at the location where the pressure is measured and is given in m"

DWT is simple in construction and easy to use. Desired range of pressure measurement can be easily obtained by adding weights or by changing the piston-cylinder arrangement.

Electronic Pressure Gauges

Electronic pressure gauges (EPG) are special forms of the pressure gauges used for automated devices like washing machines. The output of these pressure gauges is in millivolts (mV). The output varies according to the pressure applied. In these gauges the electronic techniques are applied to improve performance.

EPG Types by Sensing Principle

Different types of sensors are available to measure pressure (https://www.processindustryinformer.com/a-world-under-pressure-pressure-measurements-for-process-industries/). Piezo-resistive sensors are the most used sensors, due to high accuracy and robust construction. Most piezo-resistive sensors are based on a Wheatstone bridge principle. When strain/pressure is applied, the value of each

resistor in the bridge changes, and then this change can be used into a variety of electrical outputs.

Capacitive sensors come also in a big variety of shapes and forms, with generally very simple shapes. One plate of capacitor is a thin diaphragm. The pressure applied on the diaphragm will cause the elastic deformation/movement of the diaphragm and hence a change in the electrical capacitance. By measuring the change in capacitance, applied pressure can be measured. Capacitive sensors have high sensitivity.

Inductive sensors have a similar approach to capacitive sensors. A sensing (elastic) capsule moves a core element inside of a linear variable differential transformer. The applied pressure can be measured in terms of the induced electromotive force (emf).

Resonant pressure transducers are some of the most accurate sensors. When stress is applied to resonant sensor, frequency of a resonator changes in accordance with the applied stress. Applied stress is measured in terms of change in frequency.

EPG Types by Output

There are two main types of pressure sensors based on output signal. One is continuous output (mV, V, mA, and Hz) and another discrete or digital output. An mV output is desirable if the signal has to be modified in a customized application and display is at short distance, while a V output or mA output can be sent over relatively long distances. Nowadays digital output pressure sensors are becoming more popular as they can be easy integrated into digital systems (computer, wireless, Bluetooth, etc.).

Pressure Sensor Metrological Characteristics

It is extremely significant to understand metrological characteristics of pressure sensors to ensure a suitable sensor is chosen for the intended application.

The main metrological parameters are as follows.

Signal Offset

The output of the sensor at zero applied pressure is known as signal offset. The ability of "re-zero" is desirable in a sensor. Measuring and resetting such offsets require a calibration and maintenance plan to ensure accuracy in the measurement. Offset is shown in Fig. 12.

Sensitivity

The sensitivity of a sensor is the ratio of the output signal change and the pressure change. Let the output of any sensor change be 3 V, while the pressure changes by 1000 Pa; then the sensitivity will be 3 mV/Pa. This is an important parameter for the way we would use the signal in the application.

Precision

Precision is the term used to describe sensors' behavior in terms of its repeatability, linearity error, and signal hysteresis. Precision tells the behavior of the sensors. For example, is it repeatable? Is it linear? Is there hysteresis? Repeatability is the

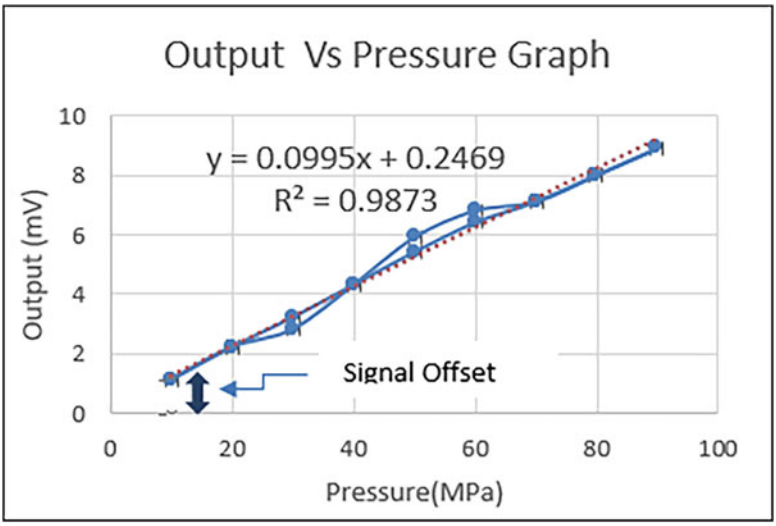

Fig. 12 Output vs. **pressure** graph for a sensor

closeness of the agreement between the successive measurement results of the same pressure carried out under the same conditions of measurement in a relatively short period of time. Often the repeatability is determined as the standard deviation of the repeated measurements. Linearity error is calculated taking the difference between the measured value and the theoretical line which assumes linear behavior of the sensor. R-squared (R^2) indicates the percentage of variance. If R^2 is close to "1," this means linear error is less. Linearity error is shown in Fig. 12. Solid line (-) represent the measured data and dotted line (. . .. . .) represent theoretical.

Hysteresis

Pressure hysteresis error is the difference between two separate measurements taken at the same point but one where the pressure is increasing and another where pressure is decreasing. The hysteresis graph is shown in Fig. 11.

Long-Term Stability (Drift)

Stability of a measuring instrument is the property, whereby its metrological properties remain constant in time. The drift is expressed as a tolerance range, D = +/- 10 Pa; hence it should be included in the overall accuracy of the instrument. Generally, the pressure sensor exhibits some form of drift over time; hence it is important that systems are designed with the potential to be adjusted for both: offset and span drift. This problem requires a calibration and maintenance program.

Accuracy and Uncertainty

Accuracy measures the product's performance quality. Generally, uncertainty is the measure of statistical dispersion of the values measured, including the impact of systematic error, random error, and drift.

The accuracy of a pressure sensor or of a measurement is obtained as part of the measurement uncertainty. Most of the time, the accuracy is evaluated as expanded uncertainty. Type A, type B, standard, and expanded uncertainty can be calculated using equations described elsewhere (Sawla 2000). Without accuracy evaluation, any measurement has no meaning. If accuracy of pressure measurement is not in desired limit, it can be dangerous specially in aircraft, chemical, and process industry. Accuracy estimation is a difficult task. Several common terms (Compilation of ASTM Standard Definitions 1986) for accuracy measurement are defined below. These definitions are commonly used in metrology.

Accuracy. This indicates how close a measurement to its true value. Since we cannot know true value exactly, accuracy can be estimated only. Most of the users use the error for accuracy. For example, measured value is 98.5 % of accepted value, it is said to have an accuracy of 1.5%.

Confidence level. We define confidence level in terms of standard deviation (sigma, σ) (https://news.mit.edu/2012/explained-sigma-0209). For accurate measurements, we take a large number of observation, and plot of results follows normal distribution. The deviation is how far the measurement point is from the average value and the standard deviation is square root of average of all squared deviations. One standard deviation (1σ) is the region that includes 68% of all the points in normal distribution curve. Two standard deviation (2σ) includes 95% and three standard deviation (3σ) includes 99.7%. If the errors are assumed to be distributed normally and uncertainty is specified 0.5% at the 2σ level, it means that there is 95% probability that the measured value is within 0.5%.

Error. It is the difference between measured value and true or expected value. Error can be estimated only. Errors can be represented as absolute error, relative error, and percentage errors, but generally the error is represented in percentage.

Linearity. Performance quality of any instrument is described in terms of linearity. It tells us how perfectly the instrument measures correspond to reality. It is a misleading indicator.

Precision. It is referring to closeness of two or more observations at the same point to each other.

Random error. Random errors are erratic differences in repeated measurement of a quantity. It is often characterized by standard deviation.

Repeatability. The closeness of agreement of measurement made under the same conditions is characterized by repeatability.

Reproducibility. The closeness of agreement of measurement made under the different conditions is characterized by repeatability. Reproducibility may also be on the measurement that is repeated over a long period of time.

Sensitivity. The ratio of change of output to change in input is known as sensitivity.

Traceability. The documented relationship between uncertainty of the instrument and the recognized standard. For example, traceable to CSIR-NPL means the instrument is calibrated relative to the standard maintained by the CSIR-NPL.

Head correction. If position of pressure gauge under calibration and pressure standard is at different elevation, the hydrostatic head contributes to error in calibration. The hydrostatic head correction is independent of pressure; it changes with fluid density and height difference between calibrator and gauge under calibration. For a fluid with a density of 1 g/cm^3 in acceleration due to gravity of 980 m/s^2, the correction will be -98 Pa for every cm increase of height of gauge under calibration.

Influence Quantities

Influence quantities (temperature, humidity, atmospheric pressure, electromagnetic fields, vibrations, noise, etc.) are any external (i.e., not included in the input/output) quantities, which can influence the performance of a pressure sensor. Most of the time, the pressure sensor manufacturers provide the range for the influence quantity and its effect on the metrological characteristics of the sensor. The influence quantities and their effect should be supplied by manufacturers through their datasheets.

Calibration of Pressure Sensors

Calibration is a process of configuring an instrument to provide an accurate measurement. The calibration process generally involved a calibrator, an instrument which is more accurate (4 times more) than the sensor to be calibrated. In past years, pressure sensors would be taken out of the system into which they are incorporated and calibrated in a metrological laboratory. In modern times, most of the sensors are calibrated "on the spot" using pressure calibrators. Also, many of the calibrators can evaluate the calibration uncertainty (many times referenced as "accuracy").

MEMS Pressure Sensors

"MEMS" (microelectromechanical systems) pressure sensors (Song et al. 2020) can be used to measure the pressure of gases including air. Their basic construction is shown in Fig. 13. The pressure is sensed by a thin silicon diaphragm of typical thickness 100 mm on a silicon substrate. When the pressure to be measured is applied to the diaphragm, it bends under the action of the applied pressure.

The deflection of the diaphragm can be measured by the following methods:

1. By mounting piezo-resistors on the diaphragm surface
2. By measuring the change in capacitance between the diaphragm and a silicon beam above the diaphragm

The relation between output and input of a piezo resistor is linear. In type 1 the output is considerably affected by temperature changes. The size of devices based on

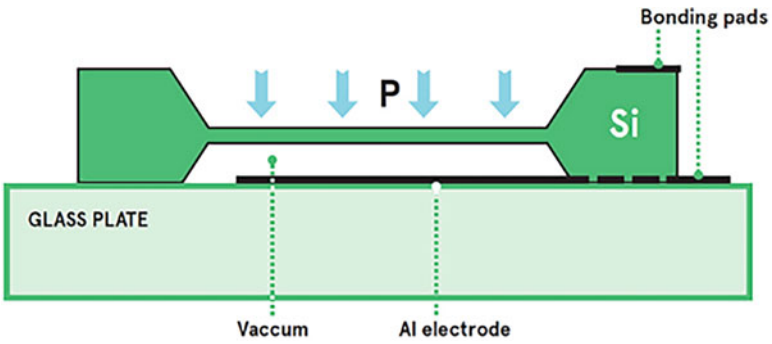

Fig. 13 Structure of the MEMS pressure gauge. Picture has been taken from reference (https://www.avnet.com/wps/portal/abacus/solutions/technologies/sensors/pressure-sensors/core-technologies/mems/)

the capacitive method are much larger, but output is less impacted by temperature changes. They have a nonlinear input-output relation. MEMS gauges based on capacitance are cheaper than piezo-resistive ones. Different versions of MEMS pressure sensors can measure gauge and differential pressure. The accuracy of pressure measurement by MEMS gauge is typically ± 3% of full-scale reading. They are used in large numbers of industry including automotive and medical.

Thermal Conductivity Pressure Gauges

The thermal conductivity pressure gauge is based on change of thermal conductivity of gases according to pressure change. Generally, when pressure of a real gas increases, its density also increases, and hence the ability of gas to conduct heat increases. These gauges consist of a wire filament, a thermocouple, or resistance temperature detector (RTD). The filament is suspended in a chamber whose pressure has to be measured. This filament is heated by flowing current in it. RTD or thermocouple can be used to measure the temperature of the filament. The temperature of filament is dependent on the thermal conductivity of surrounding gas and hence on pressure. Therefore, by measuring the temperature of filament, we can measure the pressure of chamber. These gauges can be used from 0.5 torr to 10^{-3} torr.

Pirani Gauge

The "Pirani gauge" was invented by "Marcello Pirani." The construction of Pirani gauge (Morris and Langari 2016) is shown in Fig. 14. The main component of a Pirani gauge is a metal wire made up of gold-plated tungsten or platinum. This wire is exposed to the pressure being measured. The wire is heated by passing the current through it and cooled by the surrounding gas. The cooling effect of the wire is directly proportional to the thermal conductivity of gas and hence on pressure. The resistance of the wire varies with temperature. Resistance of wire can be calculated

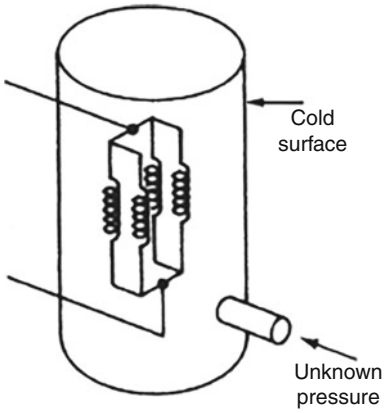

Fig. 14 Pirani gauge. Picture has been taken from reference (Morris and Langari 2016)

by noting supply voltage and current which heats the filament. By knowing the resistance, the gas pressure can be determined. Useful range is 10^{-5} mbar to 1 mbar.

Ionization Gauge

Ionization gauges (Soloukhin et al. 1991) are used to measure very low pressure as they are the most sensitive gauges for very low pressures. The structure is shown in Fig. 15. They sense pressure indirectly by measuring the electrical ions produced when the gas is bombarded with electrons. Fewer ions will be produced by lower-density gases. The calibration of an ion gauge is unstable and dependent on the nature of the gases being measured, which is not always known. Thermionic emission generates electrons, which collide with gas atoms and generate positive ions. The ions are attracted to a suitably biased electrode known as the collector. The current in the collector is proportional to the rate of ionization, which is a function of the pressure in the system. Hence, measuring the collector current gives the gas pressure. There are several subtypes of ionization gauge. Useful range is 10^{-10}–10^{-3} torr (roughly 10^{-8}–10^{-1} Pa).

Capacitive Pressure Gauges Using Dielectric Material

The solution for adverse effect of temperature and inelastic behavior on the gauge performance is given by many researchers using capacitive pressure gauge (Andeen et al. 1971; Collwel 1979; Kumar et al. 1999; Kumar et al. 2003; Kumar and Yadav 2017; Kumar 2021). Andeen and co-worker (Andeen et al. 1971) used a variation of capacitance of parallel plate capacitor of CaF_2 solid dielectric with applied pressure to measure the pressure. This gauge demonstrated good sensitivity and repeatability of the pressure measurement. Colwell (Collwel 1979) made significant improvement

Fig. 15 Ionization pressure gauge. Picture has been taken from reference (https://www.directindustry.com/prod/stanford-research-systems/product-7218-1865284.html)

in the design of the gauge by using two capacitors of different materials. Vinay et al. (Kumar et al. 1999; Kumar et al. 2003; Kumar and Yadav 2017; Kumar 2021) demonstrate the use of $Pb(Mg_{1/3}Nb_{2/3})O_3$ [PMN – lead magnesium niobate] and $Pb(Fe_{2/3}W_{1/3})O_3$ [PFW – lead iron tungstate] relaxor material either single or in combination with other to fabricate dielectric pressure sensor for high-pressure measurement up to 450 MPa.

High-Pressure Measurement (Greater than 7000 Bar)

Pressure range above 10^9 Pa is usually measured with "manganin pressure gauge" (Morris and Langari 2016). These gauge works on the principle of change in resistance of special material with pressure. Manganin is the preferred material for these gauges since its variation of resistance with pressure is more linear in comparison of other material and it is most sensitive. The pressure equation can be obtained by studying metrological properties using piston manometer. A manganin pressure sensor consists of a coil of manganin wire enclosed in sealed, kerosene-filled, flexible bellows, as shown in Fig. 16. The two ends of the wire are soldered to electrical lead. The unknown pressure is applied to one end of the bellows, which transmits the pressure to the coil. The coil resistance changes according to the applied pressure. By measuring the resistance of the coil, pressure can be calculated.

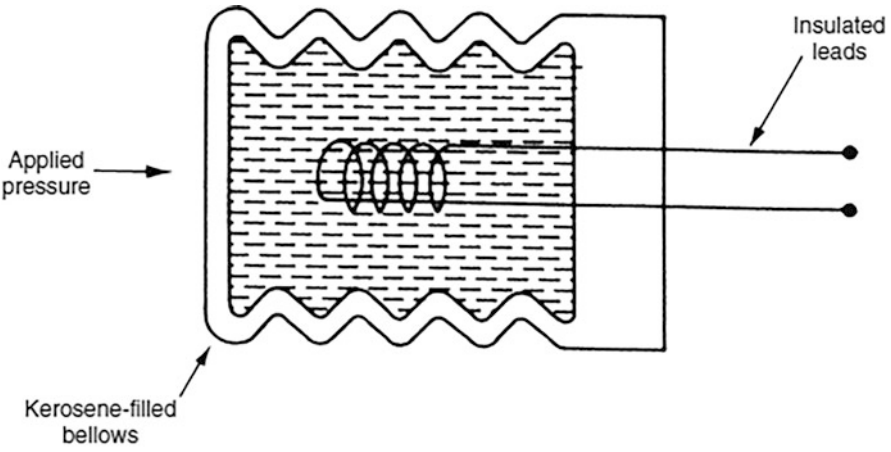

Fig. 16 Structure of manganin pressure sensor, picture has been taken from reference (Morris and Langari 2016)

Pressure up to 3000 MPa can be measured by a "manganin wire pressure sensor," with a typical inaccuracy of ± 0.5%.

Measurement Standards and Facilities

The measurement standards can be classified in to two types: primary standard and secondary. The primary standards are not calibrated against other standards, but for accuracy check, their measurement result must compare to other standards (intercomparison), although parts of primary standard may be calibrated to standards of other units. The design of primary standards must be based on physics laws relating quantity (pressure) to be measured to the measuring components. For example, in case of pressure standard, the relationship between applied pressure and measuring quantities like mass, length, temperature, time, etc. must be known. The uncertainty analysis of primary standards requires thorough knowledge of operation of the instrument and effect of environment conditions. Examples of primary pressure standards are "McLeod gauges," "liquid column manometers," and deadweight testers.

The secondary or transfer pressure standards are calibrated against primary standards. Any instrument with well-established stability can serve as secondary standards. The uncertainty of instrument is always greater than the primary standards. Repeated calibrations of transfer standard are required. If there is much difference in measurement value, either secondary or primary standard is malfunctioning.

The approved CMCs of different countries' NMIs for the different pressure range and with uncertainty are given in Table 3 (Rab et al. 2022; Calibration and measurement capabilities 2022).

Table 3 Approved CMCs of different countries' NMIs, data is taken from reference (Rab et al. 2022; Calibration and measurement capabilities 2022)

Countries, NMI	Pressure ranges and approved CMCs	Reported measurement uncertainties through equation (pressure p, p_l, p_{line}, and D_p are in Pa, if not specified)	Mode and medium of pressure
Argentina	1500 Pa to 5000 Pa	2 Pa	Gauge, gas
	1E8 Pa to 4E8 Pa	4E-05p + 2.1E-13p^2	Gauge, oil
	5000 Pa to 7E6 Pa	1 + 4E-05p	Gauge, gas
	−1500 Pa to 1500 Pa	0.3 Pa	Gauge, gas
	7E6 Pa to 12E6 Pa	5E-05p	Gauge, gas
	1E8 Pa to 4E8 Pa	4E-05p + 2.1E-13p^2	Absolute, oil
	−5000 Pa to −1500 Pa	2 Pa	Gauge, gas
	2E5 Pa to 1E8 Pa	30 + 5E-05p	Absolute, oil
	1E5 Pa to 1E8 Pa	30 + 5E-05p	Gauge, oil
	1500 Pa to 4.00E4 Pa	4Pa	Absolute, gas
	−1E5 Pa to −5000 Pa	1 + 4E-05p	Gauge, gas
	4E4 Pa to 7E6 Pa	2.0 + 5E-05p	Absolute, gas
	7.1E6 to 1.21E7	6E-05p	Absolute, gas
Australia	2 kPa to 7000 kPa	1 to 1.7E2 Pa	Gauge, gas
	0 kPa to 105 kPa	1 Pa	Absolute, gas

Conclusion

Nowadays, physical quantity pressure is a very important quantity with which we encounter in daily life like tire pressure, hydraulic breaks, hydraulic power in different machines, etc. Many instruments are available to measure pressure. The accurate measurement of pressure plays an important role in many industries such as automobiles, aerospace, steel, chemical, medical, and manufacturing. The accurate pressure measurement is important for quality and safety requirements. No single instrument can measure the pressure in the entire range of interest with the same accuracy and reproducibility. "Pressure" and "temperatures" play a major role in the fields of "pipeline constructions," "water supply," "hydraulics for irrigation," "thermal power," "hydraulic power," "aviation of flights," "human blood," etc. In this chapter, I dealt with study of pressure and its various pressure-measuring instruments. Reader can understand basics of pressure, pressure units and its conversion, various types of pressure, commonly used pressure-measuring instruments, and pressure sensor's metrological characteristics. Also, reader can find the basic definitions related to metrology in section "Pressure-Measuring Instruments." The approved pressure CMCs of different countries' NMIs are compiled in this chapter. The NMIs have CMCs of different ranges starting from 0 Pa to 1400 MPa. Some countries have enough CMCs but some have very less. This chapter is highly useful for students, researchers, and stakeholders as they find most of the information related to pressure at one place. Although large numbers of equipment are available to measure the pressure in different ranges, still more research is required to develop instruments with improved accuracy, portability, and cost-effectiveness.

Abstract

Recently, as the power industry is revolutionizing, the smart grid concept is gaining momentum continuously around the world. For real-time supervision, protection, and control of the behavior of the power grid, phasor measurement units (PMUs) are being installed at a large scale. This chapter presents in detail the electrical power system, the structure of the Indian power grid, synchrophasor technology, wide area monitoring system (WAMS), PMUs in monitoring, and control of the power grid. Also, the Unified Real Time Dynamic State Measurement (URTDSM) project, which is being implemented in the Indian Power System, is elucidated, along with the details of PMU and the role of

synchronization techniques in PMU. The IEEE synchrophasor standards associated with the measurements, compliance, and testing and the PMU calibration system of the CSIR-NPL, along with its traceability to the country's national standards, are dealt with in detail. The chapter finally ends by highlighting the implementation issues and challenges faced by the power grid and their solutions, such as load management and automation of the grid, which are essential to transform and augment the power sector into a responsive, stable, and secure system.

Introduction

The power grid is currently evolving at a very swift rate. The modernization of the grid is full of challenges as the power grid network is very dynamic and heterogeneous in nature. The power industries across the globe are facing new cutthroat difficulties in planning, generation, operation, and development of this sophisticated infrastructure, which is capable of capturing the grid dynamics and can also support diverse requirements of varied applications. Also, as globally the power demand is rising exponentially which is putting a lot of pressure on the existing infrastructure. To increase the generation capacity of power sector and focusing on the green energy to reduce carbon dioxide emission, new renewable sources are being introduced into the grid. With the integration of these substantial generating resources in the grid, the complexity of the power grid is also intensifying. The power systems, being very sophisticated, are susceptible to blackouts and outages (Khatkar et al. 2022a), and when the instances of outages and blackouts increase in the power network, the control and protection of the grid becomes very difficult. Conventionally, supervisory control and data acquisition (SCADA) systems were used to keep track of the electrical power network (HyungSeon 2017), but these systems are protracted, nonsynchronous, and steady-state measurement systems with the inability to monitor the dynamics of the system. Hence, to observe and check the dynamics of the power system networks, WAMS is overtaking SCADA system.

WAMS is now becoming a widely accepted monitoring system, which renders addendum to the existing SCADA system. In WAMS, PMU plays a major role as it is the device that records the time-stamped synchrophasor data at a very high speed. In the twenty-first century, the PMU is attaining high importance in order to monitor, supervise, and correct the power grid (Nicorescu et al. 2019).

Here, in this chapter, complete details of the electrical power system, Indian perspective of power system, synchrophasor technology and its applications, and WAMS and its architecture, advantages, and applications along with the presence of WAMS in the Indian power grid are described in detail. Furthermore, a brief

description of PMU, its architecture, the role of different synchronization techniques in PMU, IEEE standards, CSIR-NPL traceable PMU calibration system, and the performance evaluation of PMU as per the IEEE standard are elucidated in detail in this chapter. The chapter ends with the protection systems that are possible due to synchrophasor inputs and power grid automation and load management, which are the need of the hour in order to transform and augment the power sector.

Electrical Power System

The electrical power system is described as the network of electrical components that are used to generate, transmit, distribute, and consume electric power (Agüero et al. 2017). Traditionally, electric power is delivered to the end users from the generators by using an infrastructure that consists of AC power systems. The voltage and current waveforms in the normal operating conditions of the power system are modeled as sinusoidal signals, as shown in Eq. (1):

$$x(t) = A_o.\cos(2\pi f_o t + \varphi_o) \tag{1}$$

where A_o is the nominal peak amplitude, φ_o is the initial phase at $t = 0$, and f_o is the nominal power system frequency.

The power system exhibits dynamic behavior even in normal operating conditions and is never in a steady-state operation (Tan and Novosel 2017). Hence, the parameters, as shown in Eq. 1, are hardly ever time-invariant because of the changes related to generation imbalances, large generator inertia, automatic speed control of generators, and frequency fluctuations, which are among the most evident phenomena. During faults or events of switchover, these frequency fluctuations are even more pronounced. So, based on these dynamic events, a generalized signal model incorporating all these phenomena can be expressed, as shown in Eq. (2):

$$\begin{aligned} x(t) = a(t)\cos(2\pi f(t)t + \psi_o) + \sum\nolimits_{h=1}^{H} A_h(t)\cos(2\pi f_h(t)t + \psi_h) \\ + A_{DC}(t)e^{-\frac{1}{\tau}} + \varepsilon(t) \end{aligned} \tag{2}$$

where the main tone is represented by the first term, the instantaneous frequency $f(t)$ is close to the nominal frequency f_o(50 Hz or 60 Hz), $A(t)$ represents the instantaneous peak amplitude, and the instantaneous phase is represented by $\Psi(t) = 2\pi f(t)t + \phi_o$.

It is assumed that the initial phase ϕ_o is constant, which implies that the instantaneous variations in phase are attributable only to the frequency variations of the generator, thereby removing the possibility of multiple couples of frequency that give the same $\Psi(t)$. The superposed sinusoidal tone and the harmonic effects, interharmonics, and subharmonics are modeled by the second term of Eq. (2). In the second term, $f_h(t)$ represents the instantaneous frequency of each tone, $A_h(t)$

represents the peak amplitude, and the instantaneous phase is described by $\Psi_h = 2\pi f_h(t)t + \phi_h$, where ϕ_h is the initial phase.

The peak amplitude in the case of normal operating condition is one order lower than the main tone $A(t)$. In Eq. (2), the third term represents the decaying DC component, A_{DC} being the initial amplitude and τ the arbitrary time constant. The last term $\varepsilon(t)$ expresses the wideband noise.

In electrical engineering, the phasor transformation is adopted to simplify electrical signal analysis. Eq. (1) can be rewritten as:

$$x(t) = A\ cos(2\pi ft + \Psi) \tag{3}$$

$$= R_e\left\{A.e^{j(2\pi ft+\Psi)}\right\} \tag{4}$$

$$= R_e\left\{A.e^{j\Psi(t)}\right\} \tag{5}$$

In Eqs. (3), (4), and (5), as $x(t)$ is stationary, dependency of $\psi(t)$ on time is disregarded. And then, the sinusoidal term $x(t)$ can be associated with complex number X, which is called a phasor, and can also be represented in polar or rectangular coordinate as shown in Eqs. (6) and (7):

$$x(t) \leftrightarrow X \approx A.e^{jw} \tag{6}$$

$$= X_r + jX_i \tag{7}$$

In Eq. (7), r represents the real part, and i represents the imaginary part.

Hence, phasor is a complex number that is used to represent both magnitude and phase angle of sinusoidal wave or time-varying electrical quantity. The phasors are used to describe the behavior of the power system when it is dynamic in nature. Therefore, the phasors function as basic tools for analyzing AC circuits and represent the steady-state sinusoidal waveform of fundamental power frequency.

Indian Power Grid

The power grid is an amalgamation of generation of electrical power, its transmission, and consumption (Gyanendra Singh and Tiwari 2017). The Indian power grid stands third based on power generation globally (Rao 2019). India produced 1669 TWh of energy as opposed to 8537 TWh by China and 4381 TWh by the United States in 2021. The total installed capacity of power stations in India in February 2022 was around 395.6 GW. The contribution of thermal, nuclear, and renewable sources was 235.93 GW, 6.78 GW, and 152.89 GW, respectively (Installed Capacity Report 2022).

In early sixties, the management of grid on regional basis was initiated, and the grids of the states were integrated to form a regional grid. By the integration of grids, all the regions of India were divided into five regions, namely, Northern (NR),

Eastern (ER), Western (WR), Northeastern (NER), and Southern region (SR). In 1991, taking the concept of integration further, the ER and NER grids were also connected. Moving further in March 2003, the WR and ER-NER were also synchronized. In August 2006, the Northern grid and Eastern grid were interconnected. Hence, a central grid was formed with four regional grids, i.e., NR, ER, WR, and NER, synchronously operating at one frequency. On December 13, 2013, the SR was attached to the central grid in synchronous mode. This was done with the commissioning of 765 KV Raichur-Solapur transmission line. By doing so, the grid of India achieved the target of "One Nation-One Grid-One Frequency" (Sarkar et al. 2015).

Synchrophasors

The phasor concept is a stationary hypothesis and hence cannot be applied directly for the real AC power system analysis as it does not hold good in the real world. During electromechanical oscillations or power swings, that is, when the power system is not stationary and is in dynamic state, the current and voltage variations can be treated as quasi-steady approximation, that is, the stationary hypothesis is applied, and, hence, phasor analysis of waveform can be done. Without following the sinusoidal steady-state hypothesis, it becomes impossible to approximate phasor measurements at various positions of the grid without having a common time reference because the phase of a sinusoidal waveform is dependent on time scale t, and, hence, it cannot be precisely expressed without a common time reference. The phasor concept is extended to synchrophasor, owing to this reason.

The phasor representation was represented by Steinmetz in 1893 (You et al. 2021), and, through the development of the PMU by Phadke and Thorp in 1988, the Steinmetz's technology was used for real-time phasor measurements, which are synchronized by a common time reference (Vallakati and Ranganathan 2017). These synchronized phasor measurements are referred to a synchrophasor.

The IEEE 1344-1995 (1995) first defined the synchrophasor concept as a phasor that is calculated from samples of data, which are referenced to a standard time reference. Again, the concept of synchrophasor was reviewed and defined by IEEE C37.118.1-2011 (2011) standard as instantaneous phase angle, which is relative to the cos function at nominal frequency [50 Hz or 60 Hz] and is referenced to Coordinated Universal Time. However, the definition of synchrophasor is confining and gives rise to ambiguity. Hence, an inclusive definition of synchrophasor is one which refers to both phase estimations and the amplitude referred to the common time.

So, for the signal $x(t)$ represented by Eq. (2), the correlated synchrophasor is expressed as:

$$x(t) \leftrightarrow X(t) \triangleq A(t).e^{j\Psi(t)} \tag{8}$$

$$= A(t).e^{j(2\pi f(t)t+\Psi)} \tag{9}$$

Table 1 SCADA system and synchrophasor technology (PMU) comparison

Attribute	SCADA	PMU
Observation	Steady state	Dynamic
Resolution per second (sample)	1 in 2–4 seconds	10–60
Measurements	I, |V|	I, |V|, δ, frequency, rate of change of frequency (ROCOF)
Synchronization	No	Yes
Accuracy	Low	High
Focus area	Low area	Wide area

Table 2 Synchrophasor technology applications

Offline applications	Online applications
Power system model validation	Visualization and monitoring of wide area of power system
	State estimation
Post disturbance analysis	Monitoring of voltage, instability, oscillations, frequency instability
	Fault location identification and protective relaying

In Eq. (9), $A(t)$ represents the instantaneous peak amplitude, and $\Psi(t)$ represents the instantaneous phase of $x(t)$.

Traditionally, SCADA was used to observe the power system, but these measurements were protracted and were based on steady-state analysis of the system and hence were unable to observe the dynamics of the power system (Domijan and Jain 2011). The comparison between SCADA and synchrophasor technology or PMU measurements is given in Table 1.

As, PMUs bring forth the best knowledge and precise information of the current or dynamic situation of the grid, hence are being deployed at very high rate in the grid across India as well as the whole world. In 2000, there were only 15–20 PMUs deployed across the Indian National Grid, whereas, currently, around 1700 PMUs are deployed and are providing real-time information of the Indian National Grid for wide area situational awareness.

Table 2 sheds light on the application of synchrophasor technology. The applications are varied, such as monitoring of voltage stability, angle and frequency, real-time control of power system, thermal overload monitoring, steady-state and dynamic estimations, state measurement, wide area stabilization, congestion management, restoration of system, post-event analysis, adaptive protection, and planned power system separation.

Wide Area Monitoring System (WAMS)

As the power sector is proliferating in India, the Indian power grid is forced to operate very close to its operational limits to efficiently and effectively exploit all available resources. Hence, it becomes essential for the grid operators to remain

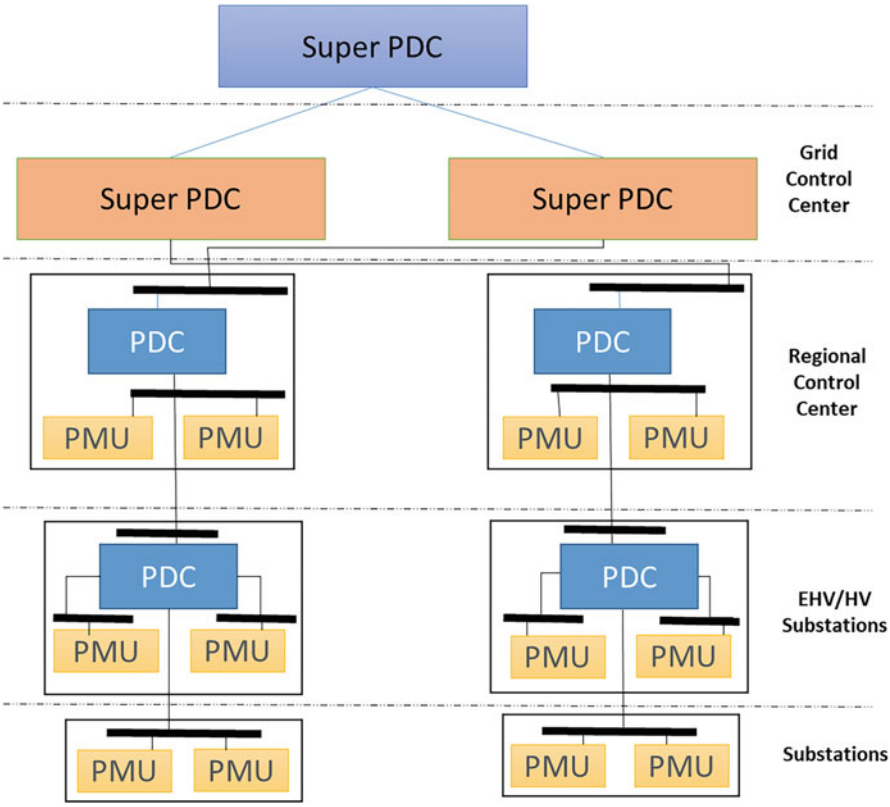

Fig. 1 Architecture of wide area monitoring system

extra vigilant and alert in observing and monitoring the health of the grid so that it functions smoothly. The situational awareness of the grid can be enhanced by deploying PMU-based WAMS (Abdullah Sufyan et al. 2018). The PMUs that are deployed over a large area and are interconnected together to monitor and control the regions are generally known as WAMS.

The WAMS network has the capability to transfer data at a very high rate generally 10–60 samples per second as opposed to one sample per 2–4 second in the existing SCADA system. Synchronized measurements are an indispensable part of the WAMS network to get the panoramic view of the complete grid. The WAMS architecture is depicted in Fig. 1. Typically, WAMS networks consist of PMUs, phasor data concentrator (PDC), and a communication network. The PMUs are optimally placed throughout the grid to get a comprehensive grid view (Saha et al. 2015).

WAMS: Importance and Application

The deployment of PMUs and the successful implementation of wide area management system are playing crucial roles in proper visualization, monitoring, and

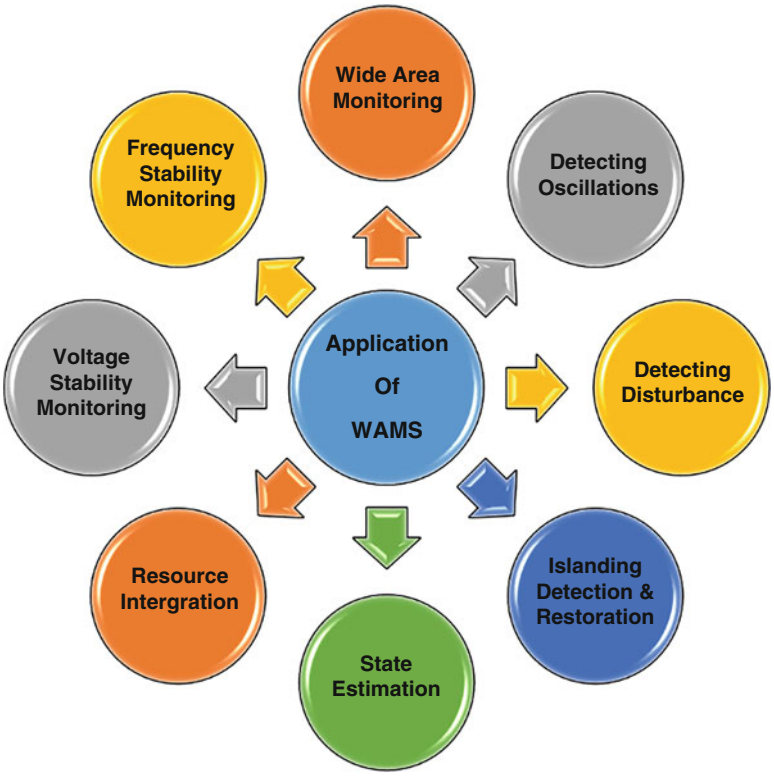

Fig. 2 Applications of wide area monitoring system

control of the power grid. The application offered by successfully implemented WAMS is summarized in Fig. 2 (Rihan et al. 2013). The main benefit offered by WAMS is that it works as a tool to provide better understanding and control of various events occurring in the grid. Because of the grid operator's real-time situational awareness, WAMS plays a critical role in preventing grid collapse. WAMS also provides better visualization of imbalances in power grid in the form of low-frequency oscillations and helps in preventing power outages and blackouts. WAMS facilitates the grid operators by being an analytical tool providing accurate and precise measurements to help secure the power grid in an effective and unerring manner. Also, WAMS helps in postmortem analysis of the grid by providing data in the offline mode (Kanabar et al. 2013).

WAMS in the Indian Power Grid

In India, the synchrophasor initiative was pioneered in the form of a pilot project in May 2010 in the Northern region of the grid. In a similar fashion, many projects were conceived in different parts of the Indian power grid, which is summarized in Table 3

Table 3 Summary of PMU and PDC installed in different pilot projects

Sr. No.	Region	No. of PMUs	No. of PDCs
1	ER	8	5
2	WR	11	1
3	NR	8	1
4	SR	6	1
5	NER	6	1
6	NLDC	18	1

(Saha et al. 2015). After the successful implementation of these pilot projects at regional levels, these projects were integrated at the national level and these synchrophasor projects communicated through PDCs at regional level to the PDC that was located at National Load Despatch Centre (NLDC), New Delhi. This PDC in New Delhi receives data from around 604 PMUs for real-time event analysis and monitoring. Also, some vendors have installed PMUs apart from the ongoing pilot projects, but these PMUs also report to the NLDC (Agrawal et al. 2011a).

By using the data from these pilot projects, monitoring classification, analysis and detection of fault, mitigation of low-frequency oscillations, synchronization, dynamic model validation, coherence group detection, islanding detection, and PSS tuning are accomplished. Gleaned from the positive insights from these WAMS pilot projects, a synchrophasor project, known as URTDSM, was envisaged and implemented in the Indian Power System in 2012 (Agarwal 2012; Agrawal et al. 2010, 2011b; Unified Real Time Dynamic Measurement System 2012; Zuhaib and Rihan 2017; Soonee et al. 2015). In URTDSM project, installation and commissioning of around 1669 PMUs across pan-India has been done. This project is put into effect in a phased manner. The PMUs that were installed earlier in the pilot projects are also integrated into URTDSM project. The PDCs that lie in the state control centers are integrated to the regional PDCs, and these are integrated to the national PDC, also known as super PDC. The URTDSM (WAMS project) covers 34 state, 5 regional and 1 national control center along with backup. The URTDSM project is providing the required wide area situational awareness to the operators. However, in order to improve the system and utilize the data properly, some improvements in the system are sought. Based on the operational experience of the existing system, Power System Operation Corporation Limited (POSOCO) has suggested some improvements for proper functioning of URTDSM project in 2021 (Power System Operation Corporation Limited 2021). This includes the improvement in the graphical user interface (GUI) or visualization of the data in real time. The phase voltage should be displayed in real time in order to identify the fault in the phase and understand the issue in real time.

Along with this, a single user interface should be used in which the operator can visualize the real-time data and can compare it with the historical data. Also, the window size to picture the real-time data should be increased. In some locations the need is felt to increase the range of monitored frequencies for which high sampling rate of PMUs is required. Also, the PDC's capability should be increased to store data of high sample rates. In the current scenario, the PDCs can store data of 25 Hz

only. In addition to this other improvements which are sought in the existing system are challenges related to interoperability aspect of PMUs of different manufacturers, development of logic based analytical tools to enhance situational awareness, non-generation of alarms failing to detect oscillations which are present in the system, high noise in PMU, which results in bad data analytics, loss of confidence in system and poor performance, frequent issues related to time synchronization and low of pulse per second (PPS) signal. Besides these challenges, some future requirements of the PMU project are analytics for this big data system to full potential of the system, techniques to store and compress historian data with minimal loss, secure and reliable communication infrastructure, event detection tool, development of real-time analytical applications, online inertia assessment, voltage stability monitoring, and automatic islanding detection (Power System Operation Corporation Limited 2021).

Phasor Measurement Unit

The PMU is a device that monitors and captures information at high rate and time-stamps each input to a common time reference (Khatkar et al. 2022a). The principal role of PMU is elucidated in Fig. 3 (Khatkar et al. 2022a). The main components of PMU are:

- Analog inputs: The current or potential transformers that are installed at sub-stations deliver the measured current and voltage values. The secondary windings of these transformers are connected as the analog input to the PMU.
- Anti-aliasing filters: These are low-pass analog filters that filter out the components having greater frequencies from the input signal to ease out phasor estimation.
- Global Positioning System (GPS): GPS offers very accurate time synchronization signal. It utilizes high-accuracy clock from the satellite to deliver synchronized time at diverse positions of the grid.

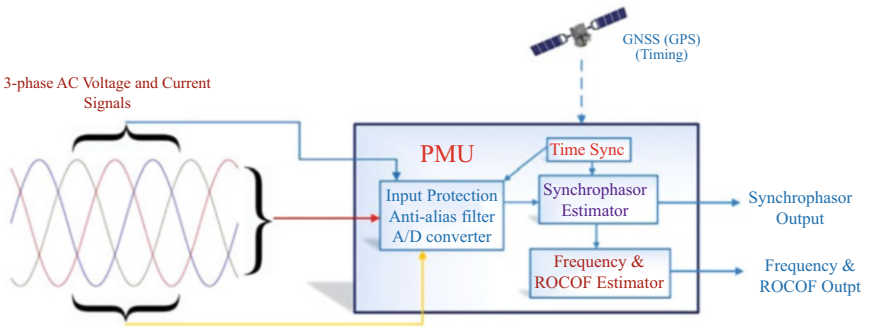

Fig. 3 Phasor measurement unit

- Phase-locked oscillator: This oscillator and GPS reference source delivers a high-speed synchronized sampling.
- Analog to digital converter (ADC): The ADC converts a continuous time and amplitude analog signal into a discrete time and amplitude signal. The sampling rate of converter is the rate at which new digital values are sampled from the analog signal.
- Microprocessor: The microprocessor calculates positive frequency values of all the current and voltage signals using the discrete Fourier transform (DFT) techniques.
- Modem (modulator-demodulator): It is the device that is used to modulate the analog signal in order to encode the digital information and again demodulate this signal to decode the transmitted information from signal.

PMUs are gaining importance in the twenty-first century, as these are the synchronized devices used for magnitude and phase angle estimation (Adamiak et al. 2005). These provide situational awareness of real-time measurements to the grid operator. Thus, PMUs have a key role in the expansion of the grid along with keeping a track of the health of the grid. A large number of PMUs are being optimally placed in the power grid to monitor real-time conditions. For real-time measurements from the PMU, the time synchronization of these devices is crucial. This is done through the global positioning system (GPS), and all the devices are synchronized to the Coordinated Universal Time (UTC) (Stenbakken and Zhou 2007; Stenbakken and Nelson 2007; Tang and Stenbakken 2012).

Time Synchronization in PMU

PMUs of different vendors have electronic clocks that sometimes provide inaccurate time. The various reasons that may be accounted for this inaccuracy are the manufacturing defects, oscillator aging, interference of electric and magnetic fields, or temperature changes. These inaccuracies are at times due to random variations in clock or can also be systematic due to uncalibrated clock. In timekeeping, even the smallest fraction of errors are critical as they significantly add up in due course. So, accurate time reference plays an important role in correct functioning of PMU. The reference of the time is from the instant when the samples of voltages and currents at nodes are taken. The samples are either synchronized directly to the timing reference, i.e., 1 PPS signal, or through software by post-processing. Accurate and precise synchronization of the sampling pulses is essential to accomplish a common timing reference and is achieved either by internal or external synchronization source deployed with the PMU. In the case of internal, the synchronization source is built-in, i.e., integrated with PMUs, while, in external, the timing signals are provided by external source (local or global) to the PMU. In both cases the timing signal is referenced to UTC throughout the grid without any interruption. The various synchronizing sources, which are used to synchronize PMUs, are IRIG-B, 1 PPS, and high-precision format time code. The IRIG-B format has a total of 100 bits per second, and it repeats every second. This time code is described in IRIG Standard 200-04 (Inter-range instrumentation group time codes n.d.). These bits contain

framing (sync) bits, time assignment bits, and control function bits. IRIG-B code is used in unmodulated or amplitude-modulated format with 1 kHz carrier (Dickerson 2007). The accuracy of unmodulated format is limited by slew rate of the digital signal and is more than 1 microsecond, whereas the accuracy of modulated IRIG signal exceeds 1 millisecond (one period of 1 kHz) but is generally not more than 10 microseconds. The 1 PPS synchronization signal is a one pulse per second positive pulse. The rising edge of the pulse is on time, and the second change of the pulse is responsible for precise time synchronization (IEEE Standard C37.118-2005 2006). However, as all the pulses are identical and it is not possible to ascertain which second a pulse is associated with, 1 PPS signal always has a 1-second uncertainty, which is resolved by making use of a data channel simultaneously. The IEEE Standard 1588 (IEEE 2020) describes the high-precision time code format. By using a standard connection, it delivers hardware-level accuracy of time. By using this time format and using a dedicated timing hardware for each port, timing accuracy comparable to IRIG-B or 1 PPS signal is achieved.

The IEEE Synchrophasor Standard

With the development of PMUs, a need for a standard was felt, which can be followed throughout the globe for accurate and comparable measurement results. An IEEE working group (WG) was formed in 1992 to articulate a standard to ensure compatible results of PMUs globally, and the first standard IEEE 1344-1995 (1995) for synchrophasor was developed. This standard has details only about the signal samples, communication protocol, and timing signal, but accuracy requirements were not clearly indicated. The WG in 1999 started revising this standard and published the revision as IEEE C37.118-2005 (2006). This standard transformed the communication protocol and included time stamp to UTC, and in order to assess the phasor measurement requirements, the concept of total vector error (TVE) was included with levels 0 and 1 as compliance levels to assess the measurement accuracy. The main flaws of the standard was that only steady-state operating conditions were included and dynamic operating conditions were not incorporated. In 2008, drafting of new standard was initiated, which contained dynamic conditions, and other imperfections of the existing standard were rectified in the revision. The International Electrotechnical Commission (IEC) also considered to develop a synchrophasor standard. So, in 2011, the IEEE C37.118-2005 standard was bifurcated into two standards, one for measurements, i.e., IEEE C37.118.1 (2011), and one for communication aspects, i.e., IEEE C37.118.2 (2011) standard. In measurement standard, measurement (M class) and performance classes (P class) were added for compliance testing, and it updated the synchrophasor definitions and formulas. In this, the steady-state performance compliance requirements were polished, and for dynamic performance tests further specifications were added. The IEEE C37.118.1a2014, a revision to the 2011 standard (IEEE Standard C37.118.1a-2014 2014), was published in 2014. The currently existing standard IEC/IEEE 60255-118-

1 (2018) jointly prepared by IEC/IEEE working group (WG) replaced the C37.118.1 and its amendment and was available in December 2018.

PMU Calibration System

In today's rapidly developing world, as we move to the smart grid concept, it is important to calibrate PMUs for phase and amplitude and seriously assert that the multi-vendor PMUs in the Indian grid comply with IEEE standards. The PMU calibration system (PMU-CAL) is an important tool to help PMU manufacturers verify that their PMUs comply with IEEE standards (Svensson et al. 2018). The calibration system helps to ensure the reliability of the PMU by validating the outputs of the PMU (Acanski et al. 2016). The system provides the ability to validate the performance of PMUs before deploying them in the field and periodically calibrate the PMUs, thus ensuring quality and reliability (Tang et al. 2013; Pirret 2012). Conventional PMU calibrators are complex and time-consuming and require skilled professional operators to operate them manually. Performance depends on operator expertise handling complex measurement setups, which ultimately makes the process costly and time-consuming. Calibrating the PMU in manual mode usually takes 2–6 weeks. In addition, to ensure accuracy and reliability, the calibrator must be traceable to the primary standards. The recommended uncertainty for the PMU calibrator is less than 10% of the limits provided in the IEEE standard. PMU manual calibration systems sometimes fail to meet these stringent accuracy requirements due to the potential for human error and also require high test processing times. The automatic PMU calibration system overcomes these limitations of manual methods. Therefore, for consistent, fast, authentic, and traceable PMU calibration, these manual techniques are replaced by automated PMU calibration systems (Ahmad et al. 2021). This calibration system can be used easily, even by someone who is not an expert in the field, producing complete and accurate test results in hours instead of weeks in the case of manual tests.

CSIR-NPL PMU-CAL System

The PMU-CAL system illustrated in Fig. 4 is located at CSIR-NPL, New Delhi, India. The built-in PMU calibration system conforms to IEC/IEEE 60255-118-1: 2018 and C37.242-2021 (2021) to perform testing as well as the certification process. The CSIR-NPL PMU calibrator is an integrated and fully automated system; therefore, even amateur users can operate the system and perform tests on the PMU. The system can perform more than 300–500 automated tests (including steady-state, dynamic, and latency tests) over a period of 6–7 hours for different frame rates and measurement and protection class conforming to IEC/IEEE 60255-118-1: 2018 standard. The calibrator's power supply system consists of three power supply standards, one for each phase and are connected together in a server rack. The power supply system is connected to the timer controller and the host PC. The GPS

Fig. 4 CSIR-NPL PMU-CAL system

receiver provides the time source for the system and the PMU that is being tested (6135A/PMU Operators Manual 2020). This time is used by the PMU to mark the time for each report made by the Device Under Calibration (DUT). The client personal computer is connected to the server and operates the calibration system. The server controls the calibration system by receiving information from the client's PC. The PMU calibrator can simulate static and dynamic conditions, close to what the PMU experiences in the power grid, and test the PMU against the performance standards written in IEEE C37.118.1a-2014, IEEE C37.118.2, and IEC 60255-118-1:2018. The PMU-CAL system is more than ten times accurate than the PMU test limits described in the standard. The PMU's calibration system can generate the required voltage and current signals under conditions similar to those of the electrical

network in the grid. Figure 3 illustrates the calibration setup to evaluate the PMU (Khatkar et al. 2022a).

Traceability of PMU-CAL System

CSIR-NPL, as a National Metrology Institute (NMI), is responsible for verifying, maintaining, and improving the country's primary standards. Figure 5 shows the traceability of the PMU-CAL system that has been established from CSIR-NPL national standards. The PMU-CAL system is traceable to national standards (programmable Josephson voltage standard (PJVS) for DC voltage, quantum Hall

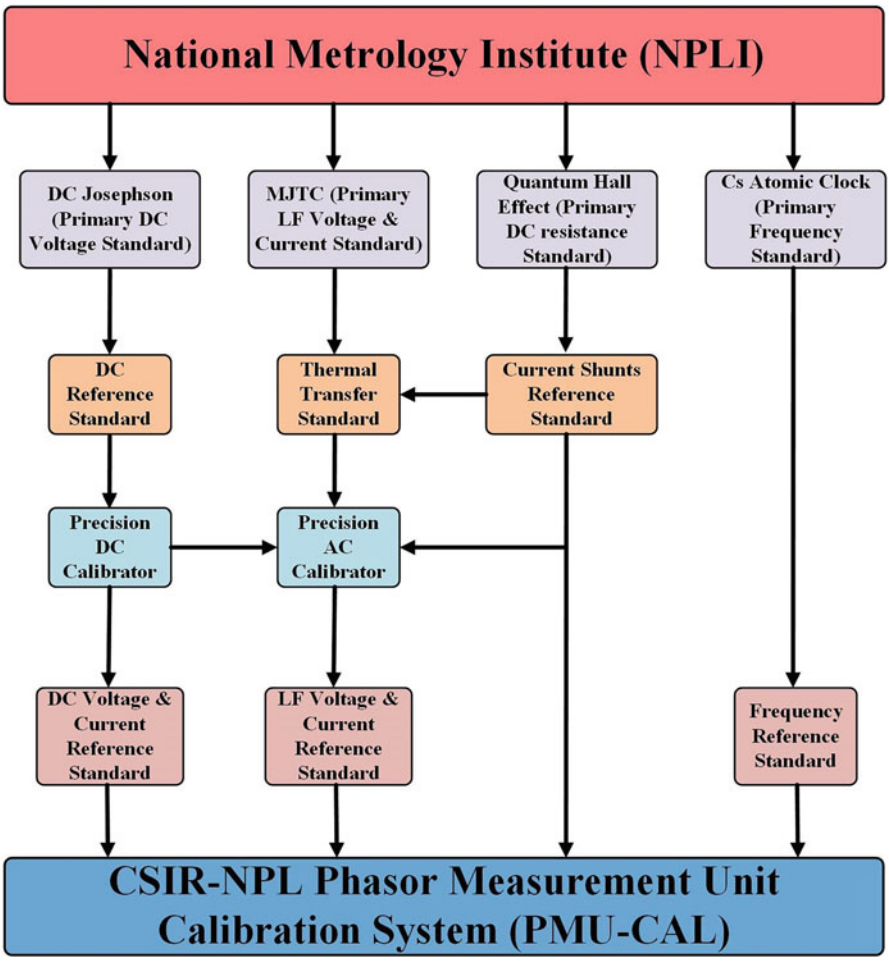

Fig. 5 Traceability of the PMU-CAL system

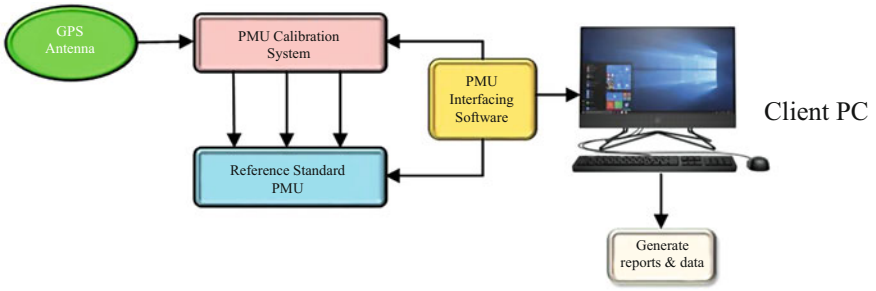

Fig. 6 Calibration setup of PMU-CAL system

resistance (QHR) for DC resistance, multi-junction thermal converter (MJTC) for low-frequency voltage and current, and cesium atomic clocks for frequency) (Ahmad et al. 2021). These primary standards are used periodically to properly calibrate the CSIR-NPL PMU calibration with measurement uncertainties ranging from ±50 ppm to ±100 ppm (Khatkar et al. 2022a). The PMU-CAL system traceability for SI units ensures that the PMU measurements are consistently stable and compliant with IEEE synchronization standards, thus avoiding ambiguous, potentially misleading data, which can impede the security of the national electricity grid and lead to financial loss for the country (Fig. 6).

Synchrophasor Calibration

During calibration, the PMU can be configured for a nominal frequency of 50 Hz or 60 Hz, and for the PMU to generate synchrophasors, it must have a built-in or external device for time synchronization with UTC. Alternatively, the PMU can be tested as a measurement (M class) or protection (P class) device (Khatkar et al. 2022b; Qiu et al. 2022; Barros et al. 2017) as per the latest IEC/IEEE standard 60255-118-1 (2018). Compliance testing (steady-state, dynamic, and latency testing) is performed according to the IEEE Guide for Synchronization, Calibration, Testing, and Installation of PMUs (IEEE C37.242-2021 2021). The performance evaluation criteria as per IEC/IEEE 60255-118-1 is used to perform reliability studies presented in the chapter. Figure 7 depicts test results after configuring the PMU as a measuring device for offline monitoring and post-event analysis. The M class test results for 63 V, 1 A, 50 Hz, and 50 frames per second are shown in Table 4. All the reported values of total vector error (TVE), magnitude error (ME), phase error (PE), frequency error (FE), and rate of change of frequency error (RFE) are highly stable and are well within the range as per IEC/IEEE 60255-118-1:2018 as shown in Table 4. The maximum measurement reporting latency reported is 109.651 ms, while the limit as per the standard is 140 ms. The minimum reporting latency is 108.359 ms, and the standard deviation is 0.090145 ms.

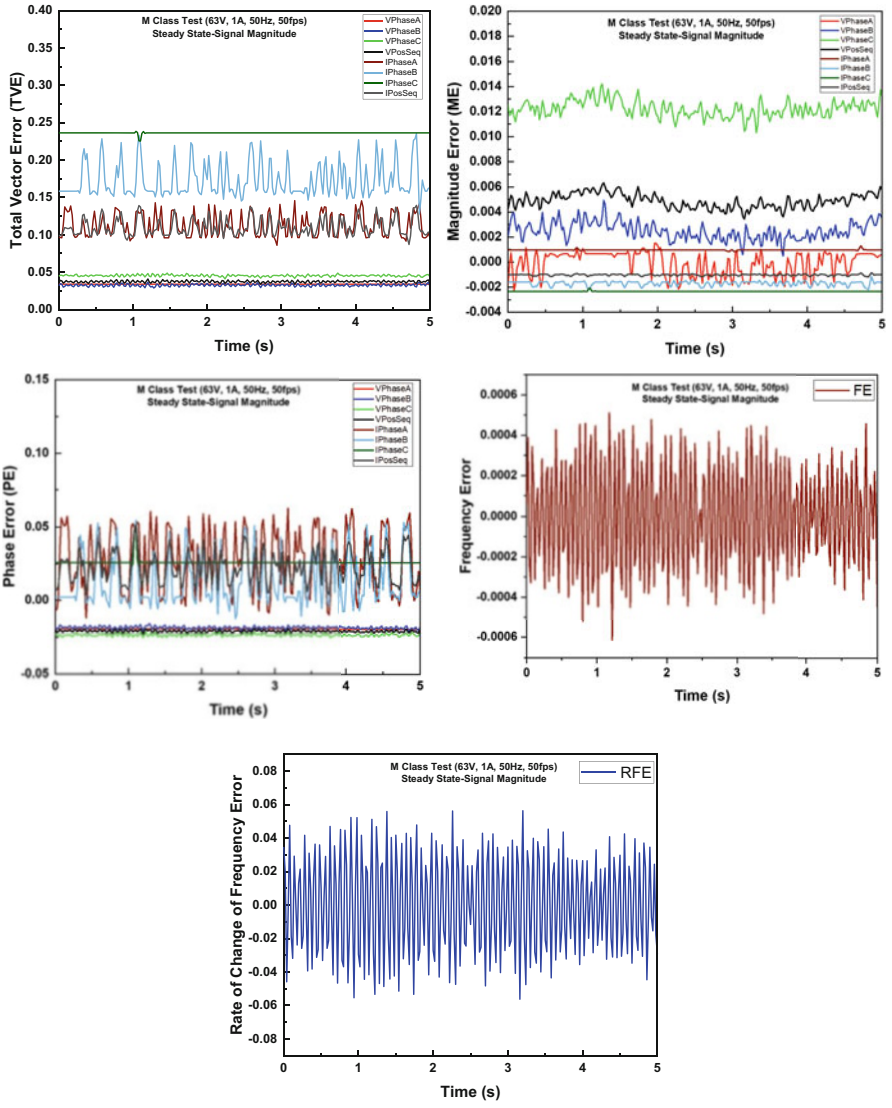

Fig. 7 Results of M class test at 63 V, 1A, and 50 frames per second

Automation and Load Management of Power Grid

Automation and load management of the power grid is a subset of WAMS to proactively identify and isolate stressed areas of the grid in real time, automate load management and load shedding functions, and integrate and implement tele-protection functions in order to maintain the efficiency, health, and stability of the

national power grid at all times (Ivankovic et al. 2017). Each PMU provides phasor status, frequency and frequency offset, frequency change rate, phase angles and relative phase shifts, and configuration information at very high data rates according to the IEEE standard. This data can be effectively used for automation and load management of the power grid to implement grid stabilization, grid automation, and automated load management to realize a (intelligent) national power grid. This would automatically identify and isolate the problem areas that are overloading the grid so that the problem in any one sector of the unified national grid does not threaten or collapse the complete national power grid. This would comprise PMUs operating in M class mode providing data at 50 frames per second, user configurable interface, and implementation and integration of teleprotection functions to initiate automated trip commands. To achieve this, the IEEE 37.118 PMU data from the multiple PMUs shall be fed to the server to monitor the phase shifts and phase angles at various points to automatically identify, isolate, and island the problem areas by disconnecting the offending areas from the national power grid, thereby ensuring the stability of the national power grid. In order to realize reliable functioning, it is extremely essential that the IEEE C37.118 data from all PMUs be time-stamped to a 1PPS source that is calibrated to a national reference and with an accuracy of better than ± 1 microsecond to accurately account for any phase shifts and phase angle deviations occurring within the power grid and take remedial actions to protect it. Accurate monitoring of phase angles and their deviations/phase shifts across the entire power grid using the IEEE 37.118 PMU data can be effectively used with modern IEEE 61850 protection protocols, such as GOOSE, to effectively implement

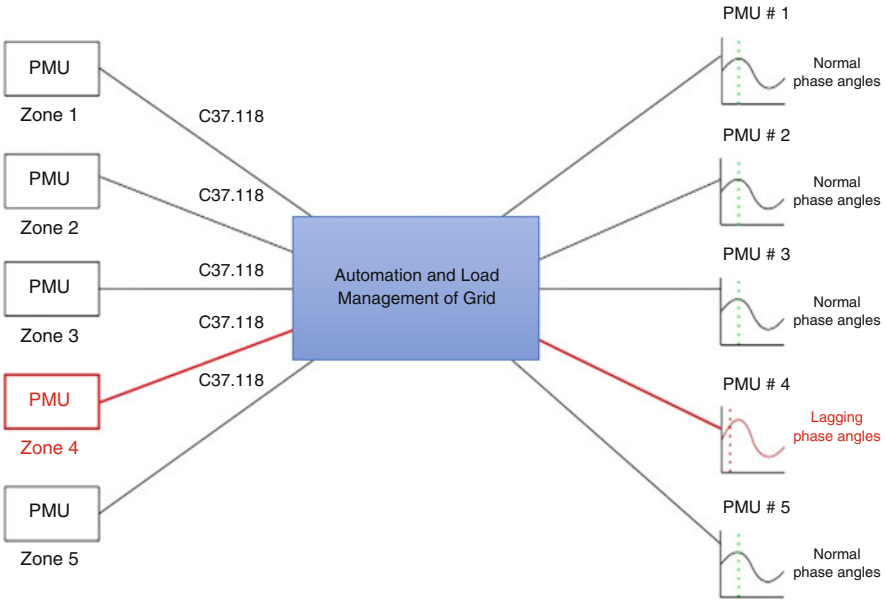

Fig. 8 Typical application of automation and load management of grid

and automate load management functions. GOOSE was primarily designed for layer 2 networks and designed to work within the substations. But GOOSE messages, using teleprotection protocols, can be extended beyond the boundary and the confines of the substation network over encapsulated IP packets, C37.94 optical links, and E1 channels to trip protection relays in remote locations to effectively manage the stability of the power grid and to isolate the problem areas that are excessively loading the grid, which were resulting in phase angle changes/deviation in the phase angles/phase shifts that are beyond the grid operator's mandated limits. A block diagram, illustrating a typical automation and load management system, is provided in Fig. 8. In this, IEEE C37.118 data is received from multiple PMUs across various zones. The system analyzes time-stamped data it receives from various PMUs, and if the phase angle variation of any one zone exceeds the user prescribed threshold, it automatically generates warning messages, alarms, and trip commands to the protection relays to disconnect and isolate the offending zone from the main power grid to ensure that it remains healthy and stable.

Conclusion

PMUs are widely deployed in the power grid for real-time monitoring of the static and dynamic performance of the smart grid. The operators at power grid rely exclusively on PMU data for power grid protection and analysis, so it becomes essential to evaluate the performance of the PMU before deploying it in the network. PMUs deployed without any operational and viable software that can be effectively used for an automated load management and grid stabilization application will not serve the purpose of transforming the national grid into a smart grid. All power grid PMUs must be integrated with automation and load management system to automatically identify hotspots and isolate stressed areas of the line using real-time analysis and actively help maintain the efficiency, health, and stability of the national electricity grid. The load management system will automatically manage the load of distribution line and load shedding functions and will actively assist in maintaining the efficiency, health, and stability of the national power grid, which are essential to transform and augment the power sector into a responsive, stable, and secure system.

Abstract

The use of artificial intelligence in metrology became inevitable after declaring the theme of Metrology in the Digital Era on the World Metrology Day 2022. Consequently, the 27th meeting of the General Conference on Weights and Measures (CGPM) has considered the digital transformation to collect, aggregate, analyze, and interpret the networked sensor data that would be acquired during metrology applications (Draft Resolutions of the General Conference on Weights and Measures 2022). It emphasizes the secured data sharing at the international apex down to a local level at various stakeholders (i.e., governments, industry,

academia, and civil society). Digitizing the International System of Units (SI) provides confidence in the accuracy and global comparability of measurements. CGPM also drafted a resolution to adopt the FAIR (Findable, Accessible, Interoperable, and Reusable) principle to develop and promote an SI Digital Framework. The framework covers (1) digital representation of the SI – dissemination of SI standards – exchange of metadata; (2) digital data exchange standards and protocols, digital certificates; and (3) digital twins to simulate the measurement process (Proceedings of the 26th meeting of the General Conference on Weights and Measures (CGPM) 2018; International Committee for Weights and Measures (CIPM) 2021). Turing's legacy in computing is far from leaping from the equations to the phenomena, from calculation to modeling (Machinery, Computing 1950). Turing is the first to think of competing humans with computer intelligence.

Introduction

Traditionally, researchers fit the data points extracted from a surface to a known geometrical shape. Digital representations of the surface of geometric object used coordinate measuring machines. Computerization is important to estimate the accuracy of fitting the measured coordinate cloud. The tolerances required in the design process and the accuracy of the fitted model parameters are both needed to accept the built model. Often, the geometric fitting problem is a nonlinear minimization problem to be solved through iteration and has been widely recognized as an analytically and computationally difficult problem.

In contrast, present-day metrology applications demand next level of intervention of the computer simulation (Arif Sanjid 2021). Recent arena of the additive manufacturing, X-ray tomography, and super-resolution microscopy adopt the framework of simulation techniques from bioinformatics (Shu et al. 2021). Especially, dimensional metrology that determines the shape of objects with nanometer accuracy is quickly emerging into computer-aided simulations of experimentation (Zhao et al. 2020). Unlike earlier, metrologist aims to demarcate the computational methods to simulate measurements, propagation of uncertainty, and optimization of experimentations (Boudjemaa et al. 2003). Simulation-aided measurement originates from the matured field of metrology, statistics, probability, and evolving computer applications.

Dimensional Metrology

Engineers design new products with improvements to meet the functional requirements of consumers. The art of creating the novel designs and new routes of production needs critical understanding and the knowledge of the dimensional metrology. Dimensional metrology stretches from defining the geometric product

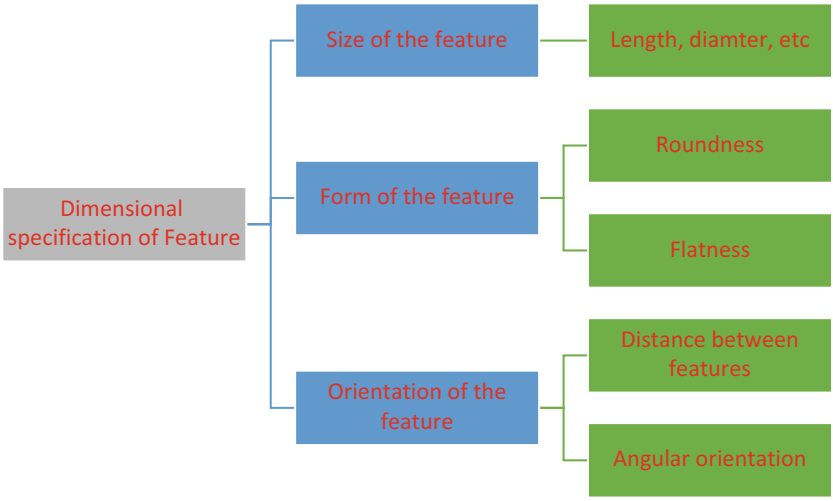

Fig. 1 Dimensional parameters of products

specifications, producing the parts according to design tolerances and the quality assurance of processes and products. Therefore, the digital transformation of dimensional metrology encompasses aspects of measurement of dimensional parameters, their standard measuring methods, and machines to supplement these requirements (Leach et al. 2020). Figure 1 depicts a simple classification of the geometric features referring to the dimensional measurements.

The basic dimensioning starts by identifying various features (e.g., line, point, surface, circle and cylinder, etc.), specifying their size (i.e., linear parameters – radius, length, and pitch). Moreover, the location, the orientation, and the form of features are also essential to achieve the desired functionality of mechanical parts. The geometric parameters are broadly into six groups. They are (1) radiations of Mise en Pratique – Matter of Practice, (2) linear dimensions, (3) orientation or angular parameters, (4) form of the surfaces, (5) complex measurands, and (6) basic instruments. Figure 2 shows the chart of linear dimension artifacts. The remaining five categories can also be branched as depicted in Fig. 2. The artifacts realize the length in desirable form according to the application. For example, the geodesic lengths are measured using a woollen tape or displacement measuring electronic devices. Over the above, the quantum phenomena based standard optical radiations realizes the SI definition of length. Therefrom, the optical radiation shines the end standards (i.e., gauge block) in an interferometer to disseminate the traceability down to basic working instruments, viz., micrometer, vernier caliper, dial gauge, etc. (Flack and Hannaford 2006).

It is apparent from the chart of linear measurements that the artificial intelligence is likely useful. Also, the AI algorithms are based on heuristic strategy; hence they tend to be less accurate. On the contrary, the traditional and standardized dimensional measuring methods are sufficiently suitable for the accurate mathematic

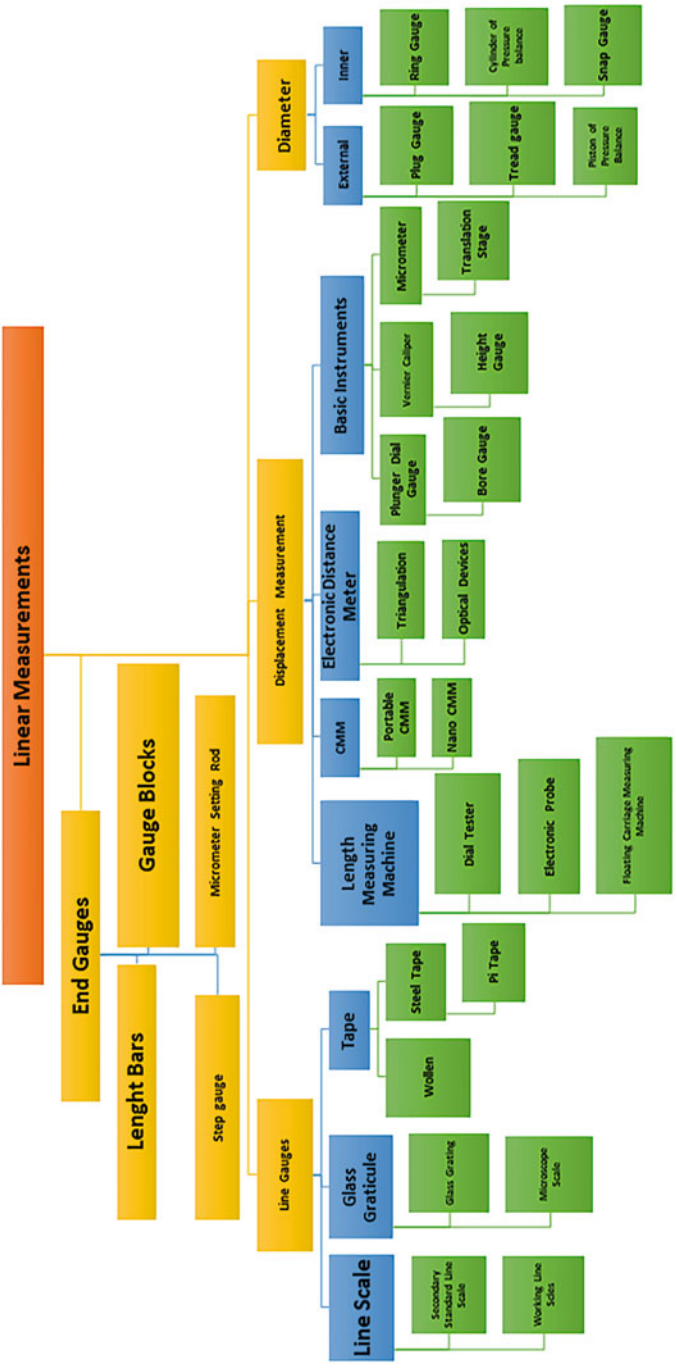

Fig. 2 Linear measurement and associated standard artifact standards

analysis of the observation/ readings. Nevertheless, the diameter measurements insist the optimization of the peak detection of cylindrical curvature. Recently, simulation methods are employed to rectify the misalignment and peak detection for the measurement of the inner as well as the external diameter measurements (Sanjid et al. 2018). Some worker used genetic algorithm to reduce the eccentricity during roundness measurement of flick standard and the algorithm is registered under a copyright (Arif Sanjid and Chaudhary 2013). Another AI algorithm that is the swarm particle optimization is workout to estimate flatness and straightness measurement (Wang et al. 2012).

Present scenario of digitizing the International System of Units (SI) and the FAIR Framework will need the new computational algorithm to generate metadata and simulate the digital twins. Consequent automation of measurement method invariantly seeks the AI methods. A brief background of AI is discussed in the next section. Subsequently, the prospects of using AI in dimensional metrology are envisaged.

Artificial Intelligence

AI techniques enable computers to mimic human behavior; more specifically, they are inspired by the biological intelligence. Some of the well-established AI techniques such as (1) neural networks, (2) self-organizing maps, (3) growing cell structures, (4) evolutionary algorithms, (5) cellular automata, (6) expert systems, (7) fuzzy logic, (8) simulated annealing, etc. are discussed here. Traditionally, machine learning algorithms define a set of features in their data. These features are handcrafted. Machine learning algorithms process data in order to achieve the tasks as shown in Fig. 2. Different algorithms, viz., support vector machine, naïve Bayes classifier, linear regression, K-mean, hierarchical clustering, Apriori, the principal component analysis, Q-Learning, etc., are the example. The list is growing with the advances in research (Fig. 3).

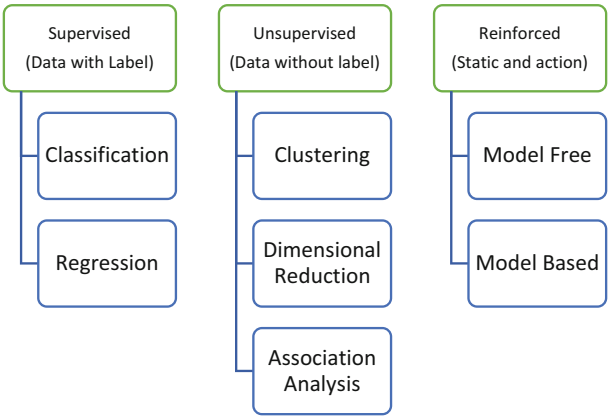

Fig. 3 A task-based classification of machine learning algorithms

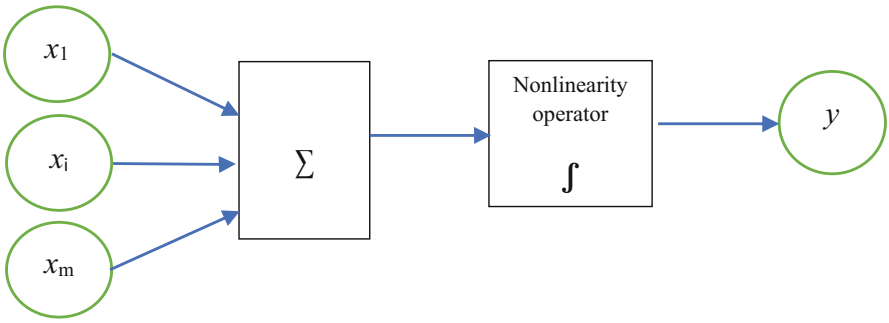

Fig. 4 An AI neuron

Neural Networks

The preceptor propagates the weighted stimuli after summing through a nonlinear threshold to result a response. Thus, the preceptor adopts the behavior of biological neuron. The weights are adjusted (mathematically) according to training data set using back propagation algorithm. The training data set is a map of input to responds of the given physical system, which has to be simulated. Figure 4 depicts a basis neuron cell.

$$y = g\left(\sum_{i=1}^{m} w_i x_i\right) + b_0 \tag{1}$$

y: Output of AI neuron
$g()$: Nonlinear function/threshold
w_i: Weight of the input x_i
x_i: The ith inputs up to m
b_0: Bias if any

Iterative tuning of weights finds the local minimum of the objective function of given application. Setting the learning rate dictate the accuracy vs. speed of handles large data. Adoptive learning rate optimize between the small learning rate – slow convergence – and large rate, where overshoot occurs. The application of neural network (NN) is effective, when there is no need of feasible/reasonable to assign a mathematical model (Chandrasekaran et al. 2021). However, the NN enables to establish a new model for perfectly known or using measured data with a sufficiently less uncertain.

Self-Organizing Maps

When metrologists attempt to compare a given type measuring apparatus, it might need to arrange them into a group by distinguishing their differences as well as

correlating their functionalities. The self-organizing map (SOM) identifies similar objects set and cluster them together so that the similarities appear. Thus, the measuring machines or their results can be visualized according to their multiple attributes. The SOM performs clustering by estimating how far the points are, and it reveals them by projecting onto two-dimensional space (i.e., reduce the high dimensions into lower dimensional scale). SOM is more democratic – every node occupies a site of equal importance in regular lattice of dimensions. Unlike NN, the links in SOM are inactive, and the vector of weights at each node provides the memory. The learning of SOM is unsupervised and predicts the pattern of characteristics of objects. A numerical measure of the quality of the clustering use the Euclidian distance between the vectors of characteristics. A neighborhood is chosen by assigning a cut-off distance. The drawback of SOM is that the learning time increases with the quantum of data and the overestimation issue arises during the splitting of clustering. The SOP is useful for classification, associating, and projection – reducing dimensionality and modelling (Cartwright 2008).

Genetic Algorithm

Genetic algorithms (GAs) are heuristic search and stochastic optimization that imitate the natural selection and biological evolutionary process. GA combines the notion of survival of the fittest, random, and yet structured search. In such situation, relatively high fitness structures have a larger chance to survive and to produce higher fitness offspring. This evolutionary process can be applied to the real-world problems where heuristic solutions generally lead to unsatisfactory results (Mikó et al. 2021).

GA starts with an initial set of random solutions called a *population*. Each individual in the population is called a *chromosome*, representing a solution to the solved problem. A chromosome is usually a binary bit string. The chromosomes evolve through successive iteration, called *generations*. During each generation, the chromosomes are *evaluated*, using some measures of *fitness*. To create the next generation, new chromosomes, called *offspring*, are formed by either (1) mating two chromosomes from the current generation or (2) modifying a chromosome using a *mutation* operator. A new generation is formed by (1) selecting best parents and offspring based on fitness values and (2) rejecting others so as to keep the population size constant. Fitter chromosomes have higher probabilities of being selected. Figure 5 depicts the algorithm of generic algorithm.

There are three basic genetic operators including selection, crossover, and mutation, used to generate new chromosomes (solutions) from generation to generation. Selection is a biased reproduction process to determine which chromosomes will be reproduced in the new population. Chromosomes with higher fitness values (better solutions) have larger chances of being selected for reproduction. The crossover operator is the mating operator that allows production of new chromosomes through partial information exchange between pairs of chromosomes. The mutation operator significantly changes the structure of a chromosome and hence produces albinos.

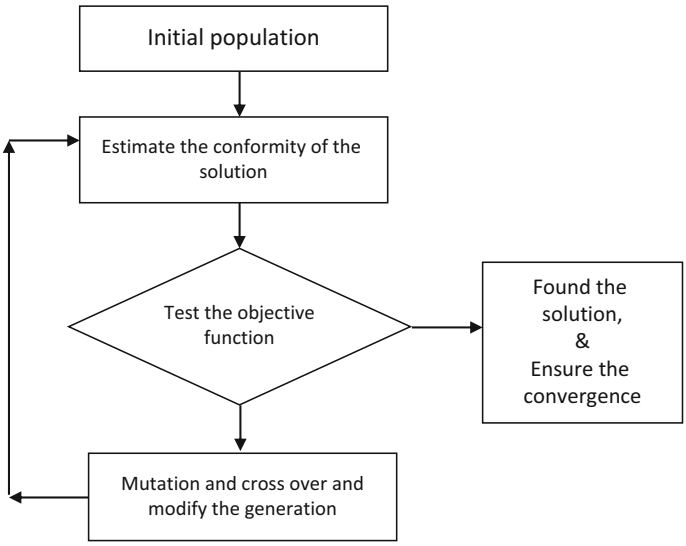

Fig. 5 Flowchart of basic genetic algorithm

Mutation serves as a guaranteed procedure to prevent solutions from being trapped in local optima. GAs are useful where the search space is large, nonlinear, and noisy.

Several characteristics of GAs suggest that they may have advantages relative to alternative heuristic solution algorithms for optimization problems. They are (1) dealing with coded parameter set, not the parameters themselves; (2) simultaneous search from a population; (3) use of objective information; and (4) use of stochastic rather than deterministic transition rule in the search process.

The fitness function is of importance for the GA to optimize a complicated problem, and it is a bridge between the optimization algorithm and the problem to be solved. The fitness function is expressed in terms of the factors affecting the optimization object.

Cellular Automata

In many dimensional metrology applications, the tactile probing system acquires temporal or spatial data. The process of moving the probe to the desirable location in coordinate measuring machine is solved using a set of differential equations. When attempted to assess the re-entrant type of surfaces, a simple analytical solution cannot be found. Then, it is necessary to apply numerical integration. In cellular automata, discrete approximation is used in many small cells to circumvent the use of differential equations. A limited number of variables are assigned to each cell change according to a set of rules. CA do not learn but offer to evolve the solution.

The cells of CA follow transition rule to update their states in each recursion/iteration. Transition rules define how the state of cell is renewed by using the current state of cell and its neighbor cell (Cartwright 2008).

Expert Systems

Expert system focuses on a single specific field unlike general-purpose problem-solving machines. It complements the human knowledge with its reasoning ability to deduce the solution from the given data. ES poses two components (1) a database relevant to the field of application and (2) the rules that set the context of the problem and method of manipulating the supplied data to it (Cartwright 2008).

Bee Colony Algorithm

CMM is suitable for flatness deviation measurement, when surfaces are of small diameters. Work is carried out using particle swarm optimization (PSO) algorithm to serve the nano scale micro/nano surface flatness error evaluation by a minimum zone method (Lei et al. 2014). There are many types of swarms, and the kind of intelligence they use varies from swarm to swarm. Their self-organization feature comes from the collective behavior by means of intuitive interactions among the simple agents. The self-organization in swarms has four characteristics:

(i) *Positive feedback*: promoting the formation of opportunity structures by recruitment and reinforcement.
(ii) *Negative feedback*: the act of countering the positive feedback and helping to stabilize the collective pattern. A negative feedback mechanism avoids the saturation.
(iii) *Fluctuations*: Randomness is significant for emerging the structures and the discovery of new solutions.
(iv) *Multiple interactions*: Agents in the swarm use the information among them to spread trigger throughout the network.

Bee colony algorithm is developed by Karaboga in 2005 that mimics the bees searching for honey (Karaboga et al. 2014). The optimization algorithms are usually divided into three kinds of bees: employment, observation, and reconnaissance. For the traditional artificial bee colony algorithm, in the last stage of iteration calculation, the employed bees will search the nectar, thereby increasing the post calculation workload. It affects the speed of search for the optimal solution with tabu strategy. Thus, bees do not search the local optimal solution again. Tabu strategies refer to form tabu list to search the local optimal solution and, at the same time, mark them so that you can avoid to search this local optimal solution late again (Ge et al. 2015).

Fuzzy Logic

The "fuzzy" word means the things that are not clear or are vague. This concept provides the possibilities which are not given by computers but are similar to the range of possibilities generated by humans. Rule base is a component used for storing the set of rules, and the if-then conditions given by the experts are used for controlling the decision-making systems (Cartwright 2008).

Let there be five measurements of a given geometric parameter of a product. The horizontal line represents the tolerance limit/reference value/conventional true value. The vertical error bars correspond to expanded measurement uncertainty. Figure 6 graphically represent the different cases of measurements.

The conformity decision would be taken as per the decision rule stipulated by the laboratory. A formal agreement with a customer or authentic approval from the regulator may be considered for each test to decide upon the decision rule. It is all about how do you pass or reject the product under test after accounting for the measurement uncertainty. Table 1 gives an example of the compliance decision taken by a lab and the associated risk. While zero (unity) represents the false (true), respectively, the fuzzy logic deals with the real number between zero and unity. In other words, it can be employed where it handles the concept of partial truth to be

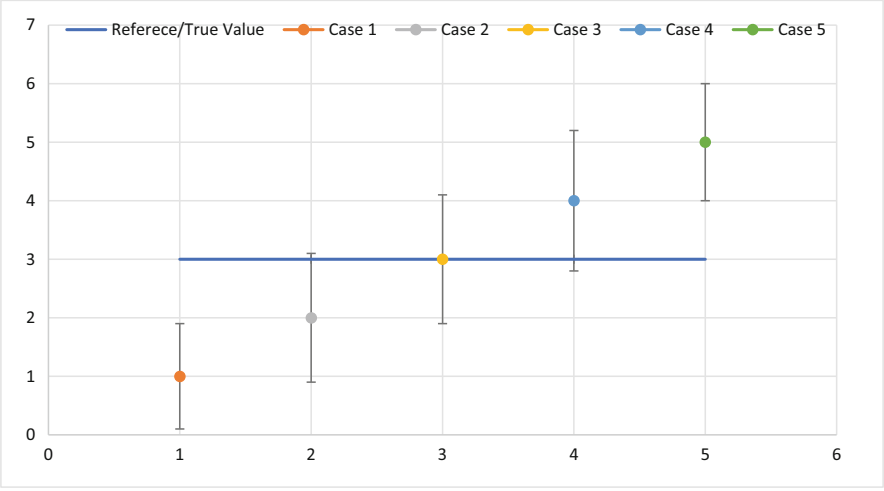

Fig. 6 Plot of measurement result with the uncertainty of measurement

Table 1 The decision taken and associated risk

	Compliance decision	Risk of decision
Case 1	Pass	No risk
Case 2	Pass	Low
Case 3	Pass/fail	High
Case 4	Reject	Moderate
Case 5	Reject	Low

dealt with. The truth value may range between completely true and completely false. In Table 1, case 3 is the partial truth. A fuzzy interface system uses the uncertainty of measurement as a knowledge base (rule set) and nonlinear fuzzy logic to map the partial truth to convincing results. Moreover, the result of a tested product must be in conformity with the specification. The decision rule is a policy matter of the metrology laboratory that dictates the risk analysis.

ILAC-G8:09/2019 provides overall guidance on how to select appropriate decision rules and compile the required elements of a decision rule (ILAC-G8 2019). A decision rule and risk associated with the decision for five measurement cases are discussed.

Simulated Annealing

In metallurgy, annealing of metal involves a process of slowly cooling to reach a state of low energy. Simulated annealing (SA) is devised for optimization analogous to thermal annealing. The thermodynamics temperature corresponds to the randomness. The temperature is reduced slowly, starting from a random search at high temperature eventually converging to greedy descent as it approaches zero temperature (Nikolaev and Jacobson 2010).

In SA, the currently assigned values to variables are compared with randomly picked ones at each step. When there is an improvement, the algorithm updates current variable; else it accepts the assignment with some probability. The algorithm is shown as a flowchart in Fig. 7.

Some AI Applications

The ANSI Dimensioning and Tolerance StandardY14.5 (Dimensioning and Tolerancing Y14.5 2018) specifies the estimation of the form tolerances on a component concerning an ideal geometric feature. And, ISO Standards (ISO 1101 2017) advocates the form tolerance evaluation according to the concept of minimum zone. Flatness tolerance is defined as the least separation between two parallel planes that enclose most measurement points. The evaluation of the minimum zone association of flatness error is a non-convex problem. Intelligent computations, such as the genetic algorithm (GA) and particle swarm optimization technique, were used to solve the nonlinear problem of flatness evaluation (Meo et al. 2013; Huo et al. 2016; Liu et al. 2021; Chandrasekaran et al. 2020).

Some workers used a genetic algorithm for the evaluation of the roundness of circular profiles using the MZT method. The standard fitting criteria that establish the reference circle are the least squares method (LSQ), the maximum inscribed circle (MIC), the minimum circumscribed circle (MCC), and the minimum zone tolerance (MZT). The MZT useful for cylindrical mating parts involves two concentric circles that contain the measured points such that the difference in radii is the least possible value.

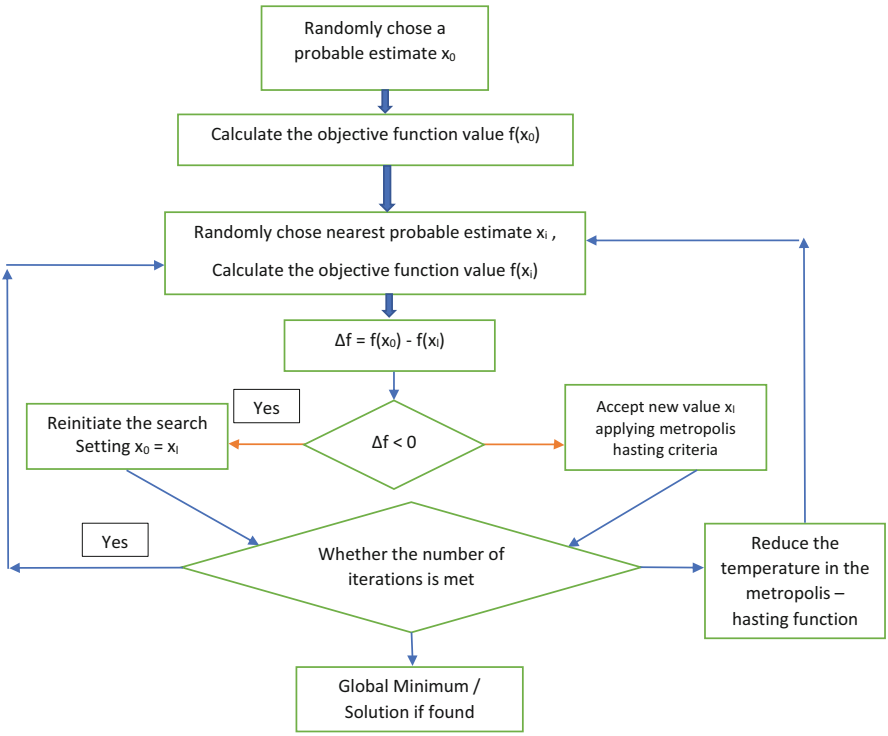

Fig. 7 Flowchart of SA algorithm

The popular characterization method of finding defects in thin film include a combination of optical defect detection with scanning electron microscopy (SEM), scatterometry or optical critical dimension (OCD) metrology, and X-ray scattering metrology. SEM register the deviations from the patterned template. An inverse algorithm is required to convert the scattering intensity data into a meaningful real space structure (Hannon et al. 2016). Despite the above discussed verity of applications, the following dimensional metrology applications are practiced.

Thermal Expansion Estimation

At length, dimension, and nanometrology division (NPLI), a study was conducted to determine central deviations and thermal expansion simultaneously. The measurement results are analyzed using simulated annealing algorithm (Zhou et al. 2018). A gauge block of size 100 mm is wrung on a platen in the automatic gauge block interferometer (GBI 300). The gauge block is measured at different temperature about 20 °C. The gauge block is thermally stabilized for at least 4 hours in the range of (20 ± 1) °C. At each temperature, readings of the gauge block are taken by entering different nominal thermal expansion coefficients values (TEC). The SA

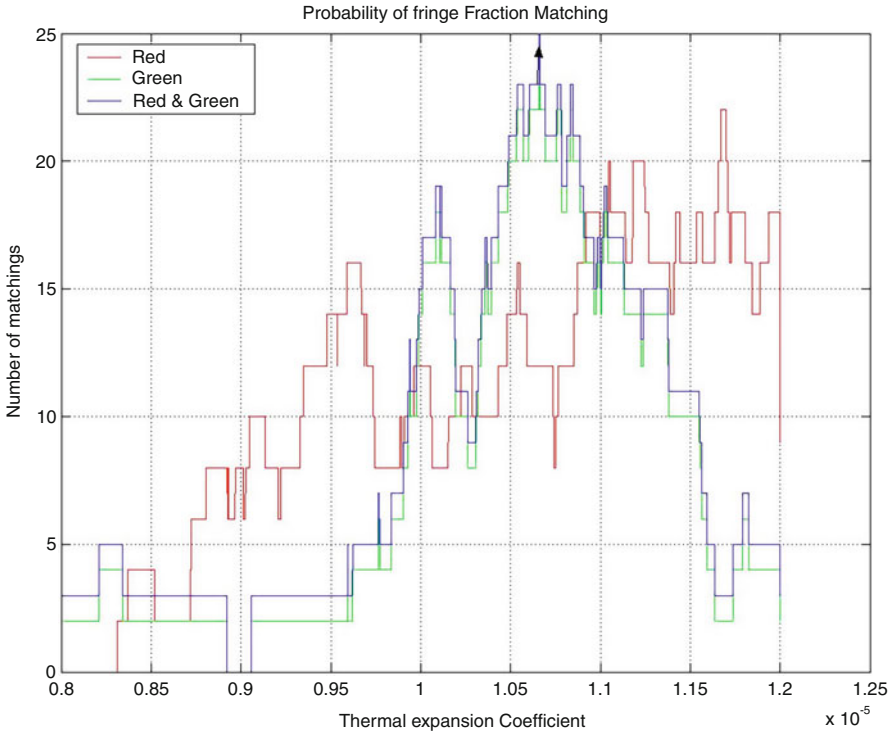

Fig. 8 Results of SA used for determining thermal expansion coefficient of gauge blocks

estimated the thermal expansion coefficient value as 10.11×10^{-6} /K. The probability distribution of measured fringe fraction deviation within the range of 19–21 °C is shown in Fig. 8. The convergence is shown as an arrow mark on the plot (Unpublished work 2012).

Flick Standard

Flick standard is a material artifact standard used to calibrate the roundness measuring machines. Flick standards have cylindrical seggetta with a discontinuity. Generally, a flick of 0.01 mm amplitude is sufficient to verify the linearity of LVDT probes and set the calibration (amplification) factor of most of the form measuring machines. The graphical parameters of the seggetta and amplitude of flick indicate filtering characteristics. Usually, the uncertainty associated with flick standard calibrated on form testing machine is the order of 0.1–0.2 micrometer. And the traceability is established through reference standard artifact – reference measuring machine; obviously their associated uncertainty is superior to that under test. A method to calibrate the flick standard using laser interferometer with rotary table on a X-Y stage is developed employing a genetic algorithm. An LVDT probe is used as

Fig. 9 Flick artifact centering using GA

null detector, and heterodyne displacement laser interferometer is used as reference measuring system. Henceforth the traceability hierarchy is established to the primary laser – heterodyne displacement laser interferometer. Further, the measurement uncertainty is improved. We have observed a main uncertainty component in this method is from type A, which is due to cantering. The associated uncertainty of measurement down to 40 nm is achievable. Software is also prepared for roundness filter, and roundness attributed by the flick standard is determined (Fig. 9).

The flick standard under test is aligned over Moore's indexing table. A laser interferometer fitted with probe is used to touch and feel the peripheral surface of flick standard. Moore's indexing table is rotated to obtain the surface profile coordinates of the flick standard at laser interferometer (Unpublished work 2014). The readings of the laser interferometer corresponding to the rotation of the index table are fed to a genetic algorithm-based program. The software program is developed using PERL (**an open-source language**) into two parts. The program accepts the probe displacement and angular position of index table readings to predict **eccentricity error of** alignment of flick standard (Sanjid and Chaudhary n.d.). The values of the eccentricity and flick depth are binary coded to implement the genetic operations (i.e., mutation, cross-breeding). The program simulated the coordinates of the flick standard with an arbitrary eccentricity error and flick depth values. The deviation of the simulated values and the measured coordinates are estimated to calculate the cost function value of the genetic algorithm. The generic algorithm

iterates the genetic operations to reduce the difference between the simulated coordinates and the measured coordinates.

Prospects of AI

Dimensional metrology involves the definition of geometric product specifications of components to be manufactured considering the feasibility of their assessment through a globally acceptable verification along with the traceable chain that snaps to SI unit of length. The partition operator is suggested in ISO 17450 to cluster the coordinate data points on the specific location on the part. After filtering the extracted points, the operation advocated in 17,450 associates them to given shape through optimum fitting (ISO 17450-1 2011). Therefore, the clustering, optimization for finding global minimum, and association operations demanded in dimensional metrology can be solved using SOM, GA, bee swarm, SA, etc. The complex structures with multiple characteristics require other than traditional methods. But the detection methods used for the complex structural components can be handled by collecting more data points. SOM is useful to classify and remove the outliers from the collected set of data.

Spirit Vials Calibration

Spirit levels are constructed by installing spirit vials of different shapes and lengths in a prismatic metallic case. Machinist's precision level is patented as US2316777A in 1940 by William B Fell. The main claims are (1) the graduated scale on a glass container of the liquid with an air bubble and (2) a metallic holder for the vial unit having pad portions. The specification and testing method are given in Indian standard 5706 (Indian Standard 5706 2006) and ISO 17123-2 (ISO 17123-2 2001). The test method recommends estimating the accuracy of the spirit level by determining the sensitivity of the bubble. A known tilt is applied to float the bubble between the graticules. Figure 10 shows the calibration setup and a spirit level. A micrometer fitted on one end of a metallic arm is used to tilt the platform. The spirit level to be tested would be placed on the platform. The operator carefully notes the stable location of bubble after tilting the spirit level. The micrometer must be adjusted precisely to shift the bubble exactly by a division. This exercise needs to be repeated 50 times to calibrate a spirit level. Its automation definitely reduces the time consumption and averts the influence of manual fatigue. Neural network is best suitable for the automation of calibration of spirit level.

The rotation of micrometer can be controlled through automation. A camera captures the location of bubble between the graduations on the vial. Tilt the spirit level, and the corresponding micrometer reading will be feed to the controller. Repeat this exercise to train the neural network. Therefore, the sensitivity of spirit level can be estimated.

Fig. 10 Calibration setup for sensitivity of spirit level

Digital Twins

Other than optimization, automation simulation of metrology experiments is in high demand with the advent of digital SI. The digital twin is a computer program that represents the practical measurement setup. Data acquired in the measuring experiments is used to train the virtual model. Further, the virtual model is evolved by reducing uncertainty components. Artificial intelligence algorithms are essential to design and develop the virtual infrastructure akin to the dimensional measuring machine and its application. The concepts of the digital twins are still progressive. Therefore, authorized/harmonized/standard methods for developing virtual dimensional metrology infrastructure instigate new field of technology (Flamigni et al. 2021; Harper et al. 2019).

The last but not the least, the advanced version of evolutionary method is genetic programming (GP). It is not limited to evolve the solution to a problem, but a computer program will evolve such that when executed will yield the desired solutions. The implementation of the GP follows the basic concept of evolutionary algorithm, i.e., genetic algorithm. The strings of command/code of the GP are randomly mutated and crossover for each cycle of generation. The crossover (mutation) operations mimic the biological cross breeding (mutation), respectively.

This chapter covered the AI and their metrology application. It is emphasized that AI methods prospect toward the implementation of digital twins and data processing applications.

Conclusion

This chapter covered the different applications of dimensional metrology supplemented by different AI techniques. GA and Swarm particle optimization are popular in analysing flatness and straightness. The chapter explained some recent AI applications to develop a digital transformation framework.

Abstract

In the fourth industrial revolution (Industry 4.0), Artificial Intelligence (AI) had been a cognitive science that produces actual value needed for relevant data with processing capabilities and algorithms. Manufacturing in the Internet-of-Thing (IoT) era will be more efficient, better quality, easier to manage, and more transparent through integration of physical and cyber technologies in Industry 4.0-based smart factories. Factory automation relies heavily on sensors and AI to make the system intelligent. Sensor technology advancements and developments linked to Industry 4.0 serve as the backbone for the inclusive expansion of industry and the economic success of any country. It is imperative that

manufacturing organizations and supply chains have access to the latest low-cost sensor technology for collecting data and putting it to good use. Standard sensor types include position sensors, flow, temperature, flow rate, pressure, and force. A wide range of fields, including motorsport, health care, manufacturing, the armed forces, and agriculture all make use of them on a day-to-day basis. Increasing efficiency through automation is the goal of Industry 4.0. The purpose of this chapter is to provide a brief overview and viewpoint on the most recent advancements in AI and the associated problems.

Attempts to define the main ideas and tools behind this new era of manufacturing in the early years of the so-called fourth industrial revolution (Industry 4.0) always ended up referring to the concept of smart machines that could communicate with each other and with the environment. When it comes to the new industry 4.0, it's the defined cyber physical systems connected by the IoT that get all the attention. Nonetheless, several tools and applications will benefit the new industrial environment, complementing the actual formation of a smart, embedded system capable of performing autonomous tasks. And the majority of these revolutionary ideas are based on the same background theory as artificial intelligence, in which the analysis and filtration of massive amounts of incoming data from various types of sensors aids in the interpretation and recommendation of the best course of action. As a result, artificial intelligence science is well suited to the challenges that arise during the fourth industrial revolution's consolidation. The purpose of this chapter is to provide a brief overview and viewpoint on the most recent advancements in AI and the associated problems.

Introduction

As Information and Communication Technologies (ICT) are increasingly integrated into industrial and manufacturing units, the concept of Industry 4.0 is becoming increasingly important in the digital transformation. Industry 4.0 includes the integration of cyber-physical systems, cloud computing, data exchange, retrieval, and storage, as well as a security framework, into industrial and manufacturing units in recent years (Hsu et al. 2018). In the twenty-first century, Industry 4.0 instantly became the focus of a global world that promoted the computerization of manufacturing (Kalsoom et al. 2020). It has revolutionized the manufacturing process, leading to intelligent manufacturing promising self-sufficient manufacturing processes by using machines and devices that communicate with each other through digital connectivity. Industry 4.0 incorporates numerous types of smart sensors that are used to measure and process quality metrics (Stăncioiu 2017; Varshney et al. 2021). These sensors process/transfer data by means of electronic

medium or wireless signal. Industry 4.0, the pioneer of smart factories, has access to a wide range of advanced technologies, including big data analytics, Artificial Intelligence (AI), advanced robotics, 3D printing, and cloud computing, all of which are critical to the modern manufacturing industry's success (Kalsoom et al. 2020).

AI is a branch of computer science that aims to create intelligent machines. It has become an essential part of the technology industry (Charniak 1985). AI creates intelligent machines and computer programs to perform various tasks that require human intelligence. Until recently, AI was confined to science fiction and academic arguments bringing about major impact of technology on the modern world (Dautenhahn 1998). But today, AI is an integral part of our daily lives, serving as a critical function in a wide range of industries. Industries including manufacturing, healthcare, and supply chains all feel the effects of this change. AI's ability to execute tasks that humans are unable to opens up a plethora of new possibilities for enhancing efficiency and productivity (Makridakis 2017). AI is a highly technical and specialized field of study. Programming computers to have particular abilities, such as knowledge, reasoning, problem-solving, perception, learning, planning, ability to operate and move objects, etc., is at the heart of AI.

Smart and integrated networks are essential in Industry 4.0 for intelligent manufacturing development (Kalsoom et al. 2020). Sensors and AI can collect and analyze data to assist in decision-making, and self-optimization in production line automation may be beneficial. Production lines can be made more efficient by automating the production process. Firms must work with experts to develop bespoke solutions due to the complexity of applying AI in industrial automation. The cost of developing the necessary technology is prohibitive for most manufacturers, who also lack the necessary qualifications and experience. Because of the widespread use of Computer Numerical Control (CNC) machines and industrial robots, production processes have become more adaptable, while Computer-Aided Design (CAD) and Computer-Aided Processing Planning (CAPP) have made computer integrated manufacturing a reality (Culler and Burd 2007). It is possible for manufacturers to implement digital transformations from several perspectives because of the IoT's practical usage, such as increased productivity, automation, a focus on the customer, and other competitive benefits. Any digital economy is seeing an increase in the collection, measurement, and transmission of precise data that can be traced back to international standards. Although Industry 4.0 was announced several years ago, digital transformation is still in the early stages of growth. Data storage and processing speed, smart sensor affordability and availability, effective data management, cyber physical system development, and other factors all play important roles in the digitalization process. However, for maintaining the highest levels of accuracy, calibration of smart sensors with respect to some digital or electrical standards is essential. The definitions and consequences of SI units also give inspiration for the development of sophisticated reference standards with lowest levels of measurement uncertainty for calibrating this smart equipment (Garg et al. 2021; Varshney et al. 2021). The IoT is more frequently employed in metrology for calibration and testing purpose.

Smart Sensor

An Industry 4.0 system consists of many elements/phases that must be designed to meet the demands of the manufacturer or industry (Vaneker et al. 2020):

- Historical data collection.
- Live data capturing via sensors.
- Data aggregation.
- Connectivity via communication protocols, routing, and gateway devices.
- Integration with Programmable Logic Controllers (PLCs).
- Dashboards for monitoring and analysis.
- AI applications: Machine Learning (ML) and other techniques.

A sensor is a device that detects and responds to a measurable digital signal to the input stimuli, which may be any quantity, property, or condition from the physical world. As an example, the input stimulus might be anything from pressure to force to flow to light to heat to motion to wetness (Schütze et al. 2018). For reading or other distribution, the response output is typically a digital signal in the form of an electric signal such as voltage or current, capacitance or resistance, frequency, or other unit of measurement. The industrial IoTs, which incorporates various types of sensors for regulating and monitoring process parameters, is a fundamental component of Industry 4.0. Depending on the configuration, these sensors can communicate with the process control equipment through radio or by placing them nearby. Varshney et al. (2021) summarize the importance of smart sensors in Industry 4.0. Process automation begins with smart sensors and actuators. Figure 1 summarizes the classification of sensors in brief of their industrial/manufacturing uses (Bentley 1984; Eaton and Smith 1997; Fan et al. 2002; Chong and Kumar 2003; Chen and Lu 2005; Rai 2007; Hu et al. 2009; Wang et al. 2010; Lebosse et al. 2011; Gómez-Robledo et al. 2013; Lee et al. 2016; Clark 2018; Leal-Junior et al. 2018; Lewis et al. 2018; Schütze et al. 2018; Sattar et al. 2019; Benitez et al. 2019; Jeon et al. 2020; Landaluce et al. 2020; Moheimani et al. 2020; Gupta et al. 2021; Lee et al. 2021; Sakai et al. 2021).

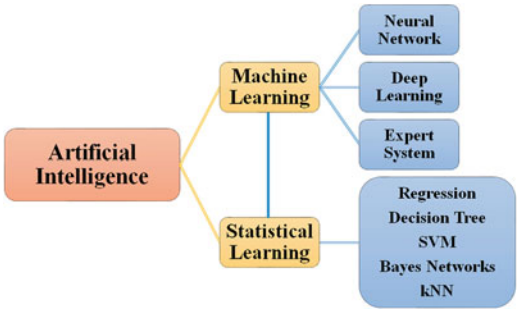
Artificial Intelligence Relevance and Implications

Artificial intelligence (Fig. 2) is a set of technologies that enable software and computers to perceive, comprehend, act, and learn on their own or in conjunction with humans. In comparison to human labor, industrial manufacturing may attain improved efficiency using AI (Lee et al. 2018; Peres et al. 2020). Furthermore, AI can allow robots to execute activities that a human would be unable to accomplish, such as managing hazardous raw materials or tiny components (Peres et al. 2020). It's critical to understand that many of these industrial robots aren't very sophisticated right now. In many circumstances, they are capable of doing a wide range of activities, although they are only programmed to a limited extent. You'll have to

Fig. 1 Classification of smart sensor

reconfigure it if you need more. The fact that this technology is improving with Industry 4.0 is driving ongoing expansion in the field.

Fig. 2 Artificial Intelligence



In 1955, John McCarthy established the notion of AI, claiming that a computer could replicate all aspects of learning and essential domains of intelligence (Andresen 2002). "While it is difficult to pinpoint the roots of AI," Haenlein and Kaplan (2019) wrote, "it is plausible to trace back to the 1940s, particularly 1942, when the American Science Fiction writer Isaac Asimov produced his short book Run about." The plot of Run-On centers on a robot developed by an engineer. Marvin Minsky and John McCarthy, a Stanford computer scientist, coined the phrase "artificial intelligence" in 1956. "The study of intelligent problem-solving behaviour and the creation of intelligent computer systems" is how AI is defined. In other words, AI describes how computers do tasks that would need intelligence if performed by humans" (Wisskirchen et al. 2017).

AI is split into two categories, according to Wisskirchen et al. (2017): weak AI and strong AI. When AI is poor, "the computer is essentially a tool for evaluating cognitive processes, and the machine mimics intelligence." Strong AI, on the other hand, refers to "processes in which computers are cognitive, self-learning processes," in which "computers can grasp and optimise their behaviour based on their prior behaviour and experience with the suitable software / programming" (Wirtz et al. 2019). Strong AI has the ability to automatically network with other computers, which has a large scalability effect (Osuizugbo and Alabi 2021). Deep learning, robotization, dematerialization, the gig economy, and self-driving cars are just a few of AI's most important economic fields (Wisskirchen et al. 2017; Osuizugbo and Alabi 2021).

Despite the fact that AI has been studied for decades, Benko and Sik Lányi (2009) believe that the discipline is wide and vague, making it one of computer science's most perplexing topics. From reasoning robots to search algorithms used in board games, AI is claimed to include everything. To put it another way, AI is expected to have applications in almost every aspect of how humans use computers in society. AI is also used in subtler ways, such as analyzing purchase histories and influencing marketing decisions (Simon 1995). According to Buchanan (Buchanan 2019), robots have always been a part of the public's perception of intelligent computers, despite early robotics efforts focusing more on mechanical engineering than intelligent control. Because of the potential of AI, robots, on the other hand, are becoming

more powerful vehicles for testing hypotheses about intelligent behavior all across the world. However, it has been argued that AI is not just concerned with robots. It's also about using computers as test beds to learn more about the nature of intelligent cognition and behavior (Simon 1995; Benko and Sik Lányi 2009; Buchanan 2019; Osuizugbo and Alabi 2021).

AI gets improved each time, and its costs falls. Implementing more complicated AI algorithms has also helped businesses to assess the purchase of new technologies that enable them to solve issues and make more complex and secure decisions (Dopico et al. 2016). AI has resulted in a shift in the way industry operates, owing to a new kind of interaction between man and machine. Intelligent factories, which have given birth to Industry 4.0, are characterized by cloud-based interactions between people and cyber-physical systems. Intelligent factories absorb automated structures and feature digital enablers that enable machines to connect with one another and with the factory's overall systems through an IoT setup. These abilities are in high demand by industries across the board, as they attempt to maintain the competitiveness of their manufacturing units in an increasingly technology environment. When used correctly, AI may provide various benefits to the industrial business (Dopico et al. 2016; Rouhiainen 2018; Azizi 2019). A list of three of the most important benefits for the manufacturing industry today is compiled and stated below:

Error Reduction – Intelligent algorithms, if taught, may perform very effectively in jobs that are prone to human mistake. Algorithms should be immune to the effects of external stimuli since they are not vulnerable to them.

Cost Reduction – Robots are being used by a number of e-commerce sites and banks to commence client assistance. If the situation is more complicated, the human attendant is summoned. Companies may cut personnel expenditures or reassign people to more important responsibilities, allowing them to enhance profits and concentrate on their core business.

Revenue Growth – Decision-makers will have more time to think about the core business and leave other AI chores to personnel who make fewer mistakes and concentrate on more vital operations.

Implication of Industry 4.0 and Industrial AI's Impact on Manufacturing

To achieve the aforesaid efficiencies, intelligent manufacturing incorporates real-time data analysis, AI, and ML into the production process. According to Trend Force, this industry is expected to develop significantly (Fig. 3). According to the International Federation of Robotics (IFR) report, the worldwide smart manufacturing industry is expected to expand to more than $ 320 billion by 2020, with more than 2.6 million industrial robots deployed in companies.

The influence of AI on manufacturing may be divided into five categories (Waltersmann et al. 2021; Kinkel et al. 2022):

i. **Predictive quality and yield**: For manufacturers of all stripes, reducing production losses and minimizing production process inefficiencies has always been an ongoing challenge. This is truer now than ever before, as rising demand meets greater competition. On the one hand, consumer expectations are greater than they have ever been, and global consumer habits are increasingly "westernizing" as the population boom continues. According to recent polls, the world population will increase by 25% by 2050, resulting in an extra 200,000 mouths to feed every day. Consumers, on the other hand, have never had access to so many options in practically every product conceivable. According to recent research, shoppers are more inclined to permanently abandon even their favorite companies if, for example, a product isn't accessible on the shelf.

   Manufacturers can no longer afford to ignore process inefficiencies and the resulting losses in the face of such a background. Every loss in waste, yield, quality, or throughput eats into their bottom line and gives the competitors an inch – providing their manufacturing methods are more efficient. Many industries, especially those with complicated processes, face a glass ceiling when it comes to process optimization. Some inefficiencies have no clear reason, and process specialists are stumped as to why they exist.

   Predictive Quality and Yield use Industrial Artificial Intelligence to uncover the underlying causes of many of the day-to-day production losses that businesses suffer. This is accomplished by continuous, multivariate analysis, which employs ML algorithms that have been specifically taught to comprehend each distinct manufacturing process. "Supervised learning" is the AI/ML approach utilized here, in which the algorithm is taught to discover trends and patterns in the data. Automated suggestions and warnings may then be created to notify production teams and process engineers of an impending issue, as well as offer critical information about how to avoid losses before they occur.

ii. **Predictive maintenance**: One of the most fundamental and well-known uses of Industrial AI is predictive maintenance. Predictive maintenance, rather than performing maintenance on a predetermined schedule, uses algorithms to predict

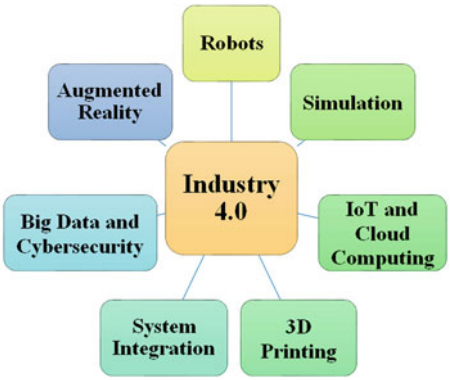


Fig. 3 Component of Industry 4.0

the next failure of a component, machine, or system, and then alerts personnel to perform focused maintenance procedures to prevent the failure, but not too early to waste unnecessarily downtime. Predictive maintenance systems, too, use ML methods to make predictions (although in a different category – unsupervised learning rather than supervised learning). The benefits are vast, and in many circumstances, they may dramatically cut expenses while obviating the need for scheduled downtime.

Systems may continue to work without interruptions if a failure is predicted using a ML technique. When maintenance is required, specialists are notified about the components that need inspection, repair, or replacement, as well as the tools and procedures to utilize. Predictive maintenance also extends the Remaining Useful Life (RUL) of machinery and equipment by preventing secondary damage and using fewer labor resources to complete maintenance operations.

iii. **Human-robot collaboration**: According to the IFR, there will be 2.67 million industrial robots in use globally by 2020. Workers will be provided training for higher-level employment in programming, design, and maintenance when occupations are taken over by robots, according to the general approach. Meanwhile, as industrial robots are certified for work alongside people, the efficiency of human-robot collaborative work is improving. As the use of robotics in manufacturing grows, AI will play an increasingly important role in protecting the safety of human workers while also empowering robots to make judgments that may improve processes based on real-time data acquired from the factory floor.

iv. **Generative design**: AI may also be used in the design process by manufacturers. Designers and engineers may utilize an AI algorithm, often known as generative design software, to explore all the potential configurations of a solution using a precisely stated design brief as input. Restrictions and definitions for material kinds, manufacturing processes, time limits, and budget restraints may be included in the brief. ML may then be used to test the set of solutions created by the algorithm. The testing step adds to the knowledge of which ideas/design choices succeeded and which did not. Additional improvements may be made in this manner until an ideal solution is identified.

v. **Market adaptation/supply chain***:* AI is pervasive across the Industry 4.0 ecosystem, not only on the factory floor. One example is the employment of AI algorithms to improve industrial operations' supply chains and enable them better adapt to and predict market changes. An algorithm may use demand patterns classified by date, location, socioeconomic features, macroeconomic behavior, political state, weather patterns, and other factors to provide market demand estimates. This is groundbreaking information for manufacturers, who may use it to improve inventory management, personnel, energy usage, raw materials, and financial choices about the company's strategy.

Metrology and Impact of Industry 4.0

Metrology, or measurement science, is an important part of production that is often disregarded (Aswal 2020a, b). It is critical to undertake this examination to verify that all component pieces fit together and function correctly. As a manufacturer, you'll want to think about more than simply the cost of a project; you'll want to think about the precision, consistency, and speed of production as well. It's crucial to think about when the measurement should take place in this procedure. Depending on your field, this will differ.

The growth of the Industry 4.0 idea brings with its new problems and a stronger metrological foundation (Varshney et al. 2021). As a result, it is necessary to reconsider measuring phenomena in order to bring Industry 4.0 and Metrology 4.0 together. For prospective industrial needs, there is a great need for online metrology. Industry 4.0's major objective is to improve throughput quality while increasing efficiency (Castelo-Branco et al. 2019). The measurement of multi-dimensional quantities in real-time mode while maintaining the accuracy of measurement findings is one of metrology's primary problems. The creation of sophisticated national and international standards governing the industry's present and future requirements is the most important aspect. Furthermore, Industry 4.0 (Wisskirchen et al. 2017) requires the adoption of proper measuring techniques and procedures that comply with applicable national and international standards, as well as the selection of appropriate equipment.

AI/ML is seeping into a variety of processes in the fabrication and packaging industries, but not always for the intended purpose (Dal et al. 2019; Bécue et al. 2021). The semiconductor business is just now starting to figure out where AI fits in and where it doesn't. AI works best as a tool in the hands of someone who has extensive subject knowledge. Certain tasks, such as pattern matching across large data sets, are ideally suited to AI. It is not as effective as engineers with years of expertise in fields like metrology, test, and inspection. However, when AI and experienced humans work together, they often deliver greater outcomes than any of them could do alone.

In the sphere of science and technology, metrology is the experimental and theoretical assessment of any measurement uncertainty. Scientific metrology, which deals with measurement standards, industrial metrology, which deals with measurements in an industry, and legal metrology, which deals with the legislation and protection of users of measuring devices (Aswal 2020a), are the three forms of metrology. The traceability of calibration and the analysis of uncertainty using international standards guidelines are two of the most important aspects of metrological infrastructure. With the use of smart sensors linked with ML algorithms for automated decision-making, the elements of measurement are changing as a result of digital transformation of industries and data analytics. The goal is to strengthen the metrological infrastructure necessary for better quality infrastructure in smart factories by implementing traceable calibrations in compliance with applicable national and international standards set in response to future industrial needs (Andonov and Marija 2018). Under the aegis of Industry 4.0, establishing a virtual link between the

calibration laboratory and client locations will be critical in calibrating various sensors in far less time without dismantling them in the system, thereby improving the accuracy, precision, and standardization of products and services (Castelo-Branco et al. 2019). Calibration may be done online/remotely via data transmission rather than instrument carriage in this scenario, and data can be supplied electronically from even the highest-level bodies such as National Metrology Institutes (NMIs) to customer sites. This will save time and money while maintaining the instrument's accuracy and specification. Sensors have an impact on smart cities and smart mobility, which is not restricted to industry. These sensors are self-calibrated and tested, and their status is recorded based on the kind and method of calibration. Calibration certificates are used to store this information. Smart sensors are utilized in Industry 4.0, which can connect through wireless communication protocols, allowing calibration results to be transferred to remote locations without requiring a lot of human work. Because today's sensors are mostly IoT devices, this measurement may be coupled to cloud services to build an Internet of Measurement Things (IoMT). The physical calibration system, the Metrological Information Infrastructure Cloud (MIIC), and an application software that may be utilized in metrology are all incorporated into the IoMT architecture provided in reference (Dopico et al. 2016; Rouhiainen 2018; Waltersmann et al. 2021).

Challenges in Industry 4.0 and AI

I defy anybody in the manufacturing business to spend a day without hearing the term "Industry 4.0" (Castelo-Branco et al. 2019; Compare et al. 2019). And, at an era when the majority of businesses are pursuing digital transformation, it's natural for manufacturing technology to evolve to cover both automation information and data interchange (Taymanov and Sapozhnikova 2018). With cyber-physical systems, augmented reality, IoT, and cloud computing all operating in unison, the possibilities for Industry 4.0 in manufacturing and beyond are almost limitless. When investing wisely in the factory of the future, keep an eye out for the following possible roadblocks (Fig. 4) (Vempati 2016; Andonov and Marija 2018; Taymanov and Sapozhnikova 2018; Horváth and Szabó 2019; Aswal 2020a; Ghadge et al. 2020; Vuksanović et al. 2020; Varshney et al. 2021):

i. **A Gap in Technical Skills**: The labor requirements are always changing. Are your personnel up to the task? When recruiting for unfilled roles, seek for candidates that have "digital dexterity," or an understanding of both industrial processes and the digital tools that support them. Only with the appropriate staff will company models be able to properly integrate and sustain new technologies.
ii. **Computing Power**: The quantity of power used by these power-hungry algorithms is a deterrent for the majority of developers. ML is the building blocks of modern AI, and their effective operation requires an ever-increasing number of cores and Graphics Processing Units (GPUs). We have concepts and skills to apply ML frameworks in a variety of disciplines, including asteroid monitoring,

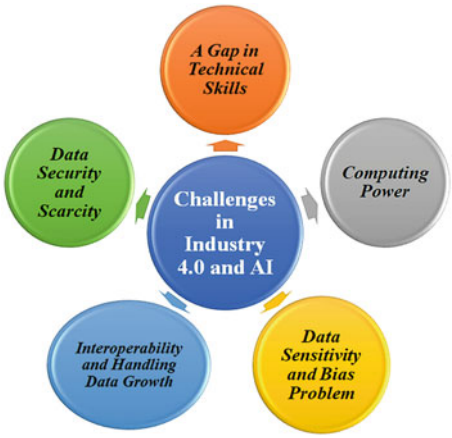

Fig. 4 Challenges in Industry 4.0 and Artificial Intelligence

healthcare deployment, and cosmic body tracing. They need the computational capacity of a supercomputer, and certainly, supercomputers are not cheap. Although the availability of cloud computing and parallel processing systems enables engineers to work more efficiently on AI systems, these benefits come at a cost. Not everyone can afford it, especially as the influx of enormous amounts of data and the complexity of algorithms continues to grow.

iii. **Data Sensitivity and Bias Problem**: The advancement of technology has also increased worries about the privacy, ownership, and management of data and intellectual property. A frequent occurrence? To develop an AI system properly, data is necessary to train and test it. To do this, data must be shared. Many businesses, on the other hand, are hesitant to share their data with third-party solution developers. Additionally, our present data governance standards for intra-organizational usage are insufficient to facilitate inter-organizational data exchange. Data is a valuable asset – safeguard it!

The quality of an AI system is entirely dependent on the quantity of data on which it is trained. As a result, the capacity to acquire high-quality data is the key to developing future-proof AI systems. However, in fact, the data that businesses acquire on a daily basis is insufficient and has no intrinsic value. They are prejudiced and serve solely to identify the nature and characteristics of a small group of individuals who have similar interests on the basis of religion, ethnic origin, gender, community, and other racial prejudices. The only way to effect significant change is to define some algorithms capable of tracking these issues effectively.

iv. **Interoperability and Handling Data Growth**: Another key problem is that protocols, components, products, and systems are not isolated. Regrettably, interoperability limits businesses' capacity to innovate. Additionally, since users cannot readily "switch out" one vendor for another or one component of the system for another, interoperability restricts system component upgrades.

As more businesses grow reliant on AI, they will be confronted with an increasing amount of data created at a quicker rate and presented in numerous forms. To sift through these massive volumes of data, AI systems must be more understandable. Additionally, these algorithms must be capable of combining data of different sorts and time periods.

v. **Data Security and Scarcity**: Another key problem is the threat posed by present and potential industrial vulnerabilities. Real-time interoperability is enabled by the physical and digital technologies that comprise smart factories – but at the cost of expanding the attack surface. When a smart factory's various machines and gadgets are linked to a single or several networks, vulnerabilities in any one of those pieces of equipment might expose the system to attack. To overcome this problem, businesses must anticipate both enterprise system and operational weaknesses at the machine level. Businesses are ill-equipped to deal with these security concerns, with many depending on technology and solution providers to identify weaknesses.

With big firms such as Google, Facebook, and Apple facing criminal accusations for unethical use of user data, many nations such as India are enforcing rigorous IT regulations to control the flow. As a consequence, these organizations now confront the dilemma of leveraging local data to construct global applications, which would result in bias. AI is heavily reliant on data, and labelled data is used to teach robots to learn and predict. Certain businesses are attempting to invent new approaches and are concentrating their efforts on developing AI models that can provide correct results in the face of data shortage. When information is skewed, the whole system may become defective.

Artificial Intelligence Application

In health sector currently, AI is being utilized in managing the medical data and records. Main application of AI is data management. AI-based robots store, collect, re-format, and trace data to provide quicker more constant access. In this section different applications of AI in health sector is discussed. Currently, AI is being utilized in managing the medical data and records. Main application of AI is data management. AI-based robots store, collect, re-format, and trace data to provide quicker more constant access. AI is playing important role in doing repetitive jobs accurately and faster of health sector such as CT scans, X-Rays, analyzing tests, data entry, etc. AI-based collected data is helping in treatment design by analyzing the notes and reports of patients.

As a result of our scientists' efforts, a low-cost and speedy diagnostic of COVID-19 patients is being developed in the healthcare industry (Mhlanga 2021; Srivastava et al. 2021). At least some people will be saved, and they will have access to an enormous quantity of information that they may use as soon as possible to protect themselves and their loved ones. AI has been used extensively in the search for a cure for COVID-19 in order to discover new drugs. The application of artificial intelligence (Fig. 5) by many researchers is aimed at discovering new treatments and

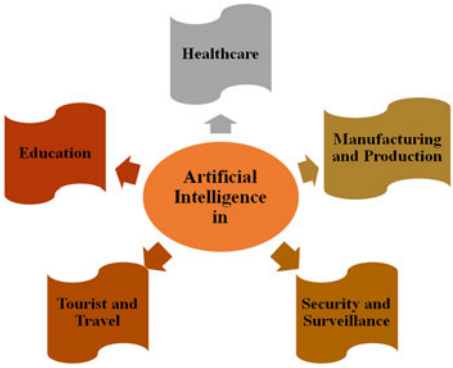

Fig. 5 Application of Artificial Intelligence

therapies for cures, with some computer scientists concentrating on the detection of infectious individuals using medical image processing, such as X-rays and CT scans (Kalyanakrishnan et al. 2018; Dal et al. 2019).

Manufacturing in the current era comprises logistic systems with ubiquitous and dominant computing networks. These systems are powered by millions and trillions of bits of data generated by systems, people, sensors, smart devices, and machines (Khemani 2012). With the fast expansion of data, the system's calculation skills must be analyzed more thoroughly and comprehensively than in the past. All of this has raised the relevance and usefulness of AI, ushering in a new era of technology known as Industry 4.0, also known as Smart Factory. Progressive cognitive computing and deep learning techniques have begun to be employed in various industrial processes and systems, such as production line inspection, problem identification, and keeping up with essential maintenance. Active efforts are made to implement and strengthen the various ways for handling the needed materials in the plants and production lines. The various methods available based on AI technology, IOT, research approaches, and cyber-physical systems are being used.

Smart manufacturing envisions systems that give us with detailed information on each stage of a product's lifespan. Deep Learning is used in descriptive analytics to evaluate product quality, diagnostic analytics to identify faults, and predictive analytics to anticipate defect occurrence (Wang et al. 2018). The first facet of implementing Deep Learning in manufacturing is product quality control. Machine vision combined with Deep Learning has been demonstrated to be beneficial for surface quality inspection. It is used to identify abnormalities on textured or non-textured surfaces such as scratches, wears, dirt, discoloration, and burrs. Furthermore, deep convolutional networks enable us to do object identification, which may be used in robot-assist tasks (e.g., a robot arm mounting a part on the CNC machine, robot object manipulation or sorting) (Hernavs et al. 2018). The second group includes diagnostic analytics and defect assessment tasks, when Deep Learning approaches are required. CNNs were utilized in equipment to analyze problems in bearings, gearboxes, rotors, and wind turbines. Under varied operating circumstances, the planetary gearbox was diagnosed using AEs and a five-layer deep neural

network (Jia et al. 2016). These examples demonstrate that Deep Learning models outperform classic Machine Learning approaches using designed features, such as Support Vector Machine and backpropagation neural networks. The last field of Deep Learning applications is predictive analytics for fault diagnosis, which includes maintenance and service prediction. RNN was used in (Malhi et al. 2011) to predict the long-term health of rolling bearings. Prediction of machining tool wear was made possible by combining CNN and bidirectional LSTM. Vanilla LSTM predicted the remaining usable life of an aircraft turbofan engine with high accuracy. These and comparable applications are critical for increasing production productivity and lowering maintenance costs.

Additive Industrial is a sort of AI used in manufacturing operations (AM). AM is commonly employed in the manufacturing process (Luckin et al. 2016). It has developed fast and massively, but its resilience and competency still need to be enhanced. As is generally known, AI is capable of jobs that humans are unable of performing with remarkable results when compared to human competence. AI-based technologies have the potential to reduce the workforce while increasing AM productivity and utilization by a factor of ten. Existing intelligent agents are used in problem statements including manufacturing, product design, and process design. The research proposes that by incorporating cloud edge computing into the already existing AM framework, the system may be greatly enhanced. As a result, as a general reflection, response time would be improved.

The various distributed AI in industrial systems is described more below. The Distributed AI (DAI) framework is utilized here to leverage the various structure and setup used for process planning in different plants and assembly facilities (Kubassova et al. 2021). The technique described above is used to divide whole production lines and jobs into smaller or subtasks. These smaller activities are carried out with the help of fundamental components known as intelligent agents. The solution is derived from all of the subsystems cooperating to solve the problem at hand – this is accomplished through the use of a method known as fuzzy management of the agents to derive the best suited solution to the problem as well as the most efficient and appropriate for implementation on the shopfloor. The foregoing is realized with the assistance of inputs from CAD, design data, short-term plan, DAI system, shopfloor observation, and so on. This offers a production plan that is possible for the actions conducted on the assembly line.

Agriculture is playing the main role in economic sector in India, and the automation of agriculture is the main concern nowadays. Traditional methods of farming are time consuming and are not sufficient to fulfill the requirement of our country. Application of AI-based sensors in various agriculture activities such as irrigation, plant disease detection, spraying, harvesting, weeding, etc. has brought a revolution. By using AI-based technologies, fertility of soil can be maintained, excess use of pesticides, herbicides, and water can be controlled, and also productivity and quality of crop can be improved. In automatic weeding manual labor is replaced by robot that uses lasers to kill weeds. In this technology robot drives through crop fields and cameras beneath display crops and weeds. AI-based software detects weeds and gives a command to remove them by attached high-energy lasers without disrupting

the soil. Similarly, in automatic harvesting systems, robots having camera, AI software, and mechanical arms are used for harvesting, to increase the speed of work and business, which is more efficient than humans and can work 24/7. AI also plays a key role in plant disease detection; around 20–40% of global food production is destroyed by pests and plant diseases. Nowadays AI-powered image recognition technique is being used for detection of more than 60 diseases.

AI plays a critical role in ensuring security in such a manner that only authorized users are permitted to access the material in order to prevent data leakage, which is referred to as digital leakage (Haenlein and Kaplan 2019). Security is the most concerned field of all time, and it should be included in all technological tools and apps, indicating the protection of each user's data and its respective information by avoiding the danger to be confronted. Several government entities are attempting to use these in order to ensure secure communication among authorized users (Ai et al. 2003). Several studies are also being conducted in order to cooperate with AI and IOT. Several Bots have been built in order to enable secure order delivery, and secure data transfer is also conceivable with this technology (Khanzode and Sarode 2020). For secure data transmissions, accurate results are produced. Data transmission occurs in a sequential way, i.e., first in, first out, in order to avoid data overlapping, and authentication and encryption of data are necessary at all times in order to enable safe data transfers. Technologies used for secure data transfer are very secret, and every time a system check is necessary to ensure that it is only accessible to authorized users. Deep learning is a branch of AI that has a copy of human learning and also analyzes multimedia, which has been the most challenging portion in the last decade.

Wireless communication appears to be the most efficient mode of communication, but it is still more prone to data leakage. There is a danger of data leaking during transmission, but it is the most efficient mode of information transfer. To prevent data leakage, the concept of artificial intelligence enters the discussion because the main concept behind artificial intelligence is completely based on human intelligence, and human intelligence includes the complete study and analysis of data encryption and decryption, and in order to successfully transmit the data, the complete study of artificial intelligence is required. Deep learning is a branch of AI that has a copy of human learning and also analyzes multimedia, which has been the most challenging portion in the last 20 years. Wireless technology is relatively loose in a certain region, and, for example, every mobile network has a data network.

The Intelligent Surveillance System (ISS) is a brand-new type of surveillance system with a focus on data analysis. The intelligent surveillance system's features include the ability to evaluate data that is used to detect or follow the behavior of forthcoming occurrences without interruption from humans. Using AI, sensors, and signal processing, this new technology can be used for a variety of purposes, including traffic monitoring, home security, and more. Sensory information from cameras is collected in enormous numbers by practical surveillance systems. A new technology in the sphere of national security, AI, is gaining a lot of traction in

technical advancement. Robotics and AI are being promoted by the US military's Department of Defense (DOD), which is expanding internationally at a remarkable rate for military objectives (Board 2019).

Travel and hospitality service companies have begun implementing AI into their operations, too, in the tourism industry (Ivanov and Webster 2017). Digital travel sales are expected to take off in the near future, and the business is expected to produce a sizable amount of revenue. These studies suggest that Internet and self-service technology are preferred by customers. Researchers believe that interactive self-service technology, based on AI, has the potential to boost customer satisfaction. These research findings indicate more than just clients' technological preferences. AI used to discover financial risk measures and monitors, which can be problematic if there is a lack of data or a lack of data protection, resulting in calculation errors. Manufacturing models, environments, and processes have been transformed by the incorporation of information technology, communication technology, product expertise, and AI. We are entering an era in which AI technology will be integrated with the Internet of Things (IoT), current generation information technologies, new renewable energy technologies, biotechnology materials, and other cutting-edge technologies. AI and AM are rising at a great rate in the manufacturing industry simultaneously, which allows them to scale the company, in the current scenario.

ML and AI analytics can be used to improve teaching quality and learning effectiveness by identifying at-risk students and providing early interventions, as part of the shift from a one-size-fits-all approach to a more personalized and personalized approach. The use of AI and other related technologies in assessing students' learning challenges may allow teachers to intervene in real-time to improve student learning outcomes. It is possible that AI can help humans become more productive. With disappointing results, computers were previously used in education. This has changed, and current AI research in education is providing extremely clear and firm outcomes (Zhang and Aslan 2021). Education resources like digital libraries and student data databases are maintained by computers. Programming abilities are being taught in schools using these computers/microcomputers, which are being used in a variety of industries. The educational sector has given a lot of thought to using computers with AI in the classroom.

Initially, AI took the shape of computer-based software and technology, eventually evolving into web-based intelligent education systems (Lee et al. 2020). Web-based chatbots and robots may now fulfill responsibilities and activities of instructors autonomously, thanks to recent technical advancements such as embedded computer systems and other technologies. Using these cutting-edge online platforms, teachers may now execute many administrative activities more efficiently and rapidly, such as evaluating and grading student performance and assignments, resulting in greater teaching quality. Many people confront obstacles while going to interviews in this competitive environment, such as introversion, insecurity, and a lack of hard or social skills. Training is required to enhance interview performance. Researchers recently created an intriguing application that simulates interviews by

merging virtual reality and artificial intelligence. They designed an interactive app for interview preparation by integrating the benefits of both technologies. To provide an appropriate answer, the system also examines the person's emotional intelligence and facial expressions.

AI is also applied in the automation of marksheet assessments and robotic teaching techniques (Malik et al. 2019). These varied approaches benefit both students and teachers, making their lives simpler. People nowadays employ advanced Natural Language Processing (NLP) to create sophisticated intelligent teaching systems. It also improves students' learning and comprehension rates by tailoring the course to each student's unique traits. The use of AI can help students acquire a variety of skills, such as the capacity to come up with innovative solutions and resolve contradictory assertions, among others.

The primary purpose of artificial intelligence in education is to give students with a personalized learning environment that helps them based on their preferences and personal attributes (Mogali 2014). Precision education requires learners to be provided with preventative and intervention methods by analyzing their learning patterns and pace, allowing the software to work as an intelligent tutor by incorporating knowledge and critical analysis of learner behaviors.

AI in India

An important part of India's strong IT infrastructure is based on the potential of various sectors, including health, education, energy, agriculture, and the environment, which have been considered by the National Science and Technology Anchor for smart applications, smart power generation and distribution, and smart management (Vempati 2016; Aswal 2020a, b; Garg et al. 2021). There are many plans for AI development in India. For this reason, the government has decided to invest their money in AI and transform India into a society that is completely automated. AI models have been pursued in order to estimate the timeline of India's oilseed output by taking into account increasing demand, policy environment, slow development in domestic production, and import charges (Marda 2018; Ghadge et al. 2020). Oilseed cultivation is an essential part of Indian agriculture because of the country's vast resources. AI is being applied in a few domains in Indian organizations, such as product creation, retail, internet, and conversational administrations (Garg et al. 2021), to discover concerns. A growing number of companies are turning to AI as a way to tailor the experience for customers. More and more businesses are adopting AI for a wide range of purposes as the technology improves and becomes smarter. There are many ways in which AI is being used in the banking business; this is just one example of how it is being used (Malali and Gopalakrishnan 2020). AI has been implemented by Indian banks to improve operational efficiencies and customer satisfaction. Its primary goal in the banking industry is to anticipate customer behavior and make operational decisions based on that information.

Conclusion

To support the Industry 4.0, a smart sensor and AI-enabled industrial infrastructure must be in place that is traceable to digital metrology, traceability, and certification. This chapter discussed the many parts of this infrastructure. This chapter covers the different issues that arise when incorporating AI into Industry 4.0 with the use of smart sensors. Manufacturing processes are made more intelligent through the use of AI and digital quality infrastructure, which is demonstrated in this chapter. The purpose of this study is to provide a succinct overview of the most recent technological advances and obstacles in this subject. AI has helped us better grasp what intelligence is and how it might be put to use in a variety of contexts. AI is a rapidly developing field that is allowing society to live as simple a life as possible. From online shopping to watching TV, it has slowly but surely permeated every facet of our life. In other words, it is the study of computers and their components. Currently, AI is a trendy topic in every industry. There are both advantages and disadvantages to the technology being developed at such a rapid pace. It has a wide range of applications, according to the research I've done. These include everything from health care to farming to businesses to transport to education. As a result of the use of high-end processors, these applications virtually eliminate the possibility of human error and human engagement throughout the process. Because AI makes education more accessible, it can help alleviate some of the unemployment that has resulted as a result of the technology's widespread adoption. As a result, AI is a huge asset to our society, which necessitates further advancement in the form of AI. There are a number of strong pillars for building a national digital quality infrastructure in the metrology area, such as the planned metrology cloud, digital calibration certificate, and development of the Measurement Information Infrastructure (MII) as that focused. A solid foundation for digitalization is provided by the integration of Indian industry with India's IT infrastructure, the latter of which is the largest IT exporter in the world. For IT as well as other fields, this is a win–win situation for expanding the field of R&D. IoT and various technological advancements in conjunction will lead to research and development in smart sensors, AI, wireless protocols, IoT devices, and cloud computing for Industry 4.0. This will serve as the backbone of inclusive growth in the economy of a country, as well as a means of increasing productivity.

Abstract

In general, the Internet of Things (IoT) concept allows any type of electrical equipment to connect the Internet (thing). As both an outcome, any "thing" will be assigned an Internet Protocol (IP) identifier and will be reachable using normal Web protocols such as Domain Name System (DNS). The IoT will be a technology or functionality associated with conventional ISA-95 automation systems in an automated environment. IoT automation elements include sensor, actuators,

Programmable Logic Controllers (PLCs), control loops, data analytics, control models, simulators, and optimizers.

The IoT, Industry 4.0, and intelligent systems might all be combined to produce a strong mixture that foreshadows an amazing future with enhanced efficiency. In many areas, especially the industrial sector, long-term growth is crucial. With the help of an intelligent system, we may be able to detect and address significant issues in Industry 4.0. As a consequence, the concept may be thought of as a physical device or a feature computed in a software system that runs on any device with sufficient computing power. An IoT device presently lacks a standardized technology. Several projects to standardize are now in the works. For example, the International Telecommunication Union has a standardization working group SG20 on "IoT and its applications, including smart cities and communities," and Institute of Electrical and Electronics Engineers (IEEE) has an ongoing IoT Ecosystem study as well as the IEEE P2413 draught standard for an architectural framework for the IoT.

This chapter provides a review of the literature on revolutionary industrial growth and the difficulties and advantages of Industry 4.0. One of the most pressing issues in the current scenario is achieving long-term growth. Air quality has become a major problem on a global scale. This chapter also includes a case study on the merging of meteorological sensors with remote sensing devices. This case study demonstrates the relationship between meteorological sensors, such as temperature, wind, and relative humidity, and Atmospheric Boundary Layer (ABL) as well as its importance in regional air quality monitoring. The case study also highlights the necessity for advanced technologies such as the IoT and Artificial Intelligence (AI) to be integrated into the field of environmental monitoring.

Introduction

The Industrial Revolution changed society in acquiring new knowledge, analyzing events, and innovations. Many structural changes have occurred in cities and their populations over the course of the industry's long history, as well as in product demand, supply chain processes, production process development research, and workplace culture. The emergence of an industry can be categorized into three fundamental pillars: knowledge, experimentation, and entrepreneurial innovation as shown in Fig. 1.

These three pillars are the root of evolution and growth of an Industry. Industry evolution has successfully acted as a medium for creating new employment opportunities for various products to satisfy people's demands (Vaidya et al. 2018). Consequently, the industry's development is spread out over a number of stages and is of equal importance. There are four stages of industrialization: the First, Second, Third, and Fourth revolutions. Industry 4.0 has utilized the previous industrial revolutions with much faster pace and incorporates a wider range of new

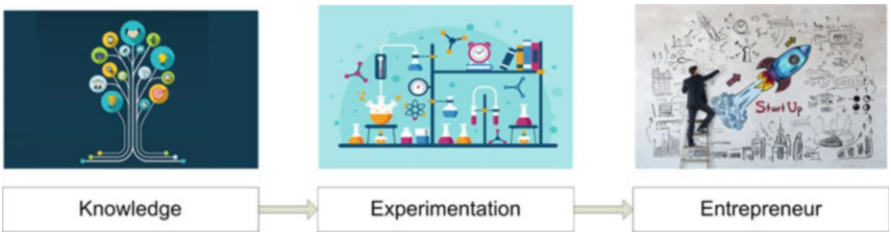

Fig. 1 Three pillars of Industry evolution

technology. Industry 4.0 has changed the internal and external aspects such as product development, distribution techniques, consumer needs, and job culture. Industry 4.0's capabilities and potential must be understood in order to maximize its potential. It is critical to be aware of the new opportunities presented by Industry 4.0 in order to collaborate with stakeholders and contribute to its growth (Prisecaru 2016).

Industrial revolutions can be planned based on the combination of the three main characteristics of industry's creation, namely, knowledge, experimentation, and entrepreneurial innovation as shown in Fig. 1. In the past, a scholar or an inventor improved their ability to absorb and integrate information, knowledge, and their research for the faster growing industry. The experimentation and collaborative works enhance the production and development process. The third component of entrepreneurial innovation is employers' belief in new discoveries, work practices, and ways of manufacturing and developing their company on unimaginable scales in accordance with the opinion in and reinvest in these breakthroughs. The development of new technologies, such as energy sources, equipment, materials, and processes alone cannot account for industrial revolutions. To be sure, economic growth over the last two and a half centuries relied heavily on these forces. Hydrostatic mills, for example, were in use many years before the invention of the computer. As a result, this era is marked by the widespread use of machines, which we refer to as machinery (Shariatzadeh et al. 2016). There have already been four major industrial revolutions, as seen in Fig. 2 (Jeschke et al. 2017).

Water, animal energy, and wood were the primary construction and combustion materials at the beginning of the first industrial revolution. Iron was commonly employed in construction throughout the Industrial Revolution, coal was the dominant source of energy, and steam was the major source of energy (Zhou et al. 2015). There were three distinct stages of industrialization documented. The steam engine was created during first of them, the so-called First Industrial Revolution, and Adam Smith was its greatest theorist. He is also credited with inventing economic liberalism (Chen 2017).

The Industry 1.0 came to a conclusion in the nineteenth century, and significant developments occurred during this time. The industrial production and consumer goods divisions have extended to nations other than England throughout this time period. Railroads, telegraphs, and steel-hulled transoceanic steamboat sailing

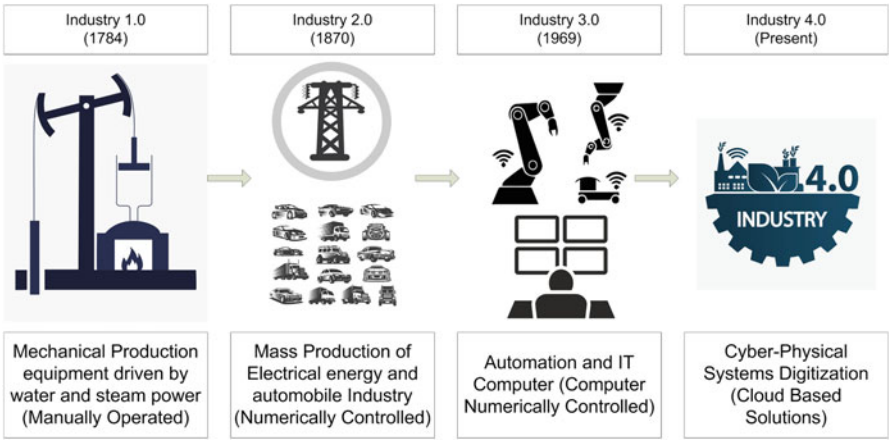

Fig. 2 Historical timelines of Industrial Revolutions

changed transportation and communication in the mid-nineteenth century. Expansion of a company's activities beyond national borders, which was formerly seen to be a combination of business and adventure, is now achievable and financially encouraged (Zhong et al. 2017).

Following Industry 1.0, the so-called Industrial 2.0 began in the late nineteenth century. It included breakthroughs in the chemical, electrical, oil, and steel industries, as well as other advancements like water steel ships, improved aeroplanes, food canning, bulk consumer product manufacturing, mechanical cooling systems, and the invention of the electromagnetic mobile phone. Throughout this time, a modern generation of industry of great potential began in Germany, the United States, France, and the United Kingdom. Taylor's modern management program (Patel et al. 2017) is how the Industrial 2.0 is known in the United States. New resource and energy sources, like electricity and, progressively oil, have aided in the changeover of Industry 2.0.

Around the turn of the nineteenth century, the world economy started to show indications of cyclicality. In the 1920s and 1930s, the growth of automotive and aviation sectors, as well as telephone and radio broadcasts, intensified the transformation in communication and transportation technology (Zhong et al. 2017). According to the author (Shariatzadeh et al. 2016), an Invention of the steam engine occurred in the latter part of the nineteenth century. While the former depended on iron and coal-fired steam power, the later relied on electricity and steel, resulting in substantial advances in communications, chemistry, and petroleum use. Because they had not yet totally replaced the previous ones, these improvements did not begin to stand out until the twentieth century.

As part of the third Industrialization (Industry 3.0), which began in the 1970s, the economic system offered collaboration as a new paradigm, stating that an organization can only be realized collectively (Domingo Galindo 2016). As a consequence, a large number of businesses were employed, and their development became more

focused on developing strong couplings with the same level of collaboration. Third-generation revolutions have ushered in a new approach to economic management, stressing more horizontal and flexible bargaining across enterprises in order to accomplish more precise and integrated economic activity (Chen and Limchimchol 2006). The development of financial economy instruments, often known as the "market economy," enabled the Third Industrial Revolution to speed media and transportation growth, as well as globalization (Patel et al. 2017). Biotechnology, computer science, Computer Numerical Control (CNC), microelectronics, and telematics integrated systems are just a few of the technologies that were widely used in Japan in the mid-1970s as part of this revolution.

"Industry 4.0" refers to a new industrial revolution that emphasizes and incorporates the most recent technical advancements, allowing for more rapid and customizable manufacturing. The phrase was coined in 2011 in Germany to represent closely related improvements in automation and information technology (Pandiyan et al. 2018). The integration of the Internet and production processes with the assistance of smaller sensors and Artificial Intelligence (AI) on machines is envisaged as part of the Fourth Industrial Revolution's objective of enhancing productivity through "smart factories" (Zheng et al. 2017). For industry 4.0, there are many different definitions and nomenclatures. However, as defined in this chapter, Industry 4.0 is a modern manufacturing model that includes a varied range of techniques that is not essentially unreported, but merged with each other and that of entire industry, and is distinguished by high immersive, digital, and scientific performance.

Although this model is still in its early stages, it already has chaotic characteristics in terms of environmental performance, as it is considered a sustainable manufacturing model, and human work, as it provides a set of potential technologies that aid the work performed by people in the industry, eliminating aspects such as intense physical effort and market positioning, as Industry 4.0 has an excellent response time to internal and external stimuli. As early as 2014, enterprises in Germany began assessing their readiness for Industry 4.0 implementation. At the time, at least 41% of German businesses had heard about "industry 4.0" and had launched some concrete efforts. The road ahead, though, is long, and many companies are still unfamiliar with the term. This is especially true for small businesses, as 44% have no idea what Industry 4.0 is.

The modern manufacturing model, on the other hand, is well-known among larger businesses, with just 17% unaware of its existence. There is also a time lag between big industries and small- and medium-sized firms in implementing Industry 4.0 strategy (SMEs). Only 17% of SMEs in Germany had implementation strategies, despite the fact that nearly 20% of original equipment manufacturers had effective implementation plans (Jiang 2018). Industry 4.0, according to Xu, (2012), is not only a technological challenge, but a reality that will fundamentally transform firm organizational structures. The authors provide five disruptive technology views, which are not meant to be exhaustive. As early as 2014, enterprises in Germany began analyzing their readiness for Industry 4.0 implementation. At the time, at least 41% of German enterprises had heard of the term "Industry 4.0" and had started the process. There is still a long way to go, and certain industries are still catching

up. According to a new poll, 44% of small-scale businesses have no understanding what Industry 4.0 is. Industry 4.0 is a paradigm shift in the following aspects:

- Improved social – technical interaction: Autonomous and self-organized production resources carry out planning activities in value chains between enterprises.
- Innovative goods: Both the products and the acceptable operating parameter of a certain manufacturing process are well-known. These goods can be bundled together to increase production.
- Personalized manufacturing: During the design, planning, production, and recycling processes, companies can take into consideration the individual qualities of client demand and product.
- Automation: Employees are in charge of configuring and controlling intelligent production resources based on context-oriented targets.
- Data Science: Managing a product's life cycle is made easier by the use of product-related data.

Significant Things of Industry 4.0

According to Tao et al. 2014, three general features of Industry 4.0 are smart plants, smart manufacturing, and smart logistics. For example, the "smart plant" is an important component of future smart infrastructure, concentrating on massive production structures and procedures, and also network distribution in production facilities and establishing the factory's designed to be completed (Bhardwaj et al. 2010). Figure 3 depicts the relationship between the three elements listed above, as shown in reference (Tao et al. 2014).

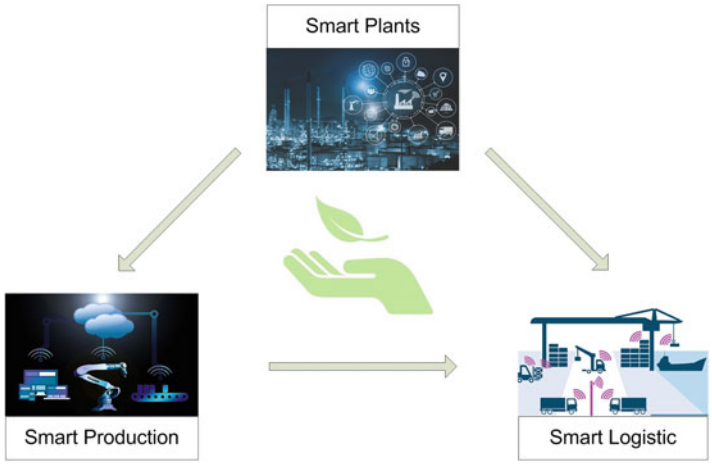

Fig. 3 The most significant things of Industry 4.0

Because of human-to-machine (H2M) contact and the use of 3D/4D technology in industrial processes, "intelligent production" is a high-capacity industrial chain capable of being flexible, customized, and actively maintained in a network. On the supply and demand sides, "intelligent logistics" works in combination with high-performance logistics resource efficiency, particularly via the Internet and logistics resource integration networks, to provide optimal logistical assistance. The production system in Industry 4.0 is made up of three unique components that work together to perform each other's jobs. Smart manufacturing, which attempts to manufacture tailored goods for consumers (Peng et al. 2009), is the foundation of this new sector.

Industry 4.0 Standards and Guidelines

Industrial Revolution 4.0 is a production industry trend or idea that stresses automation process and data transmission. The IoT, computer systems, and cloud computing are all used in this project. It is a German-based organization that pushes for total industrial process automation.

Interoperability, Virtualization, Decentralization, Real-time capability, Service orientation, and Modularity are the crucial six design principles as shown in Fig. 4 for optimum utilization of Industry 4.0.

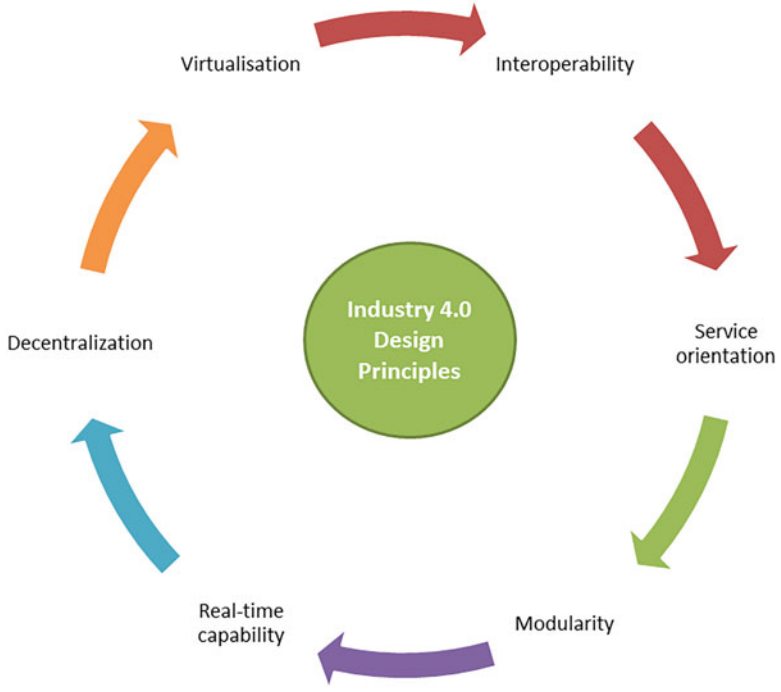

Fig. 4 Industry 4.0 standards and guidelines

Interoperability

A system has interoperability when people, machines, and objects all work together in an organization. The ability to link everything in a company, everywhere, and with everyone is critical for utilizing the insights provided by data in order to improve efficiency and procedures. In order to achieve interoperability, integrating things with cloud computing and digitization are the crucial aspects. Smart integration using open-source platforms and software such as Linux, Android, Python, Apache, and so many others are very important. Businesses can save money and time by allowing information to flow freely between systems, eliminating unnecessary duplication and allowing third-party applications to be used when necessary.

Virtualization

The term "virtualization" is used to describe two distinct scenarios, first one is where multiple physical resources are combined into a single virtual resource and second one is where many virtual resources are derived from a physical resource or a combination of resources. To begin, a business's hardware environment is replicated by building digital "twins" of actual assets derived from remotely sensed data. In the second case, software divides a single hardware resource into many virtual servers.

Using virtualization, hardware costs and physical resources can be reduced. Improved reliability and greater flexibility are two of the benefits of virtualization. With virtualization, all of an organization's computing resources are no longer tied to a single physical device. It's best to begin virtualizing for less critical assets such as desktops and servers before moving on to more significant ones.

Decentralization

In order to achieve virtually limitless scalability and adaptability, businesses have long embraced decentralization by moving systems away from a centralized computer. Using the cloud to store and transfer data, as well as automating repetitive tasks, is an example of decentralization. With both, the focus is shifted away from a single location. Industry 4.0 allows for the creation of decentralized systems across all industries on a global scale as all technology is decentralized.

Any company that adopts new technology will inevitably begin to see decentralization in their operations. To help this process, managers can disperse decision-making among a larger number of workers on the ground and delegate responsibility for day-to-day operations to smaller groups.

Real-Time Capability

The phrase "real-time capacity" refers to the ability to gather and analyze information in real time in order to make judgments anywhere at given time.

This enables a user to observe the business, and make real-time decisions to improve productivity. It also gives you the ability to look at micro trends, respond quickly to production line failures, and be proactive in addressing anomalies or inefficiencies. Data from sensors and internet-connected devices is now readily

available to the vast majority of businesses. Processing and analyzing data is a difficult but necessary task if business operations are to be continuously improved.

To help small- and medium-sized businesses (SMEs) build an inexpensive and integrated reporting platform for insights across multiple data sources, open-source tools are critical. Many services now offer embedded analytics that can be accessed at any time and from any location via cloud computing, allowing for real-time management of this data without the need to wait for reports.

Service Orientation

As a result of big data and interoperable systems, businesses now have the ability to respond in real time to their customers' needs. This enables businesses to respond to customers' evolving needs and expectations as they arise, allowing for a more personalized service. A consequence of this is a shift away from mass production and toward customized services for individual customers across all industries.

A growing number of farmers are using data insights to improve their equipment and supply chains and distribution models in agriculture. Using cloud computing and IoT devices, healthcare providers can streamline medication regimens, health reports, exercise regimens, and more for their patients.

Predictive modeling is at the heart of these services, which rely on data collection and analysis. If you want to stand out from the competition in a service-oriented model, you need to use data insights to create unique offerings for your customers. This includes identifying non-core activities that can be reduced or eliminated using technology so that employees can focus on the most important aspects of the company.

Modularity

Modularity, like service orientation, refers to a company's ability to respond quickly to shifting market conditions. Modularity can be viewed in two different ways. Small, well-defined teams that focus on specific aspects of the business operation in the first instance. In the second place, businesses that use modular systems, such as accounting or HR software platforms, are able to buy only what they need now and add more in the future as their needs change. In contrast to outsourcing, modular systems are designed to interact and connect to other parts of the business.

Both allow companies to concentrate on their core competencies. As a result, employees become experts in their core activities, providing value to customers in a variety of ways. Core activities can then be expanded as the business grows, increasing the company's agility and scalability, and allowing it to adapt more quickly to changing market conditions.

Industry 4.0 for Sustainable Growth and Smart Environment Monitoring

Industry 4.0 is changing the approach of manufacturers and regulatory authorities in the direction of sustainable growth. Sustainable growth is the need of the moment. Sustainable growth aims to develop a peaceful and prosperous society for people and

the planet. The primary focus of Industry 4.0 is upgrading the existing technologies with the latest techniques and preserving the environment, oceans, and forests. The global economy is growing at a very fast rate, which has a lot of negative effects on the environment and ecology. In order to capture the growth of the Industry while maintaining a healthy and clean environment, an effective environment monitoring system is needed (Ghobakhloo 2020).

The study of concepts and computer networks that can do activities that would ordinarily require human intellect, such as sense input and decision-making, is known as AI. "The ability of a system to accurately perceive external information, learn from it, and use what it has learned to achieve specific goals and adjusts its behavior accordingly," according to Kaplan and Haenlein (2019). To drive systems toward stated objectives, AI acts on external information supplied from IoT and other big data sources, employs knowledge-based rules (given by developers), or uses Machine Learning (ML) to identify the underlying rules and patterns. A really intelligent system can learn, generalize (if that's possible), acquire information, create goals and priorities, and reduce risk in decision-making processes.

The series of crises, such as COVID-19, overpopulation of the world, and lack of natural resources, demand an alternative approach for the world economy to grow and develop toward sustainable growth. Industry 4.0 is a revolutionary outlook for the world. It is equipped with advanced sensors, embedded systems, and data acquisition systems. The integration of the IoT makes data collection and data analysis much easier. It allows regulatory authorities to make better decisions in real time. The volume of the data has also increased multiple folds.

The cloud storage techniques solved the problem of managing a large amount of data from any world location. The ample amount of data opens the opportunity to implement the AI and ML solution on top of conventional approaches and provides an intelligent solution to the consumer. These advanced technologies lead to predictive maintenance, optimization of the process, and automation improvements to achieve high efficiencies and responsiveness to customers, which was not previously possible (Deepa and Prabadevi 2020).

"Expert systems" built on rules may be used to bring AI into industry, and this method is known as "rule-based" AI (Nilsson 1982). All of the rules that govern the dynamic behavior of the system are based on either physical principles or human expert knowledge gained via experience. In this strategy, IoT applications or sensors are used to continuously monitor the system or process. Individual system descriptors are extracted from the IoT sensors and examined using the rules. To display patterns, raw data is occasionally filtered and saved in a database. The participation of numerous unknown factors in atmosphere, the variability of meteorological parameters, and atmospheric pollutants all contribute to the high complexity of air-quality systems. This makes it difficult to translate scientists', meteorologists', and industry professionals' knowledge into well-articulated, well-defined procedures (computer programs) that may be used in AI-based expert systems (Goyache et al. 2001). Nonetheless, rule-based AI is appropriate in situations where real-time choices and control are required and regular training is not possible.

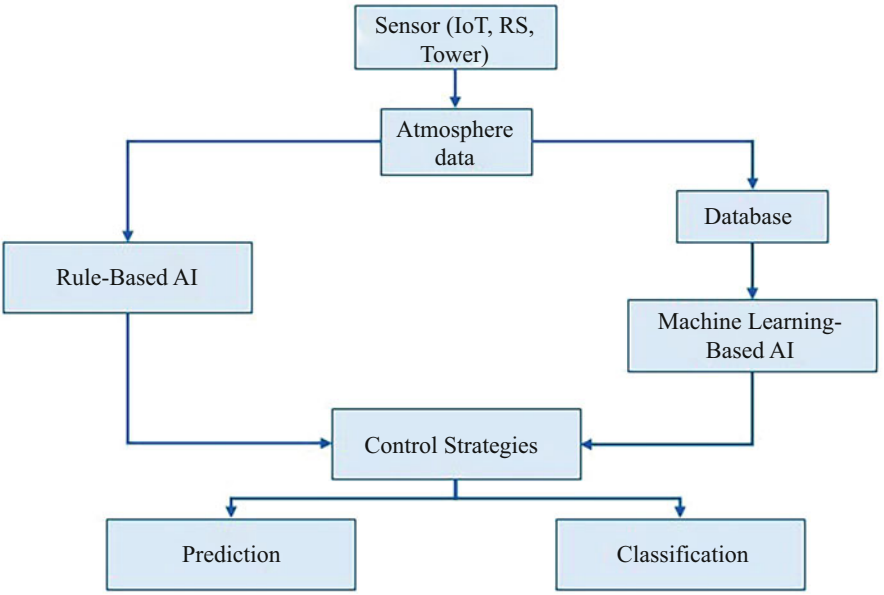

Fig. 5 Simple flowchart from sensor to data preparation and the role of AI

Because of the drawbacks of rule-based AI, ML-based AI has gained traction in recent years (Michalski et al. 2013). There could be a lag in data collection (sensing) and developing predictions or judgments in ML-based AI (for example, via IoT sensors) since the system is designed to look for data patterns (Fig. 5). ML-based AI systems currently do not employ human intelligence-based computer rules (i.e., obedience to any form of science, physical reality, or expert experiences); instead, they are completely data driven. ML-based AI is well suited to systems where frequent training is not a need and better precision is sought, as is the case with atmospheric systems.

Because the capacity to learn from the environment is frequently associated with intelligence, ML is one of the most vital aspects in AI. ML is an AI development approach that allows computers to learn without being explicitly programmed (Goyache et al. 2001; Michalski et al. 2013). Simply said, learning algorithms extract and agglomerate information from unstructured data into computer programs that may perform helpful activities like alerting users or triggering essential processes (Nilsson 1982). It delves into the research and architecture of algorithms that can learn from and forecast data; these algorithms go beyond merely static programming instructions by generating data-driven predictions and judgments (Solé 2007). The three primary categories of ML algorithms are shown in Figs. 6 and 7 shows the basic steps and process of ML.

Figure 8 depicts the numerous models that fall into these categories, as well as their technical applications. There are further in-depth descriptions of ML

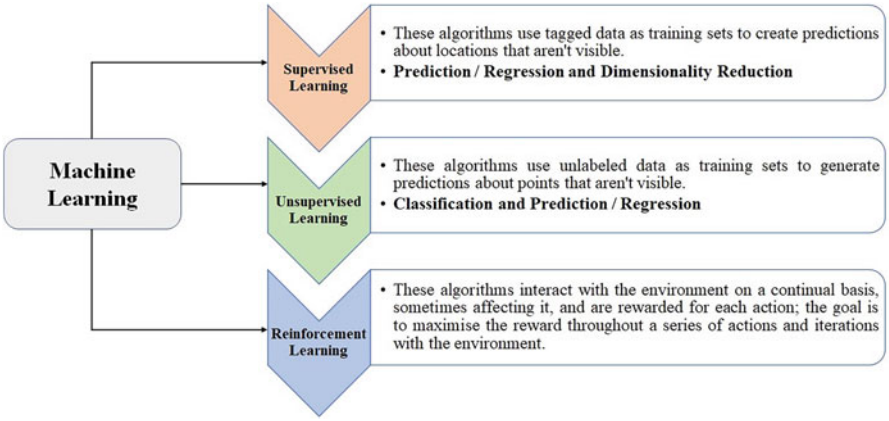

Fig. 6 Different types of ML

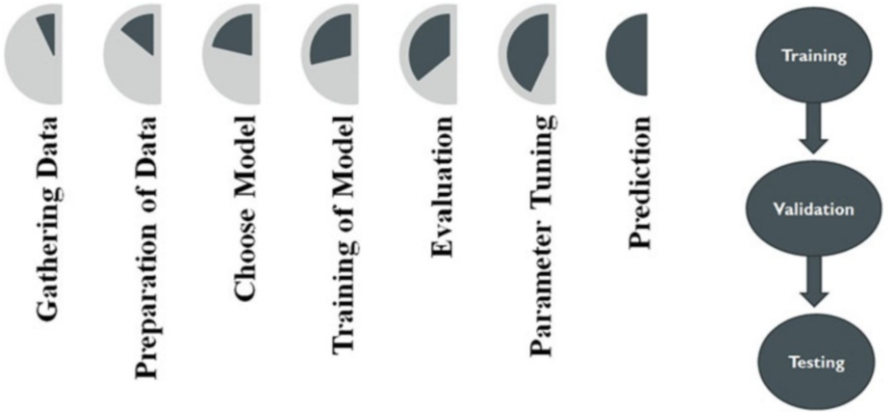

Fig. 7 Basic steps and process of ML

approaches and their atmospheric applications in (Bochenek and Ustrnul 2022; Moosavi et al. 2021).

Monitoring climate change in a time of substantial growth in the industry is also a challenging task. India is the fastest growing economy in the world. Therefore, an effective regional level monitoring of critical environmental parameters is pivotal (Chourey et al. 2022a).

The end objective of AI or big data processing in the industrial context is usually production control or automation. However, the ultimate deployment of all IoT, big data analyses, and AI systems is still up for debate, and cloud also involves collecting insights, making forecasts, and sending out alerts, in addition to automation (fault detection). The learning approaches' final nodes in Fig. 8 show some frequent instances of end applications for which data insights are developed using ML technologies.

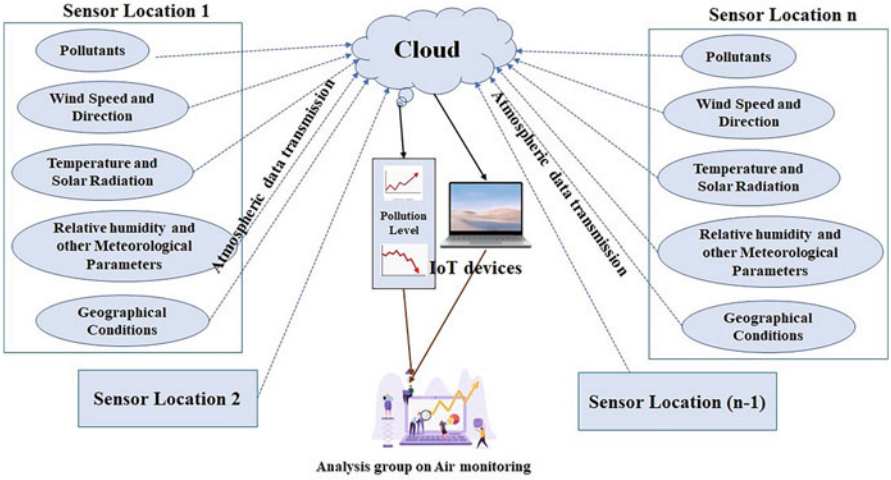

Fig. 8 Basic diagram of IoT framework in the context of air quality analysis

IoT-Enabled Meteorological Sensors and Remote Sensing

Meteorological and remote sensing sensors are critical in collecting observations from the environment. Including IoT and soft computing in the monitoring system offered insights for deeper environmental knowledge and analysis. Sensors are essential for a wide range of industrial applications (Chourey et al. 2022a). The chapter Smart Sensors for the Industrial IoT compiles the most recent research in intelligent sensor technology. It introduces the reader to the numerous industrial uses made possible by this technology. The chapter provide a broader perspective on the application of intelligent sensor devices in a variety of multidisciplinary fields such as Intelligent Transportation Systems, Healthcare, Agriculture, Drone Communications, and Security. This chapter guides the reader through the utility and improvements in intelligent sensors and their applications in a variety of study domains by providing an insight into intelligent sensors for industrial IoT.

Creating smart factories offers a fantastic chance for the manufacturing industry to reach the fourth industrial revolution. The analysis of massive volumes of big data generated from factory floor sensors provides real-time visibility of industrial assets. It can give tools for undertaking predictive maintenance in order to reduce downtime on equipment (Kumar et al. 2021a).

Using increased IoT devices in smart factories accelerates output and improves quality. Using Intelligence visual analytics to replace traditional business evaluation models reduces manufacturing errors while also saving money and time. Quality control personnel may monitor manufacturing activities from practically anywhere using a cellphone connected to the cloud. ML algorithms can help manufacturers discover flaws relatively soon, when fixes are more difficult (Talavera et al. 2017).

The principles and technologies of Industry 4.0 may be used in a variety of industries, including continuous and process production, and also oil and gas, mining, and other sectors.

The IoT promises to bring the same benefits to everyday objects as its widespread application has brought countless benefits to rural citizens around the world in the last two decades. The most adorable benefit was the ability to consume and produce data and services in real-time, which the IoT promises to bring the same benefits to everyday objects. Environmental monitoring is a broad use of the IoT that includes everything from monitoring Ozone levels to protecting national forests from smoking. With the use of Bluetooth, data from each node is transferred to a central node. The characteristics of environment monitoring sensors are shown in Table 1 for each center, which consists of five sensors with properties given in Table 1. The sensors used in environmental monitoring are listed in Table 2.

Table 1 Common details of SODAR-based meteorological sensor network (Chourey et al. 2022b)

Parameter	Sensor/Model	Sensitivity	Range
Atmospheric Boundary Layer Height (ABLH)	Monostatic SOnic Detection And Ranging (SODAR)	10 m	50–3000 m
Wind speed	Barani-MeteoWind-2	0.1 m/s	0–89 m/s
Wind direction	Barani-MeteoWind-2	1 degree	0–359 degree
Temperature	Barani-Meteotemp RH + T	0.3 °C	0–80 °C
Relative humidity	Barani-Meteotemp RH + T	1%	0–100%

Analysis of the Web and Social Media

The exponential expansion in data quantities across the Internet has stemmed from the tremendous increase in the number of computer and mobile devices in use. In 2016, 3.3 million Facebook posts, 448,800 tweets, 65,972 images, and 3.8 million Google queries are predicted to be generated each minute of Internet activity (Allen 2017). Social media data includes blogs, chats, or remarks on internet sites (e.g., news pages), blogging (Twitter), community projects (e.g., Wikipedia), social media platforms (Facebook and LinkedIn), and internet forums (e.g., YouTube and Instagram) (Olsen and Christensen 2015). Followers, shares (or retweets), likes, comments, mentions, and metadata linked with the material are all examples of metrics that may be derived from social media content provided by users. Depending on what the user wanted to reveal, the metadata connected with their activity may contain information like age, nationality, education, career, geolocation, and more.

In a nutshell, social media data is information acquired from social networks that indicates how people share, view, or interact with a user's or organization's content or profiles. As the most prominent example, people who "like" Facebook pages of corporations see brand page updates and material in their news feed. This allows companies to communicate with individuals who like or follow their pages, as well as the other way around. Almost every food company has a social presence, with a large number of individuals who follow their Facebook pages and so participate in the social interaction and data production process (Misra et al. 2020). The goal of a typical social big data analysis is to extract important information chunks from a massive quantity of complicated user-generated content (typically expressed verbally or visually) and assist government, industry, or stakeholders in making informed decisions (Fig. 9).

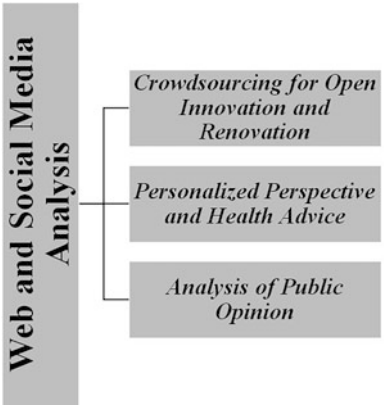

Fig. 9 Types of web and social media analysis

Case Study

Over the last century, meteorological measurements have grown in importance for aviation safety, especially with the start of the aviation age and the introduction of numerical weather prediction models. In the early decades of the twentieth century, humans gave these observations, but as technology evolved, sensors that could take many of the same types of observations autonomously were developed. As these sensors became more common, human weather watchers began to rely on them for the more basic measurements such as temperature, relative humidity, wind, etc., while concentrating on the more subjective ones.

A case study on Delhi to enumerate the fusion of remote sensing technique, meteorological sensors, and IOT for Industry 4.0 is elucidated. The revolutionization of industries imposed greater demand on ensuring stringent regulation on pollution load. Vivid parameters are taken into consideration while understanding the role of Atmospheric Boundary Layer (ABL) had been relevant. The manifestation of ground-based acoustic remote sensor, the Sound Detection and Ranging (SODAR) deployed for probing the lower layer of atmosphere is deeply understood. The fumigation period, stability layer, and the convection period are inevitable while considering the Environmental Impact Assessment (EIA) of Industrial set up. It is internationally recognized and recommended by the Environmental Protection Agency (EPA) for air quality dispersion modeling in EIA (Iyer and Raj 2013). SODAR is a cost-effective instrument for real-time monitoring of ABL height up 1–2 km. ABLH-derived ventilation coefficient (VC) is imperative to comprehend the dispersion and assimilative capacity of pollutants by the atmosphere over a locus (Gera et al. 1996). It is the need of the hour of Industry 4.0 era to contemplate the pollution aspect for ensuring environmental safeguard and sustainable enhancement of the resources.

CSIR-National Physical Laboratory (NPL) New Delhi had successfully initiated the task of development of SODAR for effective monitoring of ABL structures. Numerous modifications were undertaken and thereby the growth of industrialization demanded the incorporation of the study of ABLH for the pollution abatement plans and strategies. Wherein CSIR-NPL has been successful in installing SODARs at seven locations over India, which include Central Pollution Control Board (CPCB) and NPL at New Delhi; Indian Institute of Technology (IIT), Roorkee; Aligarh Muslim University (AMU), Aligarh (Uttar Pradesh); Indian Meteorological Department (IMD) Hisar (Haryana), Rajasthan State Pollution Control Board (RSPCB) Alwar (Rajasthan); Punjab Pollution Control Board (PPCB) Sangrur (Punjab). Here, an analysis of meteorological parameters along with ABLH using meteorological sensors and SODAR to study characteristics of ABL over seven different sites is provided. Basic variables such as relative humidity, wind speed, and temperature may be utilized to assess the boundary layer processes and thermodynamic structure. Lower tropospheric phenomena, air pollution modeling, weather prediction, and environmental monitoring might all benefit from the network of meteorological sensors and SODAR. The next part discusses a comprehensive comparative study of different climatic factors and ABLH among the selected sites.

Atmospheric Boundary Layer Height (ABLH)

The ABLH during the period from March 2020 to February 2021 is analyzed for this case study. Fig. 10 shows the ABLH for the selected seven locations. The above two graphs are from the CPCB and CSIR-NPL. The bottom five graphs are from the Aligarh, Alwar, Roorkee, Sangrur, and Hisar. The data is not consistent throughout the year and therefore month-wise seasonal analysis is also presented in the upcoming sections. In Fig. 10, daily average variation with maximum and minimum values during each day is plotted.

The data set has a temporal value (1 h = one value) for 12 months (March 2020 to February 2021). The dataset has been classified into four seasons based on North Indian meteorology, namely, summer or pre-monsoon (March to June), monsoon (July to Sept), post-monsoon (Oct to Nov), and winter (December to February) for the analysis of seasonal ABLH. All seasons ABLH is presented in the Fig. 11 (a, b, c, and d).

The maximum value of ABLH is observed during summer season while the minimum height is found during monsoon. Summer in general has large growth rate compared to other seasons. The growth is found to significantly diminish during onset of monsoon season and winter season. The ABL achieved height ~2 km during summer season. Slightly higher value tends to occur during post-monsoon than during monsoon. The governing components of the atmosphere were analyzed to characterize the fluctuation in various seasons (temperature, relative humidity, and wind speed). The vigorous mixing caused by the strong solar radiation causes the ABLH to be high in the summer. High RH means that there is more moisture in the air, which promotes intense convection and the formation of ABLH. The high ABLH throughout the summer was due to significant insolation generated by solar heating and convection.

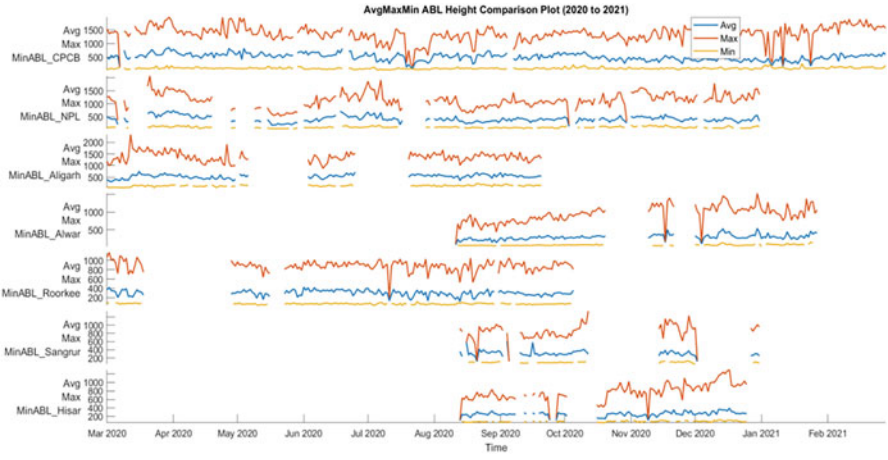

Fig. 10 ABLH Comparison of ABLH for Delhi (two locations), Aligarh, Alwar, Roorkee, Sangrur, and Hisar

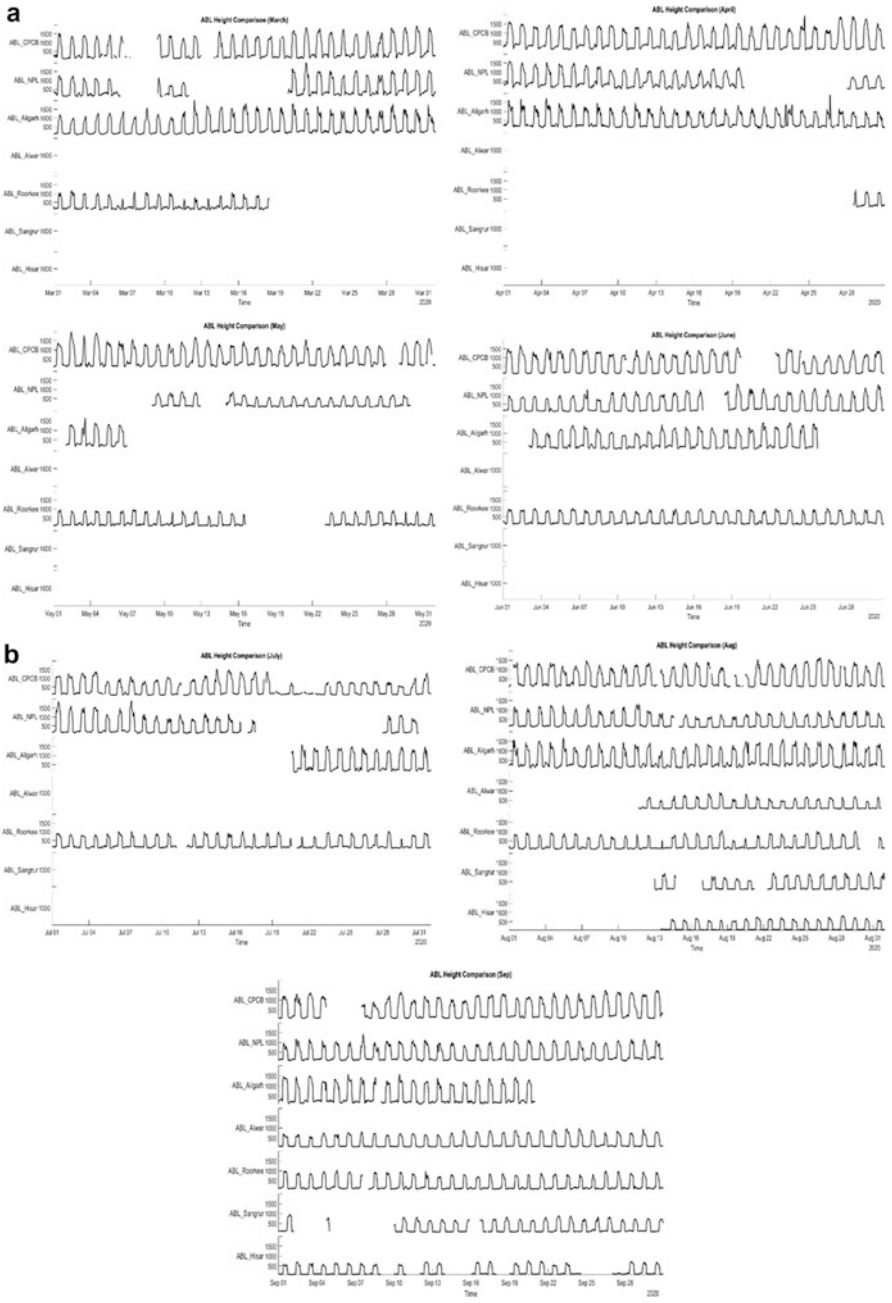

Fig. 11 (**a**) Pre-monsoon season ABLH. (**b**) Monsoon season ABLH. (**c**) Post-monsoon season ABLH. (**d**) Winter season ABLH

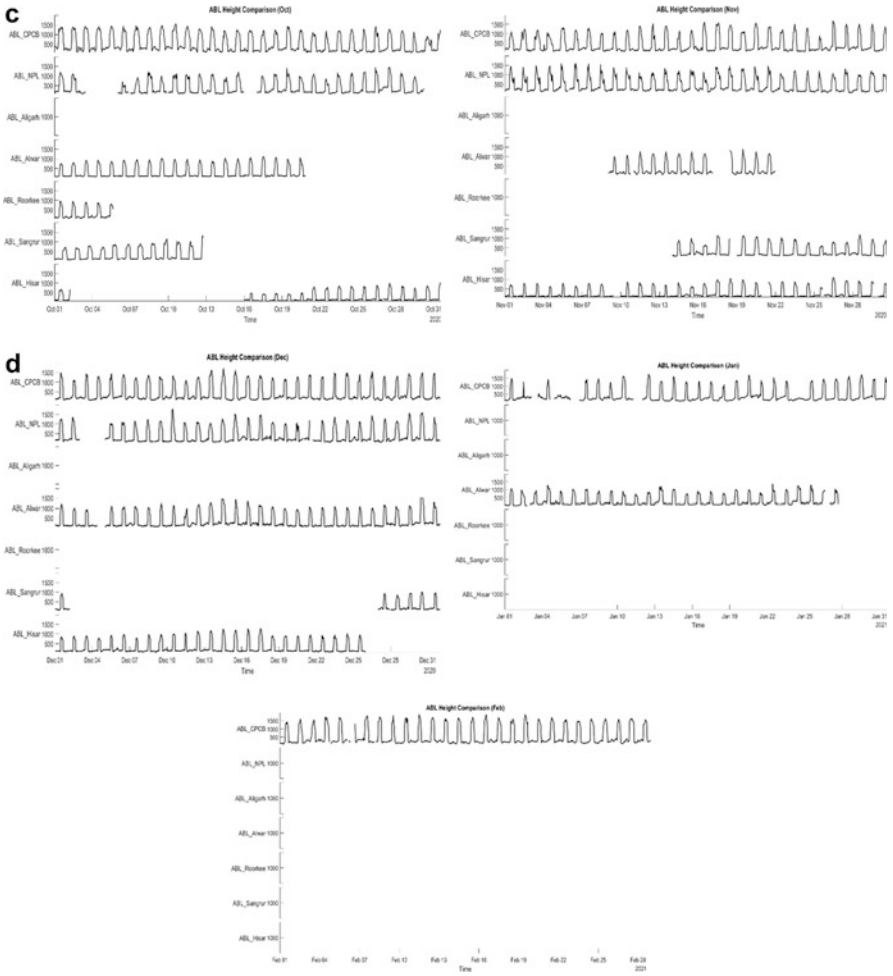

Fig. 11 (continued)

Overall, Aligarh had the highest ABLH at 2340 m; this was followed by NPL (2180 m), CPCB (1970 m), and Alwar (1860 m) (1573 m). Roorkee, Hisar, and Sangrur were to be the locations with ABLH maximums less than 1500 m. Roorkee (1390 m), Sangroor (1340 m), and Hisar (1360 m) had the highest ABLs (1290 m).

For all the seven sites, it was found that there are 2 months (August and September), which fall in commonality and thereby a comprehensive comparative study was performed for these 2 months. Variability in maximum and minimum ABLH during 2 months was stimulated through the following observatory analysis. It was found that the ABLH for Aligarh site (1680 m) was found to be maximum followed by CPCB (1650 m) and NPL (1440 m). Alwar and Hisar had maximum

ABLH of 990 m and 830 m, which was found to be the lowest maximum ABLH in comparison to other sites. Minimum ABLH fluctuated between 40 m and 90 m among these sites. Where Aligarh, CPCB, NPL, Roorkee, and Sangrur witness maximum increase of more than 1 km in their ABLH, Alwar and Hisar showed a data with maximum ABLH reaching just below 1 km. The minimum value of ABLH in all sites were witness to be less than 100 m with lowest shown by NPL having minimum ABLH of just 40 m on 12.09.2020.

Having an observatory analysis on the diurnal variation in these 2 months, it was noted that in Aligarh and CPCB the convective period during the selective months started even early at 7.00 IST and lasted till 17.00 IST. Whereas in the other sites, the convective period started at 9.00/10.00 IST, which is 2–-3 h late from the Aligarh. However, it was found that the duration of convective period over Sangrur was less in comparison to other sites. On a whole, it was figured that the rate of convection period was found to be of shorter duration for Roorkee and Sangrur. Due to the data inconsistency, the comparative meteorological parameter analysis is performed for the August and September months only.

Meteorological Parameters Analysis

It was found that the temperature in these sites ranged from ~19 °C to ~38 °C. The lowest temperature was found for Roorkee and Sangrur on different durations of time period for number of days. Since temperature has a positive correlation with the ABLH, low temperature induces maximum of inversion and low ABLH, clarifying the fact that Sangrur exhibiting minimum duration of convection period. The temperature range of Roorkee (24–36 °C), Sangrur (22–35 °C), Hisar (19–38 °C), Alwar (23–38 °C), CPCB (24–37 °C), Aligarh (26–37 °C), and NPL (24–37 °C). The temperature variation over these sites is depicted in Fig. 12.

On average, Aligarh's ABLH was found to be the highest, followed by CPCB and NPL. After already being warmed by solar radiation, the surface quickly passes the heat into the air via the ABL's turbulent motion, changing wind, temperature, and humidity, as well as modifying the ABL's thickness. The evolution of ABLH is influenced by the temperature. The next session provides a quick overview of the impact of temperature on ABLH accomplishment.

Sunlight is visible throughout the day but not at night. The lack of convection at night causes vertical stratification, which is eroded by daytime convection. During the day, the efficacy of erosion is influenced by the quantity of cloud cover. A dense layer of clouds may block much of the Sun's rays, reducing the amount of heat that reaches the Earth. Convection often engulfs the lowest 1–2 km of the atmosphere due to mixing processes. The night usually ends with a shallow nocturnal boundary layer (NBL), which is created by wind friction and causes mixing. The thickness of this layer varies depending on the prevailing wind velocity and the surface roughness, although it seldom surpasses 300 meters. Due to heat loss to space throughout the night, the air above the NBL is mildly stratified. Convective movements swiftly exceed wind shear turbulence as the sun rises, heating the atmosphere from below. Penetrative convection

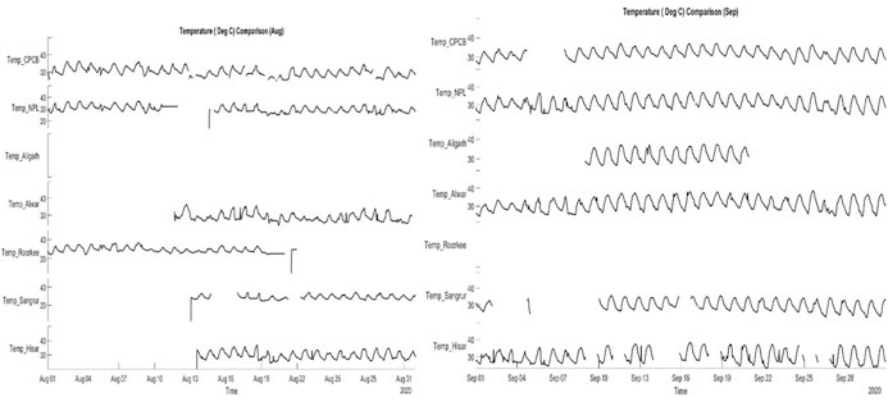

Fig. 12 Comparative analysis of daily variation in temp. (°C) for 2 months across seven sites

then takes over, gradually dissolving the stratified layer that formed throughout the night and replacing it with the convective boundary layer (CBL). Penetrative convection may be rather quick depending on how thin the stratification was above the NBL. Except near the base of the CBL, where both have comparable strength, wind-induced turbulence is substantially less than convection-induced turbulence. The surface layer is the lower layer, while the CBL is the remainder of the convective zone. The developing convective zone finally reaches the same height as the previous day as time passes (assuming perfect repeatability from 1 day to the next). Convection is halted when heat input from the surface is reduced after sunset, and the CBL transforms into an un-agitated fossil mixed layer known as the residual layer. Wind builds a fresh NBL near the ground by causing friction.

The thickness of the ABL is determined by the amount of water evaporated into the air and the degree of surface heating. In terms of humidity, NPL had 32–93%, CPCB had 36–98%, Alwar had 24–98%, Aligarh had 49–89%, Hisar had 32–92%, Roorkee had 58–98.4%, and Sangrur had 45–85%. Humidity and ABLH have an anti-correlation. Figure 13 depicts the difference in RH (%) among seven distinct sites.

Taking wind speed into account, the wind speed of NPL was found to be in the range of 0.1–4.1 m/s, for CPCB it was 0.47–7.31 m/s, for Alwar it was in range of 0.1–5.3 m/s, for Aligarh it was 0.1–2.3 m/s, for Hisar it was 0.1–1.2 m/s, for Roorkee it was 0.1–3.5 m/s, and for Sangrur it was 0.1–5.1 m/s. The wind direction or wind speed shear was able to accelerate turbulent and molecule motion from the ground up, causing heat convection to rapidly diffuse to high altitude, which was favorable for the formation of a deep boundary layer. Strong wind speed or wind direction shear reduced the strength of the temperature inversion at the top of the CBL by boosting the diffusion and entrainment effect, which carried sensible heat flow from the ground to the upper air and enhanced convection efficiency. This would greatly increase CBL and provide a dynamic environment that would encourage the production of ultra-thick CBL. Figure 14 depicts the variance in wind speed at seven locations.

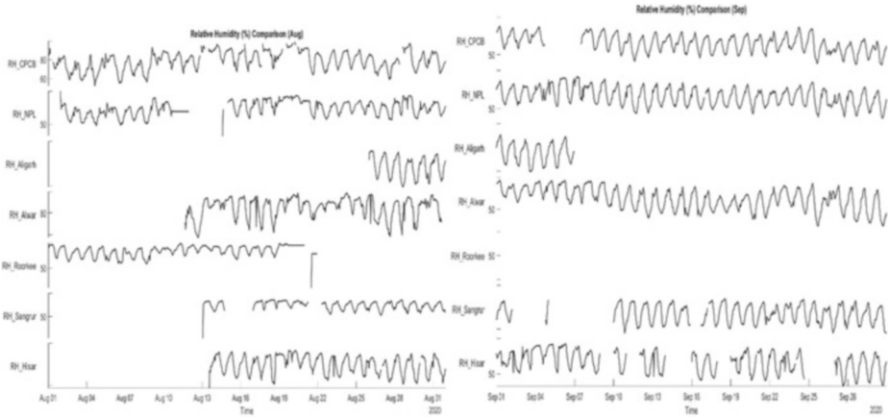

Fig. 13 Comparative analysis of daily variation in RH (%) for 2 months across seven sites

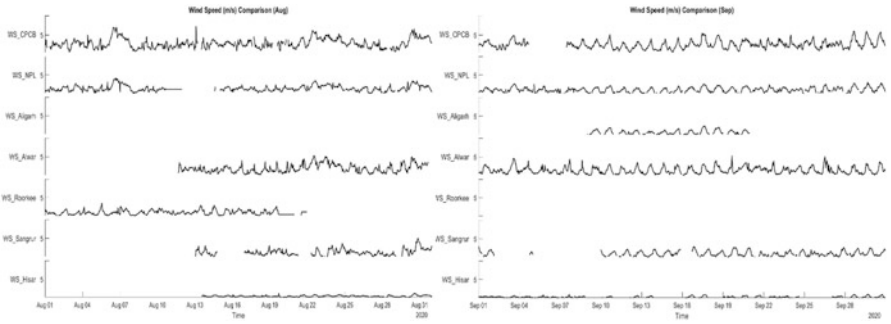

Fig. 14 Comparative analysis of daily variation in wind speed (m/s) for 2 months across seven sites

The range of wind speed showed highest wind speed for CPCB. Wind induces turbulence and causes increase in ABLH, thus sharing a positive correlation with wind speed. Thereby high wind speed can be known as a predominant factor for increased ABLH during the course of selected time interval of 2 months.

Correlation Analysis

The ABL is a turbulent, dynamic system in which horizontal and vertical air mixing is largely determined by weather and geomorphology (Bendl and Hovorka 2017). ABL shows diurnal variation with convective and stable boundary layer formation due to the influence of surface fluxes (net radiation and sensible heat) and turbulence (Mehta et al. 2017). Meteorological parameters are vital in the development of ABL. It is inferred that the ABL is more positively correlated with wind speed and temperature and more negatively correlated with RH. As the temperature increases,

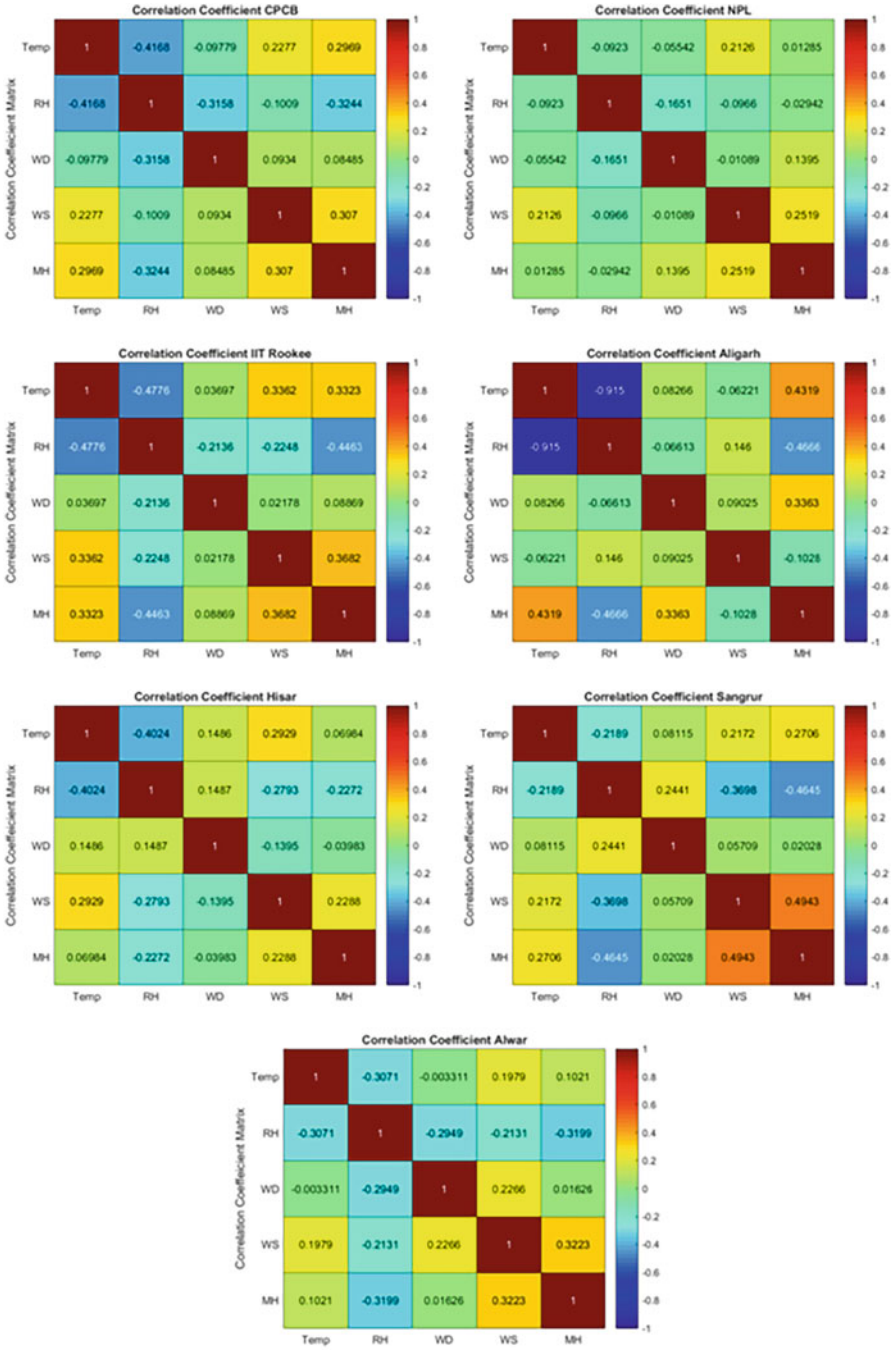

Fig. 15 Correlation analysis between the ABLH, temperature, relative humidity, and wind for seven locations

the sensible heat flux eventually increases resulting in increased boundary layer height. Similar increased turbulence due to high wind speed induces elevation in ABLH.

Strong negative correlation states the anti-correlation of RH with ABLH. The correlation between the meteorological parameters shown in Fig. 15 clearly indicates the influence of these parameters on ABL.

The case study clearly presented in this chapter is to give brief understanding about the importance of having a network of meteorological sensors and remote sensing for monitoring of air quality in a specific region. The integration of advance technology such as IoT and AI makes the monitoring and controlling more effective.

Conclusion

Together with environmental monitoring, smart sensor products may undoubtedly build an internal or even worldwide information network, combining IoT with industrialization. As a result of this tendency, the goal of Industry 4.0, i.e., a sustainable growth with a fully context-sensitive, controllable, describable, manageable, and self-regulating production system, is becoming a reality. It may be concluded that a smart and novel environmental monitoring system is required for the fast-growing Industry 4.0. The IoT-enabled sensor network is a new way to establishing "a Comprehensive Broadband Infrastructure" that focuses on the field of "Computer Networks and Communications." This chapter provides a comprehensive overview of the Industrial Revolution, encompassing invention and application, technology, protocol, and standards. Furthermore, this chapter demonstrates how smart gadgets are evolving across the world, with a substantial trend that has already spread from people's daily lives to the global industry. The case study given in this chapter highlights the need of a linked monitoring network for regional air quality measurement as a key aspect of Industry 4.0 for attaining sustainable growth. Chips, terminals, base stations, networks, software tools, testing devices, operating systems, and APPs will all be affected by Industry 4.0, as connected smart devices all over the world will provide secure, real-time, and reliable sensing, communicating, and computing services via the Internet, affecting the following aspects: chips, terminals, base stations, networks, software tools, testing devices, operating systems, and APPs. The regulatory authorities' decision-making is greatly improved by the AI and IoT-enabled environment monitoring system.

Abstract

This work reviews the recent techniques used to analyze the EMG signals to extract and classify features. The discussed techniques are used in medical applications for the diagnosing of neuromuscular disorders. Techniques such as wavelet transform (WT), principal component analysis (PCA), empirical mode decomposition (EMD), artificial neural network (ANN), support vector machine (SVM), extreme learning machine (ELM), k-nearest neighbors (kNN), and deep learning are among the powerful techniques used for feature extraction and disease classification. The many improvements made to the algorithms could increase the performance and accuracy of the models discussed in this area. Recently, the researchers focused their attention on the classification of

neuromuscular illnesses using artificial intelligence to acquire and classify myoelectric signals via electromyography (EMG). Amyotrophic lateral sclerosis (ALS) is one of the neuromuscular illnesses that drives the attention of the researchers in this field. The current work focuses on the most recent methods for extracting and categorizing characteristics from EMG data to diagnose neuromuscular disorders in medical applications. Feature extraction approaches presented here include the wavelet transform (WT), principal component analysis (PCA), and empirical mode decomposition (EMD). Artificial neural networks include artificial neural networks (ANNs), support vector machines (SVM), extreme learning machines (ELM), k-nearest neighbors (kNN), and deep learning. An example on the uncertainty evaluation in machine learning classification is introduced.

Introduction

Machine learning is a successful soft metrology application for extracting data and developing models from a certain database collection. The current work gives substantial information on measurement error in neuromuscular classification models.

Machine learning is based on recording signal data and loading into a machine to be automatically assessed. This work demonstrates the distinction between normal and abnormal signals, allowing the abnormalities in the human body to be identified. In biomedical engineering, machine learning is a potential tool for disease classification. It is concerned with extracting information from raw data signals using mathematical operations to be developed and analyzed (Fig. 1). If such techniques are developed to manage massive data connected to medical operations, they can be valuable for biomedical engineering. Since machine learning approaches have developed in many fields addressing categorization, biological signals can now be evaluated in multiple dimensions (Szkoła et al. 2011; Mannini et al. 2016; Balli and Palaniappan 2009; Ene 2008; Mierswa et al. 2006; Kordylewski et al. 2001; Lanyi and Adler 2004; Raez 2006; McCool et al. 2014; Berger et al. 2006). Supervised learning tools are examples of machine learning approaches applied in diagnostic and disorder classification (Ene 2008; Mierswa et al. 2006). Machine learning techniques are trained on a set of data and then used to reduce massive time series signals to optimally discriminated features (Kordylewski et al. 2001).

EMG is a useful diagnostic tool for studying the electrical signals generated in a muscle during contraction (Lanyi and Adler 2004). It has been widely employed by physicians and researchers for the diagnosis of neuromuscular problems in recent decades. The term “neuromuscular disorder” refers to a variety of disorders affecting

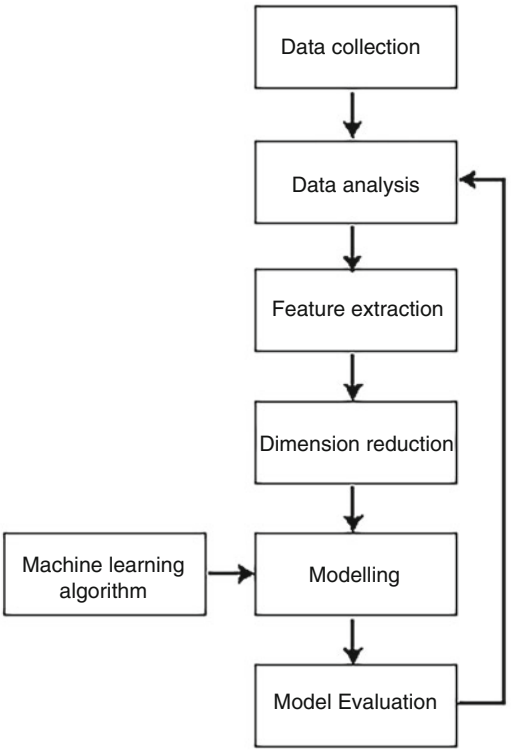

Fig. 1 Machine learning framework

the neurological system or muscle fibers. ALS is a neurodegenerative illness that affects the spinal cord and is classified as a form of neuromuscular disorder known as motor neuron disease. Another important category of neuromuscular condition is myopathy, which refers to a set of disorders that affect skeletal muscle tissue (Raez 2006). It's necessary to have an accurate diagnosis of these disorders in the early time in order to manage and treat them. In this chapter, a variety of classification and feature extraction strategies are discussed for the diagnosis of neuromuscular illnesses.

Detection and Processing of EMG Signal

The electromyographic (EMG) signal is a biological signal that detects the electrical currents generated in a muscle during contraction, resulting in neuromuscular activity (McCool et al. 2014). The smallest functional unit that can describe brain control during muscle contraction is the motor unit (MU). The motor unit action potential (MUAP) is a collection of action potentials generated by all muscle fibers in a motor unit. Noninvasive and invasive procedures can both be used to measure

MUAPs. The noninvasive technique uses EMG electrodes placed directly on the skin surface, whereas the invasive technique uses needle electrodes that penetrate muscle tissue to acquire EMG data.

The noninvasive technique, on the other hand, appears to be more flexible, but it only detects the total of actions from various motor units. Invasive techniques can detect the potentials of a single motor unit, providing additional information regarding muscle activity.

Many researchers use the EMG signal as a source of data, while developing diagnostic tools for neuromuscular illnesses. They preprocess the raw information acquired by the EMG electrodes, identify relevant features, and then classify the input signal into distinct categories using a classification technique (i.e., healthy, myopathy, and ALS patients). The major procedures for diagnosing neuromuscular diseases using EMG signal analysis are EMG signal acquisition, signal processing, features extraction, and signal classification.

Key features are extracted from the acquired EMG signal and used as input to the classification stage. The extraction and selection of features are critical for improving classification performance in the diagnosis of neuromuscular illnesses. Frequency domain (FD) features, time domain (TD) features, and time-frequency domain (TFD) features are the three types of features that can be retrieved from a non-stationary signal like EMG.

The TD aspects are analyzed by focusing on signal amplitude, which is a function of time and is affected by muscle types and cases at the time of observation. This kind requires no further signal manipulation and has the simplest analysis. The parametric approaches are applied to the power spectrum density of the signals to compute the FD characteristics. Combining TD and FD yields TFD features, which characterize frequency variation at different temporal locations on the signals (Berger et al. 2006).

To extract TD, FD, or TFD characteristics from EMG signals, several researches used wavelet transform, empirical mode decomposition, principal component analysis, and cepstral analysis.

Principal Component Analysis (PCA)

PCA is a statistical technique that has been widely employed in the analysis of biomedical signals. It's a nonparametric method for extracting important data from large datasets (Kehri et al. 2017). Data patterns can be compared and contrasted using PCA. The data dimensionality can be decreased without losing much information by finding patterns (Shaw and Bagha 2012). PCA is the most prevalent technique for dimensionality reduction for these reasons, and it may be used effectively to analyze big datasets of EMG signals (Fig. 2). The PCA algorithm is shown in Fig. 3 according to Garrone (2020).

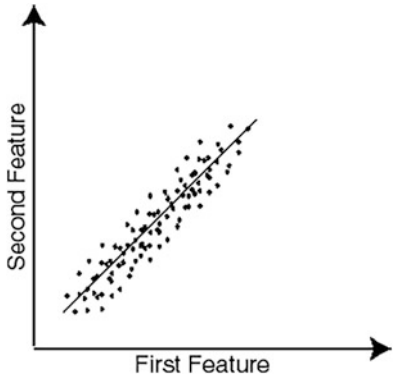

Fig. 2 Principal component analysis for two features

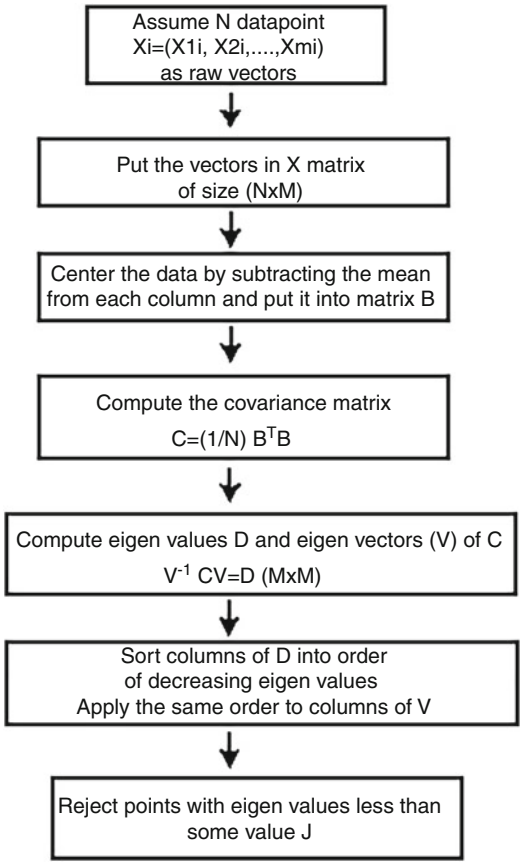

Fig. 3 The flow chart of PCA algorithm

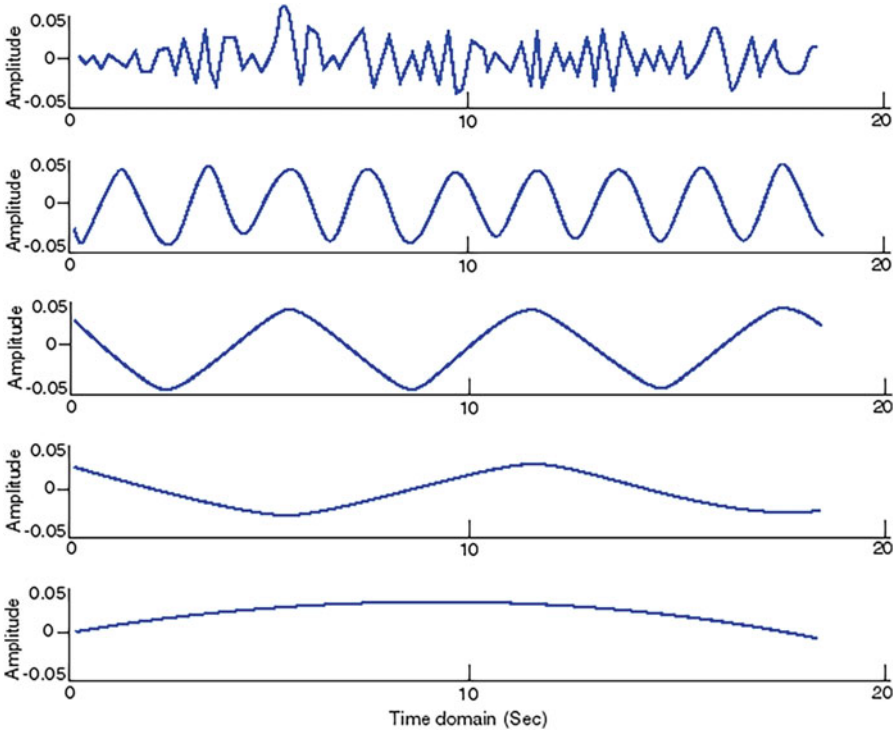

Fig. 4 Reduction of a simulation signal by EMD

Empirical Mode Decomposition (EMD)

The EMD methodology does not rely on an external decomposition function. Instead, it is a self-adaptive time-space analytic method that decomposes nonlinear and nonstationary signals like the EMG signal. It can keep the signal's temporal domain while decomposing it into many intrinsic mode functions (IMFs). IMFs must meet two main requirements, that is, only one difference between the number of zero crossings and the number of extrema should exist and the local average between the upper and lower envelopes should be zero. The EMD can be used in a variety of audio, biomedical, and image processing applications (McCool et al. 2014). EMD is very beneficial for processing complex nonlinear and nonstationary signals (Fig. 4). Figure 5 shows the algorithm of EMD method according to Cura et al. (2020).

Wavelet Transform (WT)

To handle nonstationary signal issues, the WT describes the time function in simple block form. Such blocks are a collection of functions formed from a wavelet using translation and dilation. In all frequency ranges, this approach delivers the best time-

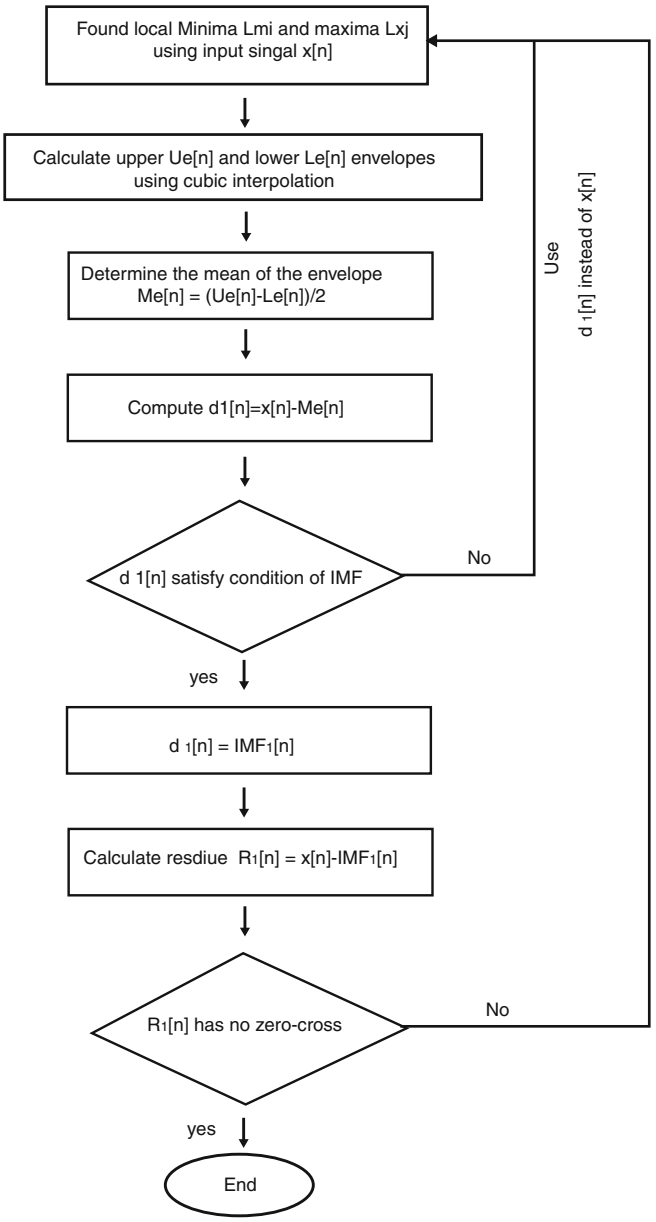

Fig. 5 The flow chart of EMD algorithm

frequency resolution (Kehri et al. 2017) (Fig. 6). Since it gives both time and frequency information at the same time, the discrete wavelet transform (DWT) can be used in a variety of biomedical engineering signal processing applications, such as EMG signal processing. The discrete Fourier transform (DFT), on the other hand,

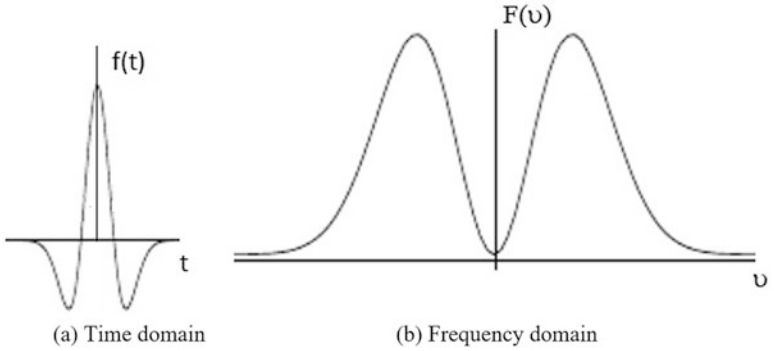

Fig. 6 (**a**) Wavelet in time domain and (**b**) its transform in the frequency domain

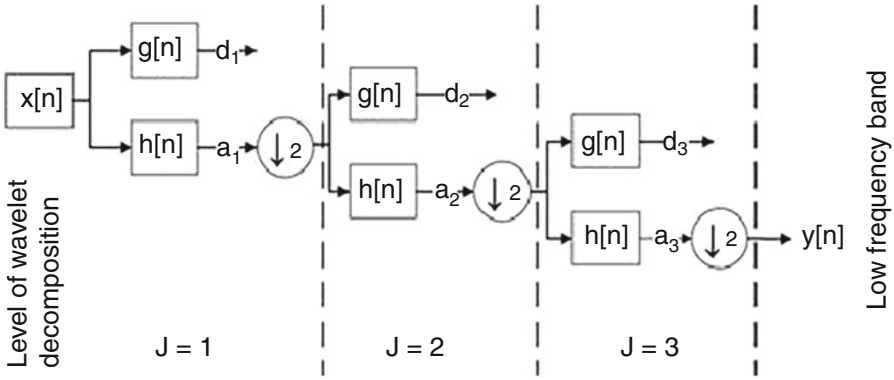

Fig. 7 Flowchart of multi-resolution wavelet decomposition (Alzaq and Üstündağ 2018)

is exclusively confined in the frequency domain (Khan and Hasan 2015). Many researchers have utilized DWT to extract features from EMG signals in order to classify neuromuscular diseases (Kehri et al. 2017; Khan and Hasan 2015; AbdelMaboud et al. 2015; Khan et al. 2016; Meena and Bansal 2016; Subasi et al. 2018). Figure 7 shows a diagram for wavelet decomposition, the block diagram of the two-channel four-level discrete wavelet transform decomposition (J = 3) that decomposes a discrete signal into two parts.

Classification Approaches

Classification approaches such as k-nearest neighbors-kNN, artificial neural network-ANN, support vector machine-SVM, and deep learning have been employed by many researchers. This section gives a quick overview of each of these methods.

K-Nearest Neighbors (kNN)

A distance function, such as the Euclidean distance function, is evaluated between a test set and k-neighboring points from normal and diseased participants in the kNN classifier. In classifying the test record, the labels of the k-nearest pattern are employed with the k values offering the best classification accuracy.

The kNN can calculate the distances between the test record and the signal records and display the k records with the least distance in ascending order. In pattern recognition, on the other hand, it can be used to classify objects based on the closest training examples defined in the feature space (Bhuvaneswari and Kumar 2016; Fattah et al. 2013). This method takes a long time and is based on learning by relationship using the Euclidean distance, with the unknown record being chosen as the most well-known class among its k-nearest neighbors (Witten et al. 2011; Saxena 2016) (Fig. 8).

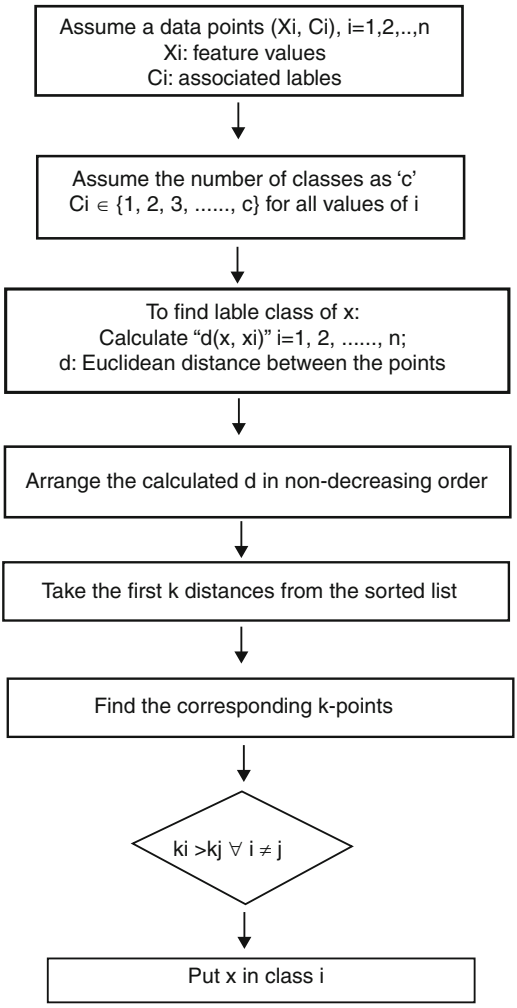

Fig. 8 Flow chart of kNN algorithm

Artificial Neural Networks (ANN)

ANNs are commonly employed in biomedical engineering to analyze data because of its effectiveness, quick recognition, and real-time diagnosis. The ANNs are trained by examples rather than by own emotional states, exhaustion, or environmental circumstances (Sharma et al. 2010).

The key feature here is the capacity to accurately simulate system complexity in input and output data using either linear or nonlinear analogies. Using transfer functions and connection settings, data is taken from an external source and transported to subsequent layers.

In pattern recognition and signal processing, the back propagation (BP)-based neural network offers a wide range of applications (Priyadharsini et al. 2015; Elamvazuthi et al. 2015). It's a multilayered structure. As a result, the data is passed to the input layer, which is connected to hidden layers with weights and then to the output layer, which produces the required output (Fig. 9). If the expected and actual outputs are not identical, the error is evaluated to update the weights, and the procedure is repeated until the error is removed (Singh et al. 2017).

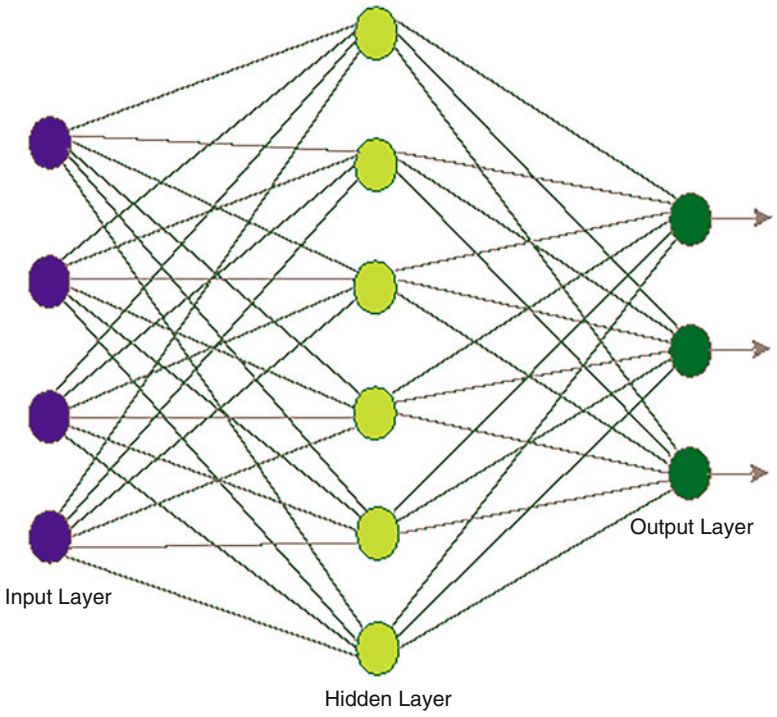

Fig. 9 Artificial neural network

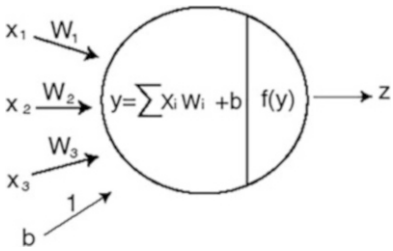

Fig. 10 Schematic diagram for a neuron function

The neuron is the main constituent in biological networks that performs computation. The connection weights manage the input signals, which are then aggregated and compared to a threshold value, which is the neuron's bias. An activation function controls the output signal (Fig. 10).

In Fig. 7, x_1,x_2,x_3 denote the inputs, while w_1,w_2,w_3 are the weights, and b is a bias. The neuron then performs a function to compute the output z.

Hidden layers occur between the input and output layers in a multilayer feed-forward network, and the neurons are linked layer by layer (Zhou 2012). Figure 11 shows a flow chart of ANN according to Illias et al. (2015).

Support Vector Machine (SVM)

It is the most accurate binary classifier for pattern recognition, and it uses a hyperplane to characterize the margin to distinguish distinct classes of data (Fig. 12). SVM models can be linear or nonlinear. The data points in the linear one are separated by a gap, and straight hyperplanes can be utilized to divide classes. Nonlinear classifiers are recommended in some circumstances where linear SVMs are ineffective. Multiclass classifications (Fig. 13) utilize one-against-all (OAA) and one-against-one (OAO) relationships in nonlinear SVM classification (Witten et al. 2011). Figure 14 shows a flow chart of evolutionary SVM according to Subasi (2015).

Deep Learning

Deep learning can deal with vast amounts of high-dimensional data with a large number of features. Auto-encoders, deep belief networks, deep Boltzmann machines, convolutional neural networks, and recurrent neural networks are examples of deep learning (Alaskar 2018). The most successful deep learning model is convolutional neural networks (CNNs) (Fig. 15). They are self-learned and self-organized networks that have lately been applied in the classification of biological data.

Diagnosing Neuromuscular Disorders by Machine Learning

The steps of diagnosing neuromuscular disease are shown in Fig. 16 including feature extraction and classification.

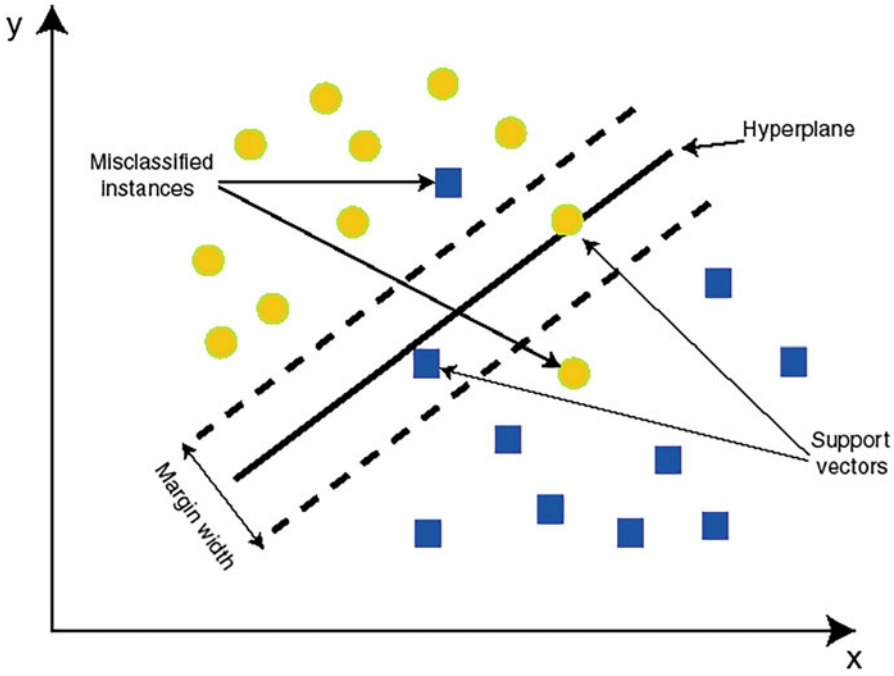

Fig. 12 A structure of support vector machine used in generating the input-output mapping from training dataset

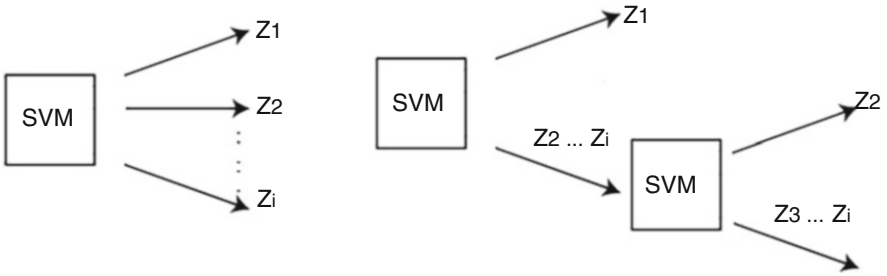

Fig. 13 Single multiclass and multistage SVM

The probabilistic neural network (PNN) was employed in Shaw and Bagha (2012), to classify the surface EMG output and distinguish between normal, myopathy, and neuropathy patients. The study was capable of extracting useful clinical information from simultaneously acquired EMG signals. They could provide a clustering technique to classify the signals with sufficient accuracy and speed and gave online information on patients' status. PCA was used to extract features from the signal. With respect to pattern length, the accuracy of the PNN obtained varies between 85 and 98%, yielding an average classification rate of 91.72%.

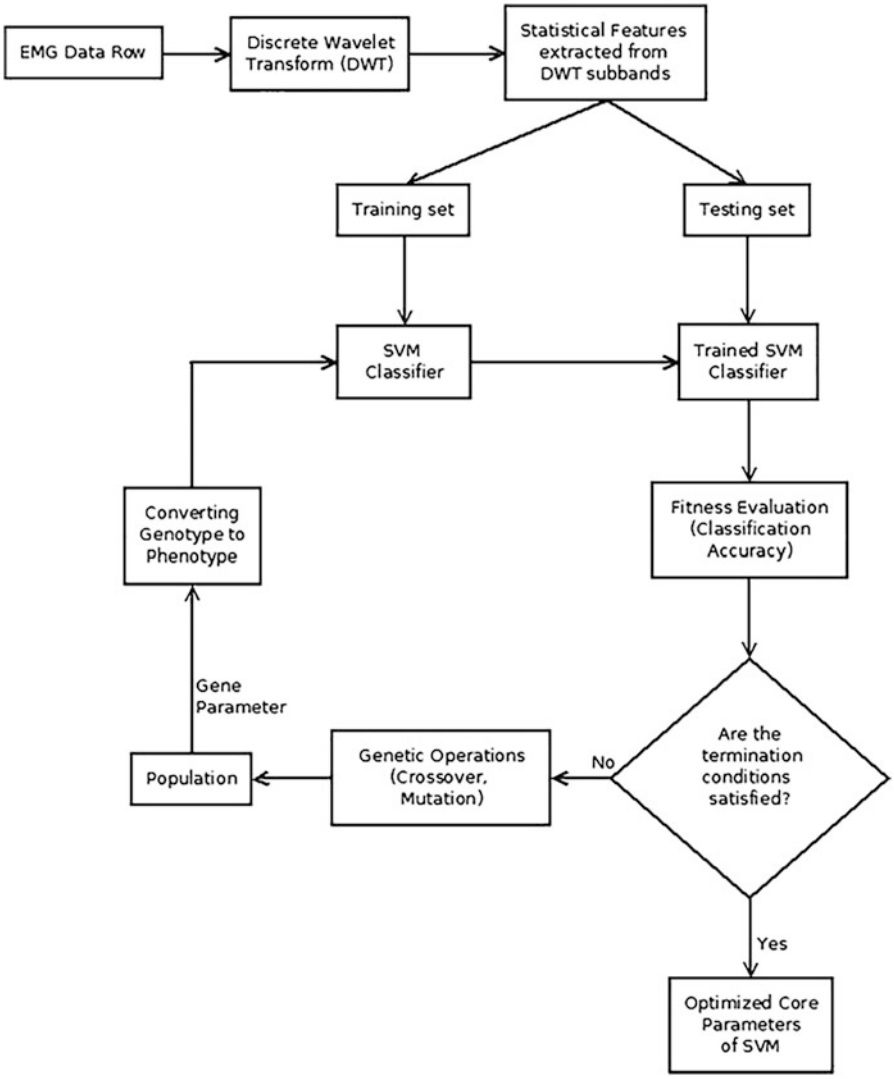

Fig. 14 Flowchart of evolutionary SVM showing feature extraction, training, and classification (Subasi 2015)

A multilayer perceptron neural network with a backpropagation algorithm was used in Elamvazuthi et al. (2015), to analyze EMG signals from 15 patients' biceps muscles (5 healthy, 5 myopathy, and 5 neuropathy). One hundred samples were randomly selected from the signal for each class (60 for training, 20 for validation, and 20 for testing). Five distinct feature extraction algorithms were used, including root mean square (RMS), zero crossing (ZC), AR, waveform length (WL), and mean absolute value (MAV). Five separate datasets (healthy/unhealthy (abnormal),

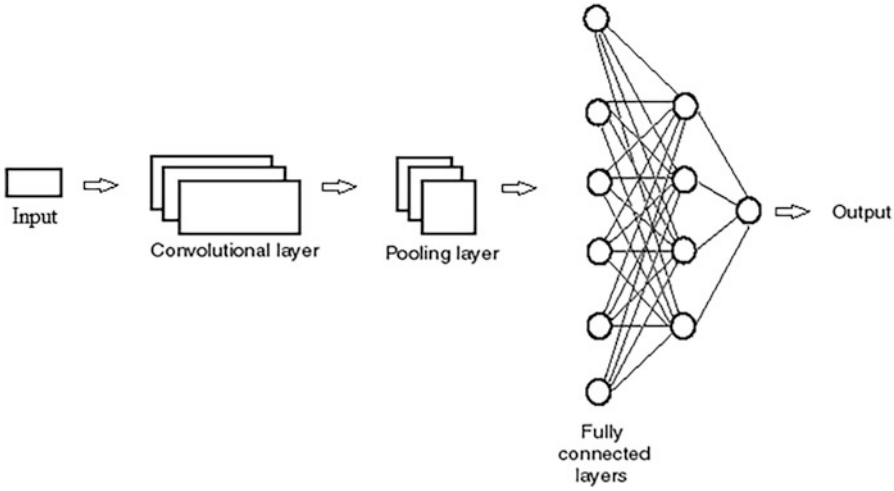

Fig. 15 CNN for deep learning

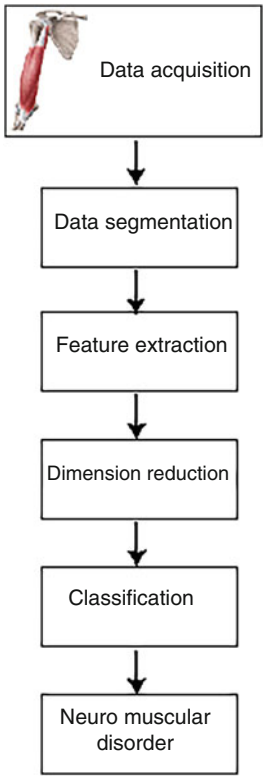

Fig. 16 Neuromuscular disorder classification framework

healthy/myopathy, healthy/neuropathy, myopathy/neuropathy, and healthy/myopathy/neuropathy) were created using the output data from the feature extraction procedure.

Using RMS, ZC, AR, WL, and MAV characteristics, it is possible to produce five distinct classification accuracies for each group. Using RMS and WL, the group of healthy and unwell subjects had the maximum classification accuracy of 82.5%. AR has the best results in the group of healthy and myopathy participants, with an 83% success rate. AR and RMS received the highest score of 83.5% in the third group. The AR approach generated the best results for the fourth and fifth groups, with accuracies of 82.5% for myopathy and neuropathy participants and 86.3% for healthy, myopathy, and neuropathy subjects. By achieving the best accuracy for four groups of five, the AR showed to be a good feature extraction technique.

The study in Priyadharsini et al. (2015), made a comparison between DWT and wavelet packet transform (WPT) as feature extraction techniques to detect neuromuscular disorders from EMG signal. The ELM was used for the classification process. They found that the proposed techniques ELM-DWT and ELM-WPT were better than the existing techniques in terms of classification accuracy and number of feature vectors. They proved that the learning speed of ELM was extremely fast, and more suitable in the applications that required fast prediction and response capability. They could achieve classification accuracy of 100% for any type of activation function.

ELM is a learning algorithm proposed by Huang et al. (2006) for single hidden layer feed-forward neural networks (SLFNs). It can choose hidden nodes randomly and determines the output weights of the SLFN analytically. The ELM technique has an extremely fast learning speed and yields to a generalization performance that is better than the imitative gradient-based learning algorithms. The ELM differs from traditional gradient-based learning algorithms in that it may be used to a variety of non-differentiable activation functions. An EMG dataset of 15 healthy participants, 1 myopathy subject, and 11 neuropathy subjects was used to test the suggested approach. Three electrodes were inserted on the biceps to record the EMG signal. With a sample rate of 1 KHz and 16-bit resolution, the signal was acquired using LabVIEW software and a data collection card. A total of three participants (1 healthy, 1 myopathy, and 1 neuropathy) were collected from a different dataset in addition to the prior one. The features were extracted individually using DWT and WPT approaches, and the ELM classifier was used to classify them. The WPT reduced the number of characteristics to a minimum and took less time to compute than the DWT. The ELM demonstrated to be a successful classification method for EMG signal categorization and diagnosis of neuromuscular diseases, with classification accuracy of 100% for both feature extraction techniques.

To classify EMG signals into healthy, myopathy, or neurogenic groups, researchers in Bozkurt et al. (2016), employed two types of neural networks: mixed neural networks and feed-forward error backpropagation artificial neural network (FEBANN). The suggested approach was tested on 1200 EMG signal patterns collected from 27 people (7 healthy, 7 myopathy, and 13 neurogenic), with 400 patterns separated into training and testing for each class. The EMG signal

was recorded from the biceps brachii muscle during a 5-second voluntary contraction and sampled at 20 kHz using a 12-bit acquisition data card resolution. To extract features from MUPs of EMG signals, researchers used AR parametric techniques such as Yule-Walker, covariance, modified covariance, and Burg procedures, as well as subspace-based methods like multiple signal classification and eigenvector techniques. The eigenvector performed the best out of all of these strategies. The FEBANN with eigenvector features had the highest classification accuracy of 93.3%, while CNN with the same feature extraction method had a higher accuracy of 94%.

ANN was employed in Singh et al. (2017), to classify EMG signals using parameters derived from the empirical mode decomposition procedure, such as mean, standard deviation, variance, and entropy of the IMFs. This method was used on 51 healthy, 111 myopathy, and 148 neuropathy subsets in a dataset. For signal categorization, 1000 samples were used for each subgroup. A 25 mm needle electrode was used to collect signals from the tibialis anterior muscle at a sampling rate of 50 kHz. When compared to other feature extraction techniques such as multiscale entropy, WT, AR coefficients, and statistical features, IMF statistical features attained a classification accuracy of 94%.

kNN was utilized in Bhuvaneswari and Kumar (2016), to differentiate healthy and neuropathy people using EMG patterns. They employed a dataset of 25 records from healthy people with no history of neuromuscular disease, people who have had polymyositis for a long time, and people who have chronic low back pain and neuropathy due to right L5 radiculopathy. A Medelec Synergy N2 EMG monitoring system with a sampling rate range of 20 Hz to 50 KHz was used to collect the data. The cepstral analysis was utilized to extract the features. Cepstral analysis is a nonlinear signal processing approach that deals with the real part of the signal and is calculated using the inverse of the discrete Fourier transform signal's log. The signal was first converted from the time domain to the frequency domain. The signal's spectrum representation was then decomposed using wavelet decomposition, which employed a low-pass filter for approximation coefficients and a high-pass filter for detail coefficients. Then, using the cepstral analysis procedure, characteristics were retrieved. After that, the dimensions of the features were decreased using minimum redundancy maximum relevance (MRMR), and the results were sent into the kNN classifier as inputs. The accuracy of categorization varies depending on the features chosen and the dimensionality reduction approach utilized.

The discussion in Fattah et al. (2013), included the employment of the kNN to classify ALS and normal signals. The EMG frame was used to extract the DWT features, which were then classified using the kNN classifier. The suggested approach was tested using EMG signals from five normal participants and five ALS patients, with 15 datasets in each class. The higher-valued DWT coefficients, as well as their mean and maxima, were employed to lower the feature dimension of DWT for ALS EMG signal detection. The classification accuracy of these three features was 100%, with the zero crossing (ZC) and mean frequency (MF) features achieving 72.2% and 69.5%, respectively.

In Kiran et al. (2018), kNN was used to distinguish between healthy people and ALS patients. The tunable Q-factor wavelet transform (TQWT) was utilized to extract characteristics from an EMG signal in order to distinguish between healthy and ALS signals. The TQWT could divide an EMG signal into sub-bands, from which statistical parameters like mean absolute deviation, interquartile range, kurtosis, mode, and entropy can be obtained and fed into the kNN classifier. In addition to the kNN classifier, the least squares support vector machine classifier was employed to categorize the same features, and the results of both classifiers were compared. The dataset utilized to evaluate the proposed approach contains 89 ALS and 133 healthy EMG signals that were amplified and sampled at a frequency of 10 kHz using a frequency range of 5 Hz–5 kHz filter settings. The TQWT sub-bands affected the classification accuracy of each classifier. The classification accuracy of the LS-SVM classifier was 74.55–90.45%. The kNN, on the other hand, outperformed the others, with a classification rate of 90.45–95%.

Through EMG signal analysis, Goen (2014), used binary SVM to distinguish between normal, myopathy, and neuropathy patients. An EMG dataset including 11 myopathy, 11 neuropathy, and 12 healthy patients was used to test the suggested approach. The EMG signal was first dissected into MUAPs. The statistical features from the MUAPs were then computed and supplied to the classifier. For two-class (normal/diseased) and three-class (normal/myopathy/neuropathy) recognition, binary SVM, SVM ensemble, and RBFNN were utilized. With classification rates of 90.1 and 91.2, the SVM ensemble offered the greatest performance for both two-class and three-class classification.

In identifying healthy, myopathy, and ALS EMG signals, the discussion in Khan and Hasan (2015), compared kNN and SVM classifiers. To extract wavelet characteristics from the data, the scientists employed DWT. The collected features were classified with an accuracy of 82% using the kNN classifier, while SVM classified them with an accuracy of 92.33%. When compared to the kNN technique, SVM demonstrated to be more effective at classifying EMG signals in this study.

The research in Artameeyanant et al. (2016), suggested a method for extracting features from EMG signals for myopathy and ALS classification based on a normalized weight vertical visibility algorithm (NWVVA). This method focuses on generating features from relationships between vertical visibility nodes and their amplitude differences as weights, as well as extracting sampling nodes based on sampling theory. The statistical features were calculated using selective statistical mechanics and measurements. These characteristics were then fed into the classifier as input. In this work, kNN, MLPNN, and SVM classifiers were employed to categorize the data, and their classification accuracies were compared. The accuracy of the kNN, MLPNN, and SVM classifiers was 96, 97, and 98%, respectively. Among the three classifiers used in this study, the SVM classifier had the highest accuracy.

The efficacy of different classifiers and feature extraction strategies in classifying EMG signals into normal and pathological patients was compared in Kehri et al. (2017). EMG data from the brachial biceps muscles were obtained using a conventional needle electrode. The signal's sample rate is 10 kHz. There are five normal and

five aberrant signals in the dataset. DWT+ANN, PCA+ANN, DWT+PNN, and DWT+SVM were used as classification approaches, with classification accuracies of 90.4%, 92.4%, 93.05%, and 94.28%, respectively. The best accuracy rate was achieved when DWT characteristics were classified using an SVM classifier.

Single and bagging ensemble classifiers were compared with different classification approaches in Subasi et al. (2018). EMG signals from the biceps brachii muscle were recorded with a concentric needle electrode and sampled at 20 kHz for 5 seconds for this comparison. The signals were obtained from 7 healthy people, 7 people with myopathy, and 13 people with neuropathy. First, the signals were decomposed into wavelet coefficients using DWT. Then, statistical features such as MAV, SD, average power, ratio of absolute mean values, skewness, and kurtosis were calculated to lower the features dimension. SVM, ANN, kNN, classification and regression trees (CART), C4.5, reduced error pruning (REP) tree, logical analysis of data (LAD) tree, and random tree were among the classifiers employed. SVM has the greatest classification accuracies of 98.96% and 99% for single classifier and bagging ensemble classifier, respectively, when compared to other approaches.

The study in Sengur et al. (2017), suggested a deep learning-based approach for classifying ALS and normal EMG signals in 2D temporal frequency pictures. Each input image is classified using the CNN based on the spatial information of the pixels incorporated into the network nodes. The CNN is made up of convolution and pooling layers, which create the characteristics that the fully connected layer uses to classify the data. During the training step, which is controlled by the convolution backpropagation technique, the parameters are fine-tuned. To increase the efficiency and speed up the training process, a new learning strategy called reinforcement sample learning strategy was used. For translating EMG signals into their time-frequency representation, spectrogram, continuous wavelet transform, and smoothed pseudo-Wigner-Ville distribution (SPWVD) were used in this study. The proposed approach was put to the test on a dataset that included 89 ALS and 133 normal EMG signals with a sampling rate of 24 kHz. The CNN had a classification accuracy of 96.80%.

For the diagnosis of neuromuscular illnesses, a hybrid classifier was developed in AbdelMaboud et al. (2015). This classifier was tested on a dataset of EMG signals from five healthy people, five people with myopathy, and five people with ALS. For EMG signal analysis, the DWT was used. The statistical values RMS, MAV, ZC, SSC, and STD were then computed. The hybrid classifier combined SVM and ANN, two different types of classifiers. To categorize one class against the other, each of these classifiers was applied to all of the individual features separately. Using the SVM classifier with the RMS feature as input, the highest classification rate of 98% was obtained for ALS. The ANN, on the other hand, demonstrated its capacity to accurately diagnose myopathy cases with an accuracy rate of 86.6%. This hybrid classifier has an overall accuracy of 85.5%.

In Shijiya and Thomas (2016), fuzzy logic and artificial neural networks were combined to increase the classification accuracy of EMG signals from normal, ALS, and myopathy. The spectral features like MF, mean power (MP), total power (TP),

peak frequency (PF), wavelet energy (WE), wavelet mean (WM), wavelet average power (WAP), wavelet standard deviation (WSD), and temporal features like MAV, variance, SI, and integrated EMG (IEMG) were used. The dataset for this study includes 75 signals from each of the 3 groups, as well as 15 signals from Parkinson's disease patients and 20 signals from Huntington's disease patients. ANN has a classification accuracy of 93.46%, and ANN with fuzzy logic has a classification accuracy of 94.61%. When compared to an ANN classifier, fuzzy logic with ANN significantly improved accuracy.

The researchers in Khan et al. (2016), also presented a multi-classifier strategy to improve EMG signal classification accuracy for the diagnosis of neuromuscular diseases. On MUAPs derived from an EMG signal, they used both time domain and time-frequency domain characteristics. A dataset of 150 EMG signals from normal, neuropathic, and myopathic patients was used to test the proposed approach, including 50 samples from each class. Different SVM and kNN single and multiple classifiers were examined. Using the time-frequency feature, the multi-classifier approach described in this work achieved average accuracy of 97%, while weighted kNN offered accuracy of 95%.

The SVM-kNN classifier has also been shown to be effective in other studies, such as Meena and Bansal (2016), where the Coiflet wavelet transform was used to evaluate the EMG signal and generated statistical features such as energy, mean, and standard deviation. These characteristics were then utilized to classify normal, myopathy, and neuropathy signals. This study employed a dataset of 500 signals from each class (350 for training and 150 for testing). To classify the collected features, a variety of classifiers, including SVM and SVM-kNN, were used to determine which classifier had the maximum accuracy. SVM had a 92% accuracy rate, whereas SVM-kNN had a 95% accuracy rate.

The article Abdel-Maboud et al. (2022), compared several bagging and boosting ensemble learning algorithms for classifying EMG data for neuromuscular disease diagnosis. The wavelet-packed coefficients (WPC) were initially estimated from the signals. Then, from the WPC of the signals, six statistical features were generated and utilized as inputs to the classifier: MAV, average power, SD, ratio of absolute mean values, skewness, and kurtosis. This study included 7 healthy people, 7 people with myopathy, and 13 people with neuropathy. With 99.08% accuracy, the AdaBoost learning algorithm in combination with the random forest ensemble classifier produced the best result.

Hence, it is noticed that ANNs are commonly employed in EMG signal categorization and have achieved great accuracy rates in identifying neuromuscular abnormalities. It's also worth noting that SVM has proven to be effective in the same field, particularly for multiclass classification.

Table 1 shows the employment of the machine learning techniques by some recent studies for classifying neuromuscular disorders. The table includes the classification techniques, datasets, feature extraction methods, and the corresponding accuracies.

Table 1 Neuromuscular disorder classification in machine learning

Study	Feature extraction	Classifier	Dataset	Aim	Accuracy (%)
Singh et al. (2017)	Functions (IMFs) generated by (EMD) process	FFBP-NN	PhysioNet (Goldberger et al. 2000)	Myopathy, neuropathy	94
Sengur et al. (2017)	C-WT and smoothed pseudo-Wigner-Ville	CNN	EMG lab (Nikolic 2001)	ALS	96.80
Khan and Hasan (2015)	DWT	kNN SVM	EMG lab (Nikolic 2001)	Healthy, myopathy, ALS	82 (kNN) 92.33 (SVM)
Subasi et al. (2018)	Features extracted from DWT	Bagging ensemble with SVM	Neurology Department of Gaziantep University	Healthy, myopathy, neuropathy	99

Uncertainty Analysis

The uncertainty is a quantity that evaluates the dispersion of the values attributed to a specific measure. The evaluation of the uncertainty is based on the systematic factors associated with the corrections. Due to the complexity of some measurement models, both stochastic and non-stochastic methods are combined to simplify the computations.

Among the publications that addressed the uncertainty in soft metrology is Lachish and Murray (2018), in which the uncertainty was evaluated based on the error factors such as the conversion and calculation errors. They started by identifying the uncertainty sources and the model by which the uncertainty was propagated to evaluate the combined uncertainty. In a different study (Pathmanathan et al. 2020), the uncertainty was evaluated based on a data-driven approach in which both the measurement and inference of variables contribute to the uncertainty.

In machine learning, the following parameters are used in estimating the uncertainty (Vallejo et al. 2020):

- Model output including error and covariance which are relevant to the deviation in the model output from the true value
- The calibration dataset that is influenced by measurement point uncertainties and used in training the model
- The input variables that are used in the inference model and have uncertainties
- The output uncertainties outside the calibration dataset

Many machine learning applications, such as decision-making, forecasting, automating scientific modeling, data compression, experiment design, and discovery, rely on accurate uncertainty estimate. Probability and statistics can help in quantifying the anticipated value and variability in the observations from the domain in case the system exhibits noise. In an incomplete system domain, probability can also be used to quantify and predict both the distribution and density of data to evaluate the capability and performance of a predictive model.

Uncertainty in SVM

In the classification stage in SVM, it is necessary to use dataset as inputs for training the classifier. But the training dataset may contain inaccurate classes leading to uncertainty probabilistic labels.

Considering the widely used support vector machines (SVMs), there is two-class classification problem, and it is necessary to find the separating hyperplane maximizing the margin between the examples of both classes. An approach in Niaf et al. (2011), proposed using both labels and probabilities as input.

The approach assumed a learning dataset (x_i, l_i) of input vectors (x_i) and labels (l_i) such that:

- In the classification stage, the class labels $l_i = y_i \in \{-1, +1\}$ for $i = 1, 2, \ldots, n$
- In regression stage, the real labels $l_i = p_i \in [0, 1]$ for $i = n + 1, \ldots, m$

So, p_i associated to (x_i) refers to the uncertainties about x_i 's class.

In order to handle the uncertain labels in SVM classification, they simulated different datasets and used RBF kernel $\mathrm{k(u, v)} = \mathrm{e}^{-\|\mathrm{u}-\mathrm{v}\|^2/2\sigma^2}$ and $\mathrm{C} = \mathrm{C}^{\sim} = 100$ to evaluate the classification performance and the probabilistic predictions by estimating the probabilities using Platt's scaling algorithm.

The performance was evaluated by computing the accuracy (Acc) of predicting the test set and Kullback-Leibler distance (KL) as follows:

$$\mathrm{D_{KL}(P\|Q)} = \sum_{\mathrm{i}=1}^{n} \mathrm{P(y_i = 1|}x_i) \log\left(\frac{\mathrm{P(y_i = 1|}x_i)}{\mathrm{Q(y_i = 1|}x_i)}\right)$$

for probability distributions P and Q.

The generated datasets were unidimensional and labeled +1 and −1 based on a normal distributions of variances $\sigma_{-1} = \sigma_1^2 = 0.3$ and means $\mu_{-1} = -0.5$ and $\mu_1 = +0.5$.

The dataset $\left(x_i^{\mathrm{l}}\right)_{\mathrm{i}=1,..,n^{\mathrm{l}}}$ denoted the learning data for $n^{\mathrm{l}} = 200$,while $\left(x_i^{\mathrm{t}}\right)_{\mathrm{i}=1,..,}$ n^{t} denoted the test set for $n^{\mathrm{l}} = 1000$. The true probability $\mathrm{p(y_i = +1|}x_i)$ was computed for each x_i and belonged to class + 1.

For $i = 1, \ldots, n^l$, the regular SVM dataset was obtained by using a probability of 0.5 as the threshold for assigning class labels y_i associated to point x_i.

If $p(y_i^l = 1 | x_i^l) > 0.5$, then $y_i^l = 1$, while in case $p(y_i^l = 1 | x_i^l) \leq 0.5$, then $y_i^l = -1$

The dataset $\left(x_i^l, y_i^l\right)_{i=1,..,n^l}$ is used to train the C-SVM classifier.

Another dataset $\left(x_i^l, \widehat{y_i^l}\right)_{i=1,..,n^l}$ was defined such that for $i = 1, \ldots, n$:

- If $p(y_i^l = 1 | x_i^l) > 1 - \eta$, then $\widehat{y_i^l} = 1$
- If $p(y_i^l = 1 | x_i^l) < \eta$, then $\widehat{y_i^l} = -1$, otherwise, $\widehat{y_i^l} = p\left(y_i^l = 1 | x_i^l\right)$

If the probability values are sufficiently close to 0 or 1 through precision and confidence, then they belong, respectively, to class −1 or 1.

The test set $(x_i^t)_{i=1,..,n^t}$ was used to find the true probabilities $p(y_i^t = 1 | x_i^t)_{i=1,..n^t}$ that could lead to the probability prediction error (KL). Figure 17 shows the probability prediction performances by the classical SVM.

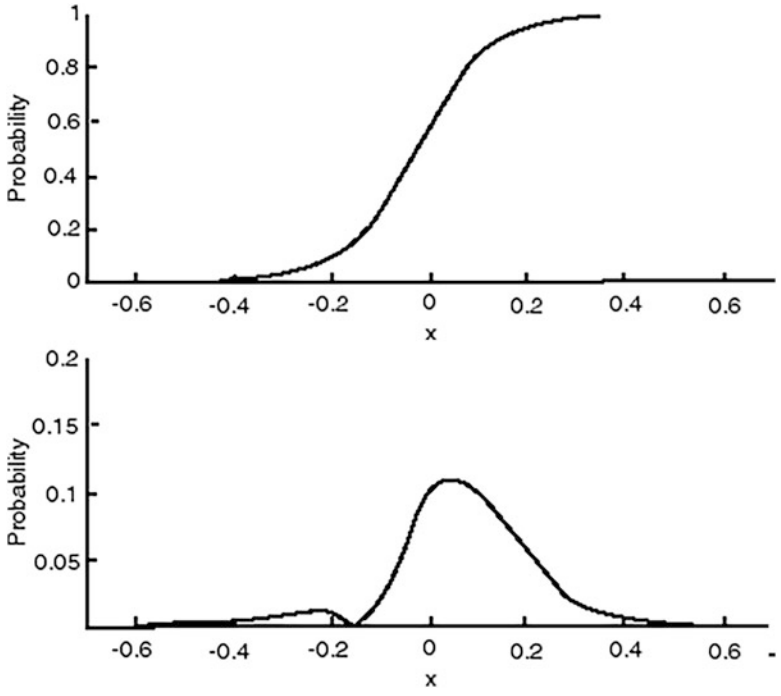

Fig. 17 Probability estimation. Top plot shows the true posterior probability with SVM estimations. Lower plot shows the distance between true probability and estimations (Niaf et al. 2011)

Conclusion

In this work, the performance of different classifiers of machine learning was evaluated. The scope was to compare between the different techniques for the classification of neuromuscular diseases with special interest to the algorithm, EMG signal analysis, and accuracy. Several challenges which face researchers in EMG signal analysis were due to signal's complexion and nonstationary nature. A comprehensive discussion on advances in feature extraction and classification was presented. The involved techniques proved significant efficiency in this field, such as DWT for feature extraction and SVM for classification. A case study on the uncertainty evaluation for the SVM classification was introduced. For future work, efficient EMG classification method with high accuracy rate can be used in real-time neuromuscular disorder diagnostic systems. The chapter provided a valuable tool that can support researchers in making decisions about which classifier could help in the diagnoses of specific diseases. Based on the comparison, the SVM model is the best-performing algorithm for classifying medical datasets.

Abstract

Metrology is the science of measurement used to measure various features (majorly dimensional and geometrical parameters) of components to improve the quality and reliability of parts for scientific and engineering applications. It needs to keep up with developments in manufacturing (e.g., automation) and current products with their associated technology, such as nanotechnology, microtechnology, and additive manufacturing to support quality management and process control effectively. When dimensions are decreased to micrometer or nanoscale, advanced measuring instruments are required to measure a

Introduction

Measurement is helpful in science, technology, and the economy because it establishes a foundation for fair trade, product optimization, and customer and corporate confidence in products. It is a process of collecting quantitative information of products in terms of units. According to Lord Kelvin in 1883, "whatever the subject may be, you have barely advanced to the science stage unless you can measure what you are communicating about and convey it in numbers. If you cannot measure it and cannot express it in numbers, your knowledge is of the same vague and unsatisfactory kind. It is the beginning of knowledge, but you have barely advanced to the science stage. This statement is applied to all research and development domains in science and engineering technologies. A measurement is an act of measuring quantities that everyone performs in our day-to-day life. All ordinary people unknowingly practice the aspect of measurement daily, but most of them are unaware of its importance. It includes units expressed with quantified numbers" (Kunzmann et al. 2005; Moona et al. 2019). The formation of units, development of measurement protocols, and a result of artifacts serve as measurement standards. Geometrical and dimensional metrology has evolved significantly in precision engineering due to increased demands generated by new manufacturing technologies and requirements for part functioning. Dimensional and geometrical measurements are the decisional basis for controlling the design, process, function, tolerances, and quality control (as shown in Fig. 1). Also, these are the primary basis with which other physical, electrical, mechanical, chemical, and thermal properties are linked. Precision in measurement becomes crucial to measure components for fitting and functional assemblies, measure required dimensions, measure an average number of pieces produced, and quality inspection to match with standard sizes. Firstly, it is done to establish units, then implement units, and finally applied for traceability (Carmignato et al. 2020; Weckenmann et al. 2007). Precision measurement achieves the following objectives.

1. To confirm items that are within acceptable tolerances.
2. To describe different manufacturing processes.

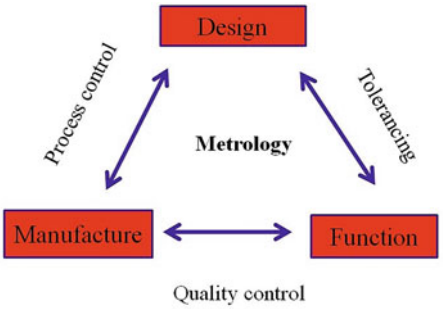

Fig. 1 Metrology in manufacturing process (De Chiffre 2007)

3. To develop standard techniques that help to decrease inspection costs and maximize measurement accuracy.
4. To maintain size variances under control and within established ranges.
5. To control the effectiveness of measurement devices.

However, it is notable that measurement science is evolved with the modern manufacturing processes. Presently, manufacturing of complex parts requires high precision to accomplish technical requirements, design parameters, and norm guidelines. Accuracy and traceable dimensional metrology support a wide variety of industry requirements, from macro-engineering to nanotechnology, and help to achieve the purpose of doing it correctly the first time, making it an unavoidable aspect of advanced manufacturing (De Chiffre 2007). However, the advancement in measuring instruments enables measuring and controlling the dimensioning up to the nanoscale range. Precision dimensional metrology, combining multiple measuring techniques into a single device with excellent resolution and accuracy, opens up various possibilities. The role of dimensional metrology becomes critical in micro and nanomanufacturing by utilizing unique techniques of measurement data fusion. This study describes the part of metrology in microtechnology, nanotechnology, and additive manufacturing. In-line metrology was discussed during the manufacturing process. The economic benefits of metrology are also explored in the manufacturing domain.

Historical Evolution of Metrology

The value of metrology was first recognized by Ancient Egyptians and applied to the construction of pyramids with incredible precision. The royal Egyptian cubit was based on the sections of a pharaoh's or king's body used as measurement standard ruling in that era. However, human-referenced measuring systems were no longer quite acceptable due to industrialization and the evolution of mass production at the end of the eighteenth century. The advancement in the manufacturing industries recognized the need for a metrology concept. Artisans had to secure the functionality of individually created parts by adapting the parts to each other. In contrast, the

industry had to provide component interchangeability to reap the economic benefits of mass manufacturing and supply interchangeable spare parts. Consequently, it wasn't enough to compare and rework two parts to make them fit together. The final dimensions of parts had to be created and measured precisely enough to ensure the assembly functions independently. Therefore, dimensional metrology had to maintain synchronization with the industry's ever-increasing demands for advanced technology. The meter agreement was accepted and internationally recognized as a length unit in 1875. It is always a comparison of the length to be measured against a length standard, the length unit. In 1983, the speed of light redefined the meter unit as "the distance traveled by light in a vacuum for 1/299792458 seconds due to the invention of laser" (Weckenmann et al. 2009, 2012; Quinn and Kovalevsky 2005). The time unit second and the time measurement define the length of a unit, which is calculated with good precision by many magnitudes. Berndt established the measurement uncertainty should not surpass the tolerance's one-tenth (or one-fifth in extreme instances) from 1924 to 1930. Over time, more precise measuring tools were created, such as length measuring machines, microscopes, profile projectors, etc. However, they could only make one- or two-dimensional measurements. The evolution of two-dimensional measuring devices such as fringe projectors and gauge blocks occurred from 1950 to 2000. The development of the coordinate measuring machine (CMM) became a boon for manufacturing. It is used to quantify various geometric features such as lines, planes, circles, cylinders, and spheres by measuring numerous points on the workpiece surface. However, due to the limited technological development, measurements were performed between two points in one dimension. Advanced measuring instruments like X-ray tomography and scanning electron microscopes are used to detect a dimensionally poor quality product. 3D noncontact metrology is contributing significantly to advance manufacturing applications. With increasing demands for accuracy, it was found that two-point measures could be confusing. For example, when measuring the diameter of a shaft with significant form deviation, it was addressed by developing improved metrology devices, such as measuring microscopes and profile projectors, which allowed two-dimensional measurements in a plane section on the one hand. However, the manufacturing industry confronted new challenges with smaller components, complicated geometry, higher tolerances, and stringent quality control. A reliable and accurate dimensional metrology environment was required to overcome these difficulties, underlining the significance of advanced dimensional metrology solutions in production. Coordinate metrology has proven to be a revolution for manufacturing, assessing deviations by taking dimensional measurements on numerous places on the work surface, and displacing basic equipment like calipers, gauge blocks, and micrometers. CMMs can measure the dimensions of a wide range of objects. Oversized items, such as aircraft, can be measured with CMMs and laser trackers, whereas micro-CMMs can perform measurements in the nanometer range. Metrology is developed for in-process adaptation for real-time monitoring of process parameters utilizing embedded sensors. The components are meticulously checked during or after production to preserve product consistency and conformity to dimensional standards (Quinn and Kovalevsky 2005). Figure 2 shows the dimensional and

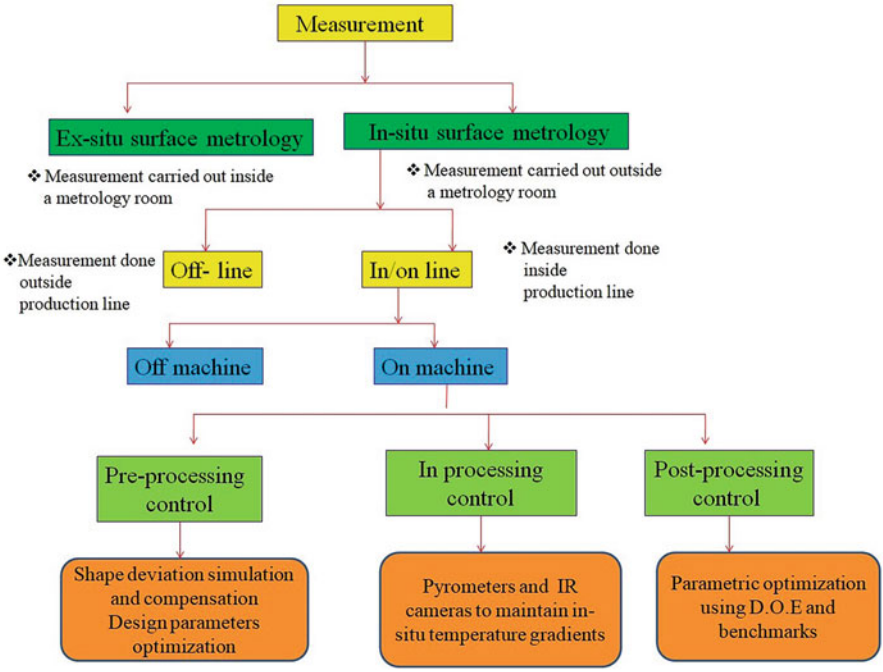

Fig. 2 Different measurement methods for precision manufacturing (Everton et al. 2016)

geometrical measurement control methods that can be performed before, during, and after production. Table 1 briefly discussed some common measurement methods in industries.

State of the Art of Metrology in Advanced Manufacturing

As the manufacturing processes became increasingly advanced to manufacture complex components that fulfill various functional and technical requirements, measuring science progressed simultaneously. The present metrological systems are more flexible, self-adaptable, and intelligent, based on cyber-physical systems, the Internet of things, and cloud technology. In this manner, the quantity of information and quality assurance of an object can be improved at the same time. Manufacturing metrology demands are set by production, so it must follow production engineering trends. Presently, additive manufacturing, Industry 4.0, microtechnology, robotics and automation, and nanotechnology are emerging fields in the manufacturing industries. Additive manufacturing has transformed the manufacturing scenario by opposing the conventional manufacturing principle. Industry 4.0 refers to a Fourth Industrial Revolution (following water/steam power, mass manufacturing, and automation through IT and robotics) and introduces the concept

Table 1 Measurement methods of metrology

Method	Role	References
Dimensional metrology	It is concerned with measuring geometric features of an object such as size, distance, angle, form, or coordinates to meet design requirements. It is required as a "toolbox" to aid manufacturing and reduce total loss. The toolbox must have a variety of instrument modules such as rulers, scales, Vernier caliper, and micrometer for measuring the dimensions of objects	Carmignato et al. (2020) and Musso et al. (2016)
Surface metrology	The measurement of a surface's characteristics (uniform patterns, abnormalities, roughness, curvatures, and critical dimensions) is known as surface metrology. It is significant for the new materials utilized in modern processes such as bearings, thermal, advanced coatings, optical, and semiconducting/electronic devices. It can be done using tactile or optical techniques such as Taylor-Hobson, atomic force microscopy, stylus profilometers, optical profilometers, photogrammetric, and interferometer	Jiang and Whitehouse (2012) and Senin and Leach (2018)
Coordinate metrology	In industry, coordinate measuring machines (CMMs) are the most popular instruments used for 3D monitoring physical elements. CMMs are mechanical systems that use the movement of a measuring probe to identify the coordinates of points on the surface of a component instead of directly measuring the attributes. Numerous CMMs are available, and all can accurately measure tiny details of components from micro- to nano-level. CMM is available with different configurations, including probe (contact or contactless, single or multiple), mechanical structure (cantilever, moving bridge, fixed bridge, horizontal arm, gantry, column, etc.), and drive controller (computer-assisted data processing, direct computer control, post-processing software, and so on). Today, noncontact probe technologies such as optical sensors, X-ray computed tomography (CT), optical interferometry, and magnetic resonance imaging are utilized to quickly increase measuring speed and the number of measurement points	Mian and Al-Ahmari (2014) and Berry and Barari (2018)

(continued)

Table 1 (continued)

Method	Role	References
Geometirc dimensioning and tolerancing (GD&T)	It plays a significant role in product functionality and quality assurance. To assure geometric conformity and standards, the product must fulfill the limit, fit, and tolerance specifications. The two primary methods, experimental methods based on geometric benchmark test artifacts and analytical methods like finite element analysis, are preferred for GD&T manufactured products. In such situations, prior assessment of geometric tolerances, i.e., GD&T features, is critical to avoid part rejection and material waste	Rupal et al. (2020a) and Ameta et al. (2015)
Ex situ/in situ metrology	Based on the environmental conditions, measuring instruments are divided into two groups: Those installed in the metrology room and those installed outside the metrology room. When the measuring environment is different from the manufacturing environment, surface metrology performed in the metrology room is categorized as ex situ metrology. The component dimensions are measured on the same workspace without isolating the component from the production environment, referred to as in situ metrology. In situ metrology ensures component quality and detects errors before final fabrication. As the component design becomes complex, the calibration and traceability procedures for advanced in situ operations become difficult. It is further divided into two groups; outside the metrology room based on their proximity to the manufacturing line. Some inspections are performed outside of the production process. When needed, the component must be moved out from the production line for surface measurement, checked by one or more equipment, and returned to the line for continuing manufacture. This type of measurement is known as "off-line" surface metrology	Gao et al. (2019) and Everton et al. (2016)

of cyber-physical systems to differentiate this new evolutionary phase from the electronic automation that has gone before. Industrial robots are frequently used to boost production, provide flexibility, and assist workers with physically demanding and risky activities. Quality control is necessary to operate intelligent automation solutions in the advanced manufacturing sector. This innovation allows for an even

greater connection, enabling manufacturers to keep their competitive advantage in a constantly changing world and to react quickly and flexibly to customer demands. Modern manufacturing metrology must keep up with these changes and broaden its horizons. It is an important task that must be performed essentially because a part's size, thickness, and shape complexity significantly impact the selected process. It becomes even more complicated when absolute dimensions are reduced to microscale or nanoscale levels. Precision is a critical function widely needed in microtechnology and nanotechnology for process control and quality assurance (Durakbasa et al. 2015).

Microtechnology

Microtechnology is a crucial technology with a rapidly expanding market in various industries. In recent years, it has advanced significantly in different application domains. Now it plays a vital part in everyday life without being widely recognized. Small electronic, mechanical, and optical components are found in computers, cell phones, and automobiles daily, and their quality must be guaranteed (Schmitt and Pavim 2008). It is a rapidly developing discipline that takes advantage of the unique features of ultrasmall-scale materials. The micro components are used in various industrial applications such as micro gears or micromotors, medical items such as hearing aids or ear implants, chemical analysis and processing (passive microfluid components), small freeform lenses in mobile phones, optical devices (optical switch component), and radio frequency technology components. It is often hard to achieve all the micro-level inspections with a single inspection technique. Different measurement concepts or configurations need to perform to inspect the various shapes, dimensions, and geometric specifications. It indicates that the measurement system relies on the object's attributes. This reliance is problematic for monitoring flexible manufacturing lines, such as small-series manufacturing printed circuit boards (PCBs) or micro-lasers. Multiple sensors technology is mandated during the production to assess the individual features of different parts to expand a microproduction unit's inspection range and adaptability (Nicholson and Wallace 2007; Tosello et al. 2009). As a result, advanced measuring devices have been required to measure dimensional and geometrical features of micro components in the submillimeter to micrometer range. Many micro-metrology procedures are already used in the industrial sector. Some are based on optical or nondestructive test (NDT) principles due to their micro-world benefits (touchless, noninvasive, fast, and accurate measurement results). The measurement system's simple interaction with the (micro-) items under scrutiny could harm or damage them if the surface is not smooth. Microelectromechanical system (MEMS) is a specialist field that refers to technologies that allow existing sensors, actuators, or system products to be miniaturized (De Chiffre et al. 2003).

Nanotechnology

The science of measurement at the nanoscale is known as nanometrology. Today, nanometrology is dependent on semiconductor technology advancements to a significant extent. Nanometrology is imperative in producing nanomaterials and devices with high accuracy and reliability in nanotechnology. The demands for new nanostructured sample characteristics exceed current measurement science capabilities. Due to the advancement of the requisite metrology techniques, a comprehensive range of measuring devices has been designed to evaluate surface structures down to the 0.1 nm level. Dimensional nanometrology is a branch of dimensional metrology that refers to a set and verification of dimensional values on components having at least one important dimension or functional feature smaller than 100 nm and whose uncertainty is expressed in nanometers (Tosello et al. 2009; Ukraintsev and Banke Jr 2012). Understanding the importance of manufacturing precision in industrial metrology in the nanometric range is essential for success on a global scale. When modern computer-aided production metrology is heavily utilized to regulate manufacturing to meet this requirement, product quality based on geometrical specifications improves as dimensional product tolerances tighten. Advanced laboratory research must ensure that the product meets its design criteria at nano-level parameters for leading semiconductor and mechanical engineering industries. Optimizing dimensional tolerances and selecting appropriate machining and measuring procedures are vital to the proper functioning of any nanocomponent (Hong and Chang 2002; Lazos-Martınez and Gonzalez-Rojano 2013). In recent years, AFM with laser interferometers has been created and employed to measure nanoscale standards such as step height, one- and two-dimensional gratings, and line width. Other measurement techniques, including computed tomography, X-ray reflectometry, optical CMM, transmission electron microscopy (TEM), scanning electron microscopy (SEM), interferometry microscopy, 3D optical profilometer, and optical scatterometry, have been used to inspect nanodimensional measurements for surface characterization and layer thickness measurements. Practically, all microscopic methods, such as AFM, TEM, SEM, and optical interference microscopy, measure from the top; they cannot acquire enough data at sharp corners of structures to estimate metrics like line edge and width roughness. There are many other challenging tasks in this domain, such as sidewall measurements and accurate 3D measurements of nano- and microstructures. Some measuring instruments are listed in Table 2 to measure the micro and nanocomponents (Dai et al. 2008; Koumoulos et al. 2018).

Additive Manufacturing

Additive manufacturing (AM) is a new paradigm that opposed the subtraction principle in the manufacturing industry. Usually, a complex part had to undergo various processes to produce a net shape in the conventional manufacturing process. The inspection is required to check the dimensional stability and quality at each step.

Table 2 Methods for measuring capability (Bauer et al. 2015)

Design limit	Measuring instruments
>10 μm	Coordinate measuring machine (CMM), optical systems, pneumatic and mechanical comparators
10 μm – 1 μm	Micromechanical comparators, CMM, optical and electric comparators spin resonance
1 μm – 100 nm	CMM, optical interferometer, dark-field microscopes, phase microscopes, electrostatic and magnetic comparator
100 nm – 10 nm	Roughness measurement devices, laser interferometers, and fluorescence microscope
10 nm – 1 nm, 1 nm	Laser confocal microscope, X-ray microanalyzer, scanning electron microscope (SEM), transmission electron microscopy (TEM), scanning tunneling microscopy (STM), atomic force microscope (AFM), electron and X-ray diffraction system

In contrast, AM evolved with a new revolution where a complex part was made from a single machine source with less assembly operation. The wire, powder, and sheet form materials are joined into a layer-by-layer pattern. It is an early phase of progress; it still provides enormous design freedom opportunities in lightweight components for aerospace, intricate design features, cooling channels for the automobile industry, porous structures for medical implants, etc. (Behera et al. 2021). Metrology is vital in engineering applications, including aerospace, automotive, biomedical, marine, and medical, where accuracy is crucial, and quality control depends on precise product attributes and process control information. The most visible unfavorable exterior consequences on additive-produced components are shape variation and texture. Many diverse factors contribute to these effects, but each layer's height and thermal stresses' easing play a significant influence. Therefore, a metrological assessment of the components is required for quality assurance and post-process planning. Focusing on the metrological aspects of AM components is necessary because the part is fabricated with a less tight tolerance scheme (Vora and Sanyal 2020; Huang et al. 2015; Leach 2016; Shulunov 2016). However, no particular provision of standardization and tolerance has been established yet.

However, the National Institute of Standards and Technology (NIST) has attempted to narrow the AM competence and qualification gap. NIST hosted a session on "Measurement Standard Issues in Rapid Prototyping" in 1997. NIST issued rapid prototyping industry standards in 1999. The ASTM F-42 group was in charge of setting guidelines for categorizing the AM method, which resulted in seven different classes. The ASTM E-28 committee developed the tensile test requirements for AM parts (Jurrens 1999; Jadayel and Khameneifar 2020). Then, the American Society for Testing and Materials (ASTM) and the International Organization for Standardization (ISO) analyzed the potential of AM and developed a roadmap of standardization for AM technologies. These two organizations jointly worked on standardizing AM process chains, quality parameters, test procedures, supply agreements, and fundamentals to avoid the progress of several competing and potentially inconsistent standards (Rupal et al. 2020b; Leach et al. 2019; Li et al. 2018; Moroni

Table 3 Standardization activities for AM ((ISO) IOfS 2020; Standardization IOf 2020; Villarraga-Gómez et al. 2018)

Organization	Role
ISO/ASTM 52910	Highlights the effect of triangle sizing on the surface texture, effects of build direction on tolerances, the effect of overhang elements requiring support structures, etc.
ASTM F42.01	Test methods
ASTM F42.91	Terminology
ISO17296-3	It describes additively manufactured products' texture, size, dimensions, and geometric tolerances
ISO1302 and ISO 4288	Mention specification and measurement of surface texture
ASTM F42.04	Design
ISO 1101 and ISO 2768-2	Refers geometrical tolerancing
American Society of Mechanical Engineers (ASME) Y 14.46	Defines the product definition requirements particular to AM
ASTM F42.90	Executive
ASME Y 14.41	Within a digital product description data set, create a three-dimensional (3D) model
ASTM F42.94	Strategic planning
ASME B46	Defines surface topography of AM parts
ASTM F42.05	Materials and processes

et al. 2017). Table 3 shows the role of different organizations in the standardization of AM. However, the nondestructive, noncontact, real-time, in situ measurements methods are helpful for the AM process to obtain accurate, less time, and cost-consuming reliable processes and improve process control.

In-Line Metrology

With advancements in manufacturing processes, it is analyzed that the product feature should be measured simultaneously to save energy and time during production. Now, metrology can be incorporated to collect real-time data about any product or service outside the production (ex situ or off-line) and inside the production (in situ or in-line/on-line) in modern manufacturing processes. Presently, in-line metrology significantly affects accessing the real-time information of any product or process. An in-line measuring technique would be the most excellent solution for scaling up production while maintaining regularity. Traditional CMM technology provides the best metrological feedback. However, due to its time and effort, it cannot be used for in-line measurements, especially in an AM chain where component measurement is required for post-processing planning. It is based on obtaining measurement data during the production cycle and using it for immediate process control and quality assurance. The requisite changes in production processes are easily detectable using this method. Quick reactions can improve operational

stability and product quality early in the manufacturing process. It is incredibly significant for monitoring, regulating, and optimizing product fabrication and manufacturing processes to save cost by better utilizing raw material, troubleshooting, defect minimization, and improving production yield and energy efficiency (Moenning 2006; Kiraci et al. 2017). It benefits only when in-line metrology is included in the early stages of production planning and setup.

Additionally, there are two ways to carry it out: on-machine (while the workpiece is mounted on the machine) and off-machine (when the workpiece is moved out of the machine). Usually, noncontact methods are preferred for in-line metrology because sometimes contact methods can be sluggish and cannot measure hidden features or abnormalities. Metrology instruments can become a motivating factor for in situ metrology in advanced manufacturing involving additive manufacturing, microtechnology, and nanotechnology. Efficient imaging techniques such as optical, X-ray, infrared red, e-beam, computer tomography, optical CMM, ultrasound, or scanning probes can be utilized for advanced manufacturing applications (Tofail et al. 2018; Bordron et al. 2019).

On-Machine Metrology

On-machine inspection, also known as in-process inspection, can be done simultaneously during the machining operation. The inspection does not take additional time; hence, on-machine metrology can maximize efficiency. The sensor head must withstand the potentially harsh environment, including machining fluid, generated chips, vibration, and high temperatures. The associated machine tool defects, such as spindle/slide motion errors, thermal deformations, and vibration, are a substantial difference between on-machine surface metrology and off-machine measurement utilizing a stand-alone surface measuring instrument. An additional error cause is the sensor head alignment problem on the machine tool. It is also vital to look at reducing and separating these errors from on-machine surface measurement results and the problems with calibration and traceability they cause. Full-field and probe-scan systems are two measurement systems for on-machine and in-process surface metrology. A light beam is focused onto a specific work surface area to collect three-dimensional (3D) information about the surface over a region, often referred to as the system's field of view. A 1D or 2D probe, contact or contactless, is rotated by the machine tool axes to scan the work surface in a point-by-point or continuous-path mode in an on-machine probe-scan system. Table 4 shows the advanced on-machine measurement techniques (Shimizu et al. 2021; Imkamp et al. 2016).

Metrology for Economic Growth

Generally, metrological development refers to increasing the amount of information acquired about an object or decreasing the cost per unit of measured information. Some scientists, practitioners, and industrialists have viewed it as a cost factor rather

Table 4 Noncontact measuring and inspection methods

Technique	Features	Advantages	Disadvantages	References
Interferometry	It is a noncontact measuring process where the known surface shape is correlated with the unknown surface. The interference fringe is depicted as a series of differences between the surfaces	High resolution Easily measure the smooth surface Simple	High cost Error created when measuring rough surface	Abdelsalam and Yao (2017)
Fringe projection	It is a three-dimensional noncontact measurement process where a projector is used to produce different light-dark fringe patterns on measuring components	High accuracy Complex features can be easily measured Fast data processing	Expensive Uneven illumination distribution	Pineda et al. (2019) and Liu et al. (2021)
X-ray computed tomography	It is a nondestructive technique used to inspect various materials such as polymer, metal, ceramic, light metal, and fibers. It can generate geometric data for the characterization of material structure	Used for analyzing the internal and external structures High resolution Used for dimensional accuracy measurement	High cost Operational maintenance required	Villarraga-Gómez (2016) and Zanini et al. (2018)
Optical CMM	Optical CMM systems automatically use image processing technologies to provide fast and accurate measurement results. The rapid development of these measurement tools has paralleled the steady advancement of factory automation at production facilities	Portable Use for small features High resolution and speed	Required post-processing Only provide data on a few points Costlier	Sładek et al. (2011) and Gapinski et al. (2014)

Technique	Features	Advantages	Disadvantages	References
	thickness, abnormalities (internal and exterior), and assembly features.			
Optical surface topography	Optical surface height sensitivity at the nm level is required for optical surface topography measurement. Vertical resolution is the most frequently mentioned metric concerning surface height measurement sensitivity	3D measurements, fast measurement speed, simple to use, automated	Surface gradient limitation, material surface demand	Foreman et al. (2013) and Feng et al. (2019)

than a value-adding activity in the manufacturing process. Measurement is the main cost element throughout manufacturing because faulty measurement devices can lead to erroneous and uncertain outgrowths. However, if precise measurement is not considered during manufacturing, incorrect decisions may be made, resulting in rougher sampling and increased measurement uncertainties, making it costly. Hence, there is always a compromise between the amount of reliable information available and the expenses associated with gathering it through measures. Cost-benefit assessments must be carried out to determine which measuring technique qualifies best for a specific application. Suppose metrologists, engineers, and management personnel have enough knowledge about the measurement process. In that case, they can estimate what information about a process or product is needed to check its functionality, tolerances, and quality. When metrology is applied at each step of the production process, it can be considered a value-adding process. It may provide significant cost-benefits (as shown in Fig. 3) when employed concurrently during or soon after the production; hence, it can improve the quality and productivity of the overall system (Rodrigues Filho and Gonçalves 2015; Savio et al. 2016). The economic impact of metrology can quickly be evaluated by checking the cost involved in measurements and identifying the flaws in the value chain. Metrology exists from the design phase when a new product's functionality and specifications are defined and continue to the product development phase when all specifications and tolerances are set, followed by post-manufacturing characterizations. According to the studies, around 75% of all manufacturing errors are investigated in the early stages; hence, any wrong decision and insufficient or ineffective feedback regarding the process and product results in delays in the whole product life cycle, which affects the servicing (Link 2021). The following points recognize the economic benefits of metrology in manufacturing:

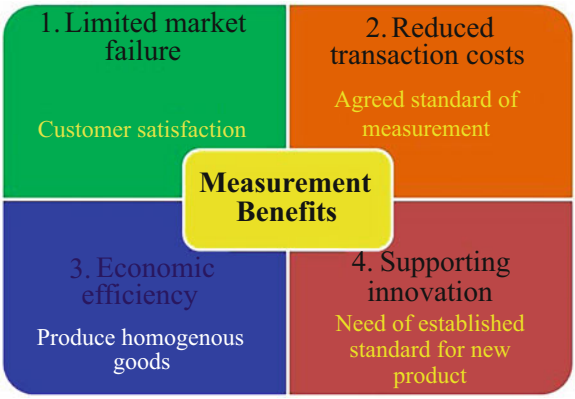

Fig. 3 Economic benefits of measurement (Robertson and Swanepoel 2015)

- Measurement acquired data is used to develop and plan the product generation and design evaluation to diminish failure modes.
- If proper inspection of the product has not been done in earlier stages, the cost of eliminating errors increases by a factor of 10 for each subsequent step of the product life cycle. Approximately 90% of a product's future costs are caused by difficulties already implemented in the earlier phases, such as fixing product attributes and designing components to determine their tolerances.
- Initially, enhanced dimensional measurement procedures may result in a slight decline in production, but better measurement capabilities open the door to improving productivity in the long run.
- Measurement helps decide the acceptance and rejection of a manufactured component. For example, in the aerospace industry, measuring in-service degradation of turbine blades concerning multiple blade dimensional parameters saves the time and cost of manufacturing.
- Telecommunications and navigation, both becoming more important in today's world, require the most consistent time and spatial measurement standards.
- Consistent measurements are essential to human health and safety in diagnosis and medical treatment.
- Only accurate and reliable measurements can protect the environment from industrial activity's short- and long-term detrimental consequences.
- Global environmental studies rely on accurate and consistent data from various disciplines over long periods, which can only be secured by utilizing measurement standards based on fundamental and atomic constants.

Conclusion

Metrology is a vital tool for gathering data at every stage of the manufacturing process. The present chapter describes the role of metrology in advanced manufacturing systems. Precision dimensional metrology is essential to ensure that

the finished product fulfills design criteria and works as expected. However, it should be noted that any false interpretation about the process and product makes metrology mere a cost factor. Metrology in manufacturing should be implemented from the start of the design process to increase product quality and reliability. In-built measuring instruments should be attached to the production line to find faults in dimensional and geometrical features. Progress of measurement science is the guidance for controlling the production process, improving quality, and increasing customer satisfaction.

Abstract

In recent years, both academically and industrially, additive manufacturing (AM) has experienced rapid expansion because of its capability of producing customized products of intricate shapes. 3D printing has evolved as a promising technology for the creation of engineering parts or applications, as it is an additive technique, unlike traditional manufacturing techniques. The advantages of 3D printing include reduced material waste, easiness in manufacturing, minimal human participation and post-processing, and efficiency in energy, which make it a viable option for industrial application. The chapter provides a brief introduction to additive manufacturing and also addresses a variety of 3D printing techniques, as well as their benefits and drawbacks. A detailed discussion of the various materials that are suitable for each type of 3D printing procedure is discussed along with the application of AM and the challenges associated with it.

Addictive manufacturing · Applications · 3D printing · Materials

Introduction

As the years progressed, the process of manufacturing has been changed as per the requirement of better flexibility, efficacy, and customization, and because of these reasons, additive manufacturing comes into the picture. Additive manufacturing (AM) also known by other names as well such as three-dimensional (3D) printing, layered manufacturing (LM), rapid prototyping (RP), and solid freeform fabrication (SFF) is a novel method of manufacturing that builds three-dimensional parts layer upon layer using computer-aided designing (CAD) data. The ISO/ASTM 52900 standard (ISO/ASTM 52900 2015) defines additive manufacturing (AM) as "the technique of combining materials to build parts from the data of 3D model, generally layer by layer, in opposition to subtractive and formative manufacturing methodologies of production." Unlike traditional subtractive manufacturing methods like conventional machining which involves removing material until the desired part is obtained, AM creates the product by adding material. The utilization of AM is viewed as another Industrial Revolution (Lipson 2014; The Economist 2012), subsequent to steam engines, computers, and the Internet. Its ability to create customized prototypes or parts of even complicated geometrical configurations with reduced production time and cost has outperformed the traditional manufacturing settings. Individuals from various fields like aerospace (Uz Zaman et al. 2019; Gradl et al. 2022), dental (Chen et al. 2016), biomedical (Ruban et al. 2022; Whenish

et al. 2022; Sontakke and Jaju 2022), construction, and defense industries (Davies et al. 2022), etc. have benefited from this. The steady increase in market competitiveness to fulfill customer requirements and satisfaction in the quickest feasible period is one of the major causes behind the fast rise of AM in diverse fields. It allows for more efficient and faster manufacturing of parts as there is no need for fixtures, tooling, and coolants in 3D printing; it also reduces wastage of material (Williams 2016), gives freedom for design, and can print complicated structures with a higher resolution and remarkable flexibility (Ngoa et al. 2018).

AM includes a variety of techniques, materials, and machines that have grown through time and have the potential to revolutionize the manufacturing and logistics sector. In 1986, Charles Hull introduced this technology by a process called stereolithography (SLA), which was accompanied by advancements like selective laser sintering (SLS), fused deposition modeling (FDM), laminated object manufacturing (LOM), binder jetting (BJ), and selective laser melting (SLM) (Liu et al. 2021) as shown in Fig. 1.

AM's ability to 3D print small batches of customized parts or products for a reasonable price is especially advantageous in the field of biomedicine, where one-of-a-kind patient-specific products are frequently required. Products that are custom-made have become the new trend in 3D printing (Berman 2012). Metals, polymeric materials, ceramics, and concrete are some of the most often utilized materials in 3D printing. The most common polymers employed in the 3D printing of composites are polylactic acid (PLA) and acrylonitrile butadiene styrene (ABS). However, the material chosen for 3D printing largely depends on the type of application it will be used (MacDonald and Wicker 2016).

Earlier 3D printing was used as just a rapid prototyping method. Furthermore, as technology advances, 3D printing is now utilized for full-fledged production with reduced time in production, lower cost, and greater flexibility; thus, it is also known as rapid manufacturing (Mohamed et al. 2015). The various incentives for pursuing AM are depicted briefly in Fig. 2. The major purposes include the production of prototypes, development of the product, fabrication of new products that are not possible to produce using traditional techniques of manufacturing, improved efficiency in production, lower production cost, fabrication of products that are customized/personalized, source of revenue, expansion of new production lines, improvement in customer satisfaction, improvement in the management of supply chain and its logistics, and others.

There are numerous variations in additive and conventional manufacturing as conventional manufacturing offers the manufacturing of a variety of parts for mass production, whereas additive manufacturing is a system that is material and design specific. Also, AM can fabricate parts in a variety of sizes ranging from the microlevel to the macrolevel. But the precision or quality of the printed parts, on the other hand, is determined by the accuracy of the printing procedure used and the printing scale.

In 3D printing, the first step is, to begin with, the basic design of the part which is to be fabricated, and it is created by utilizing CAD software. CAD then creates the file and translates it into standard tessellation language (STL) format and sends it to

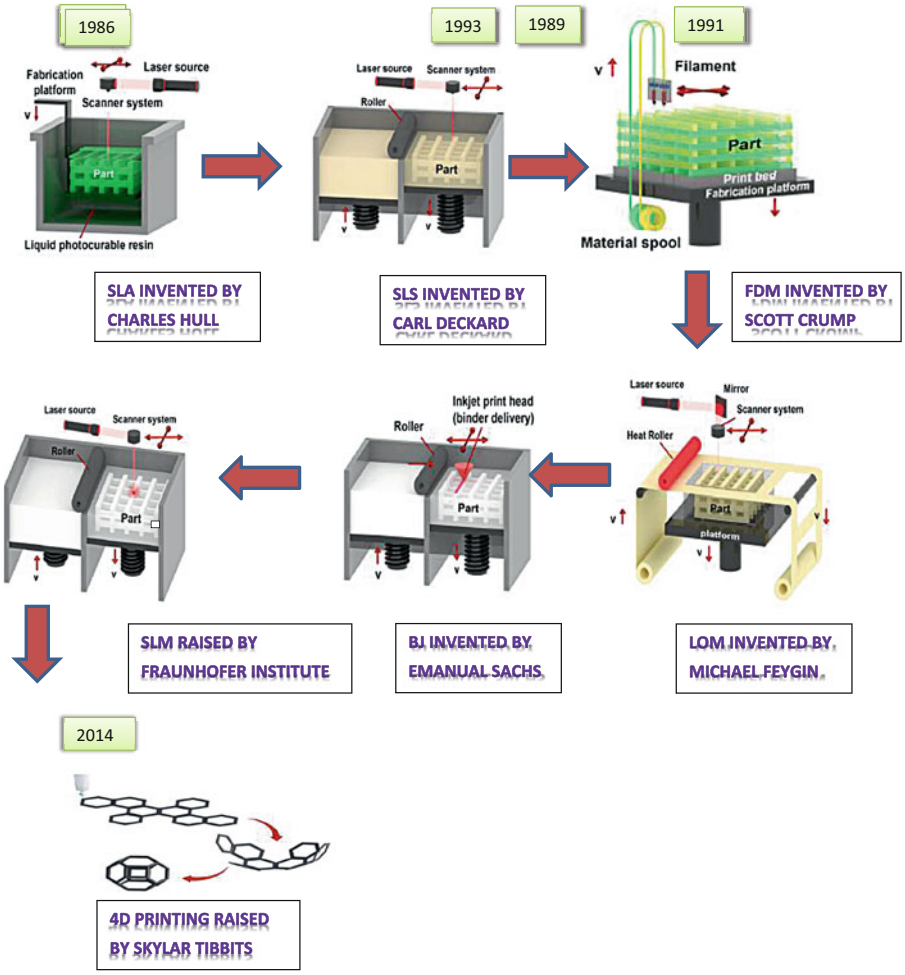

Fig. 1 Evolution of additive manufacturing (Jandyal et al. 2022)

the printer where it reads that file and builds the part by stacking layers on top of each other (Raina et al. 2021). Instead of reading the part as a whole, 3D printers read it as a single two-dimensional layer at a time. The basic procedure for creating 3D parts utilizing 3D printers is shown in Fig. 3.

The following are some of AM's distinct capabilities:

1. **Flexibility in design**. AM methods are distinguished by their layer-by-layer manufacturing methodology, which allows practically any geometrically complicated shape to be created. This contrasts with subtractive methods, which limit design flexibility because of the necessity for fixtures and a wide range of tooling as well as the risk of crashes and the complexity of maneuvering the cutter's

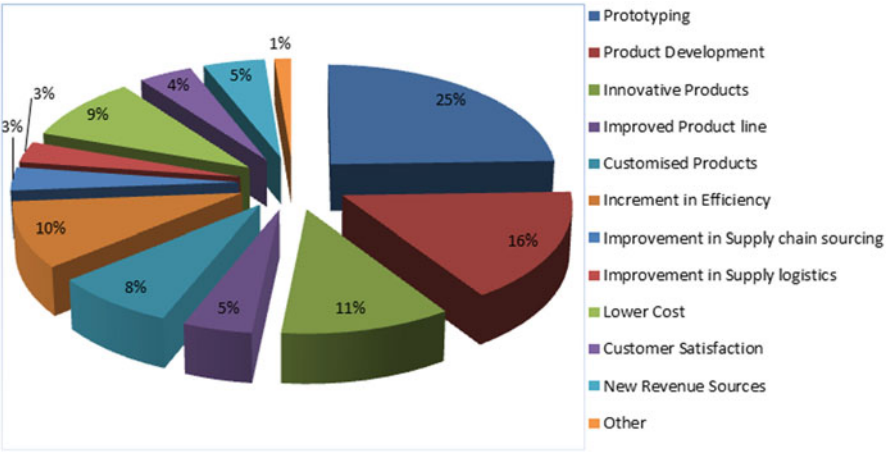

Fig. 2 Major reasons for employing AM (Dizon et al. 2018; Gartner 2014)

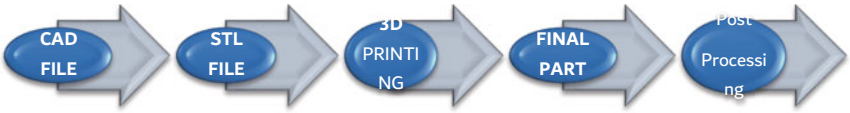

Fig. 3 Basic process in 3D printing

ability to reach deeper and parts that are not visible when it comes to creating complicated geometry.

2. **Cost related to geometrical intricacy**. In conventional manufacturing, there is a clear link between the complexity of the part to be produced and the cost associated with it, while employing AM there is no additional expense since there is no such necessity for extra tooling, refixturing, and more specialization of the operator or even the time it takes to construct the part.
3. **The need for assembly**. AM methods allow the creation of geometric designs that might otherwise need the assembly of many components if manufactured traditionally. Additionally, AM may be used to create "single-part assemblages" with integrated components. The joints and components are printed in a position and held by support material or sintered powder that should be ejected during posttreatment.
4. **Reduced overall production cost**. AM has the ability to cut inventory expenses as well as supply chain and delivery costs. When producing components with AM, there is often relatively little wastage of material, while there is some material trash in powder bed fusion technologies owing to support structures and powder recycling. Also, the ratio of the quantity of material bought to the quantity of material present in the finished component for AM techniques is extremely less (Brice and Taminger 2011). Improved designs combined with lower supply chain and delivery costs make AM technologies fit for a wide range of uses.

This chapter gives a brief introduction to additive manufacturing. The remaining sections of the chapter are arranged in the following way. Sections "Classification of AM Techniques" and "Materials Used in Different AM Techniques" describe the classification and materials used in different AM techniques, respectively, and section "Applications of AM" discusses its application. Section "Challenges and Future Scope in AM" gives an overview of the challenges and future scope of AM. Eventually, section "Conclusion" will present the conclusion.

Classification of AM Techniques

A wide range of 3D printing technologies has been developed, each with its own set of capabilities. As per the American Society for Testing and Materials (ASTM), AM is primarily divided into seven classes, viz., material jetting (MJ), binding jetting (BJ), powder bed fusion (PBF), material extrusion (ME), sheet lamination (SL), vat photopolymerization (VP), and direct energy deposition (DED) (Guo and Leu 2013) as shown in Fig. 4.

Fused deposition modeling (FDM), selective laser sintering (SLS), laminated object manufacture (LOM), selective laser melting (SLM), and stereolithography (SLA) are among the most often employed technologies.

These techniques of 3D printing have been discussed briefly including their merits and shortcomings in the subsequent subsections.

Fig. 4 Types of AM techniques

Vat Photopolymerization

Charles Hull from 3D Systems Corporation introduced the first commercialized AM technology in 1984, employing the stereolithography process (SLA), in which an ultraviolet laser was used to precisely polymerize ultraviolet curable resins to form a solidified material layer (Cooper 2001; Noorani 2006). After that, the layers are cured one by one until the component is completed. SLA builds parts at a relatively faster rate, and the minimum layer thickness is determined by the curing depth (Pham and Ji 2000). The disadvantages of this approach are process defects caused by over curing, scanning line shape, and expensive supply and material prices (Wong and Hernandez 2012). This technology is fundamentally confined to photopolymers because it relies on photopolymerization.

Material Extrusion

Scott Crump, a co-founder of Stratasys Limited, devised an AM technique in 1988 that produced layers by physically extruding molten thermoplastic material such as polylactic acid (PLA) or acrylonitrile butadiene styrene (ABS) upon a substrate (Williams et al. 2011). Fused deposition modeling (FDM) is a technology that needs generally high working temperatures and produces prints with extreme porosities. However, among the DIY crowds, affordable and flexible extrusion technologies are gaining appeal.

Binder Jetting

Binder jetting technology was marketed by Z Corporation and ExOne after it was investigated at the Massachusetts Institute of Technology (MIT) (Li et al. 2020). It is a type of inkjet printing that has been modified (Gibson et al. 2020). This procedure employs an inkjet to bind the components rather than lasers. It uses inkjet 2D printing technology and advances in layers to build 3D products. The liquid binder is accurately sprayed with the aid of a printhead that moves on two axes. This method also starts with the creation of a three-dimensional model and then transferring it to the printer software, just like any other 3D printing process (Chen and Zhao 2016). Because printing necessitates constant supply, a dispenser provides such supply by storing powder that will be utilized. The printing head adheres the binder according to the requirements after applying a powder layer of varied thicknesses. The binder-containing solvent is dried using fluorescent or electric lamps before proceeding to the next layer. The powder bed is then dropped, and a new powder sheet is deposited.

Powder Bed Fusion

The powder bed fusion process employs a beam of energy, namely, a laser beam or an electron beam so that the powder bed can be melted sequentially. After the

scanning of one layer, the very next powder layer is disseminated using a rolling device. The following layer is scanned and merged with the one before it. Polyamides and polymer composites are commonly processed using polymer powder bed fusion, which was first devised by (Deckers et al. 2012) in the mid-1980s. The most common metal powder bed fusion processes are electron beam melting (EBM), direct metal laser sintering (DMLS), and selective laser melting (SLM). EOS GmbH (Germany) and Arcam AB (Sweden) created them in 1995 and have been commercially accessible since 2005. DMLS and SLM use a concentrated laser beam to heat and melt consecutive pre-alloyed, atomized powders (Yang et al. 2010; Kruth et al. 2005; Buchbinder et al. 2011; Murr et al. 2012) like 17-4 PH stainless steel, whereas EBM uses a scanning electron beam (Shellabear and Nyrhila 2004).

Direct Energy Deposition

This approach, unlike other 3D printing procedures, is used for repairing and maintenance rather than generating components. Direct energy deposition methods facilitate material creation by melting the material as it is deposited (Gibson et al. 2015). The deposition head, which is a combination of a source of energy and two power feed nozzles, is the apparatus utilized in this process. This procedure can use either metal powder or a thin wire. The to-be-fabricated part is placed on a platform, and in certain circumstances, tubing of inert gas is also provided. The deposition head that deposits the powder beam and the laser beam simultaneously is a four- or five-axis machine. The DED technique employs a centered heat source either an electron or laser beam, and the material is adhered layer by layer as it solidifies, resulting in fixing and creating new material objects on existing products.

Sheet Lamination

In 1986, Helisys Incorporation which is now known by the name of Cubic Technologies 10 created laminated object manufacturing (LOM) technologies, which were patented in 1987.

The components produced have lower internal tension and fragility, excellent surface finish, and reduced process, material, and machine costs which are all benefits of LOM (Mueller and Kochan 1999). It is a method that uses plastic, paper, or metal laminates that have been successfully glued together and then a laser cutter to produce the required shape of the object or model. The procedure begins with a heated roller adhering a sheet to a substrate, next, using a laser or mechanical cutter to precisely cut the subsequent layers and bond in order. The finished layer platform moves lower, and the current sheet metal is rolled into place, while the platform returns to its original position to collect the next layer. The procedure should be followed until the prototype is completed.

Material Jetting

Material jetting AM techniques use drop-on-demand inkjetting to deposit wax or photopolymer droplets directly onto a substrate, which is similar to the process of inkjet printing where the ink droplets are transferred from a fluid channel to a paper's substrate in a drop-by-drop way (Le 1998; Calvert 2001; deGans et al. 2004; Sheoran and Kumar 2020).

Printing Characteristics of AM Techniques

The characteristics of printing a 3D part that are important to consider when choosing an AM technique and a construction pattern have been described in this division. These characteristics as well as other aspects might affect the printed part's quality.

Time of Build

The build time for a specific object or assembly is generally determined by the printer's speed of printing an object, the size of the object to be printed, the thickness of the layer, as well as the orientation of the build. The bigger the size of the part to be produced, the more amount of time it will take to print irrespective of the process adopted for the printing.

Resolution of Feature

The pattern of energy or material is principally responsible for feature resolution in AM systems.

Quality of Surface

The printed layer thickness determines the surface quality of a printed component.

Support and Anchors

Every AM method must have some way of sustaining the printed characteristics of the following layers to construct complicated geometries like undercuts, assemblies of printed components having moving parts, and overhangs (Mumtaz et al. 2011).

Post-Processing

Post-processing techniques that separate printed products with built-in support material are required. The procedures and easiness of uninstallation differ depending on the printing methods and building material used.

Materials Used in Different AM Techniques

The different methods of 3D printing have been discussed in the earlier section. After classification, the next thing that comes is the materials that are utilized in these methods, what sort of qualities they give, and for what processes and applications they are used. As a result, material features relevant to the 3D printing techniques have been explored in the following sections.

Figure 5 shows the material usage by 3D printer service providers in the industrial sector.

Polymers

Polymers are the most extensively utilized materials in the three-dimensional printing sectors because of their versatility and simplicity of application to varied 3D printing techniques. Reactive monomers, thermoplastic filaments, powder, and resin are all examples of polymers used in additive manufacturing. Many industries, including medical, architectural, toy manufacturing, and aerospace, have been exploring the capacity of using 3D printing of polymers and composites for some

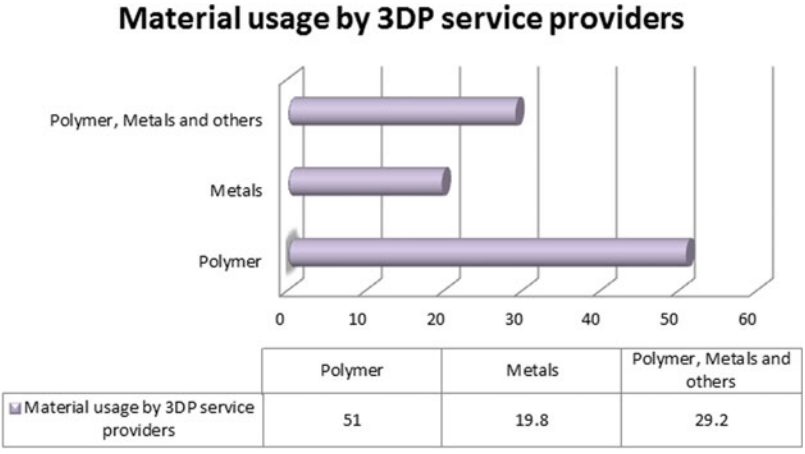

Fig. 5 Material usage by 3D printer service providers (Dizon et al. 2018; Wohlers 2017a)

years. The ability to tailor geometry with great accuracy is one of the advantages of producing composites with 3D printing. In addition, for tailored items, this procedure may be more economical than other classic formative processes like molding and extrusion (Wang et al. 2017a; Takezawa and Kobashi 2017).

In stereolithography (SLA) printing technology, photopolymer resins typically polymerize when exposed to UV light. As per Wohlers Associates' annual industry study, prototypes created utilizing photopolymers account for over half of the 3D printing market in manufacturing industries. The second leading class for 3D printing is plastic for selective laser sintering (SLS). Polyamides, thermoplastic, and elastomer polystyrene are just a few of the SLS polymers available (Ligon et al. 2017). A variety of 3D printing technologies can be utilized to process thermoplastic polymers, such as polylactic acid (PLA) (Postiglione et al. 2015), acrylonitrile butadiene styrene copolymers (ABS) (Zhuang et al. 2017), etc. The creation of 3D-printed scaffolds for tissue engineering is presently being done with PLA-based composites.

Stereolithography, selective laser sintering, fused deposition modeling, 3D bioprinting, and inkjet printing are some of the 3D printing processes available for manufacturing polymers and composites. The manufacturing of polymer composites and thermoplastics with low melting points is most typically done with FDM (Postiglione et al. 2015).

Over time, 3D printing of polymeric composites has evolved, allowing for the investigation and exploration of novel materials. The combination of 3D printing with a polymer matrix composite has a lot of potential in terms of industrial production with higher efficacy and mechanical performance.

Metals

Metal 3D printing/additive manufacturing has a lot of potential for expansion. Among the 49% of enterprises dealing with metal AM, the number of firms selling AM systems increased from 49 in 2014 to 97 in 2016 (Wohlers 2017b). This technique has mostly been employed in aerospace applications for research, prototyping, or sophisticated applications. It's also employed in medicinal, defense, and automotive applications (Wohlers 2017b). In comparison to traditional production processes, metal AM allows for a great deal of flexibility when it comes to creating complicated geometries with unique interconnections.

Melting metal feedstock which is in the form of wire/powder with a source of energy like an electron or laser beam is often the first step in 3D printing metals. In a pattern of layer, the molten metal is turned into a solid portion. The most widely used methods for printing a metal include direct energy deposition (DED) and powder bed fusion (PBF) although there are other approaches, such as direct metal writing (Chen et al. 2017), cold spraying (Sova et al. 2013), binder jetting (Bai and Williams 2015) friction stir welding (Sharma et al. 2017), and diode-based procedures that have recently been developed. These methods can provide greater precision or speed.

PBF AM methods may be used to create a variety of metallic materials, including titanium and its alloys, stainless and tool steels, nickel-based alloys, and certain aluminum alloys. Titanium and its alloys, particularly, are high-performance materials that are widely employed across a wide range of sectors (Sheydaeian and Toyserkani 2018). Based on traditional production processes, they are associated with the high cost of machining and a longer lead time. Reduction in cost of tooling, the ability to design and manufacture complex and lighter-weight parts, and multiple component unification that can remove the part assembly are among the advantages of metal additive manufacturing.

Concrete

The construction sector has embraced additive manufacturing technologies. Contour crafting, a process comparable to inkjet printing, has evolved as the primary approach for the additive production of architectural structures (Khoshnevis 2004). To extrude the paste of concrete, this technology requires bigger nozzles and higher pressure. Trowel-shaped equipment attached to the printer has been devised to achieve a smooth finish rather than a layer-by-layer look. In comparison to standard fiber-reinforced concrete, fiber reinforcement of concrete composites by 3D printing has the advantage of regulating the orientation of fiber in a printed structure. Flexural strength was greatly improved by allowing carbon fibers to be oriented freely along multiple printing pathways (Hambach and Volkmer 2017).

Ceramics

AM is now a popular technology for producing sophisticated ceramics in biomaterials and tissue engineering industry, such as bone and tooth scaffolds (Wen et al. 2017). Despite the precision of the printing, the key problems for 3D printing of ceramics are the layer-wise look and a restricted number of materials. Sintered ceramic components' post-processing to get the required shape is a time-consuming and expensive operation. Various approaches and materials have been explored in order to improve the mechanical properties of ceramic lattices produced by 3D printing when compared to traditional methods.

By adding CaSO4 with dextrin, Li et al. (2016) created a porous alumina ceramic whose flexural strength came out to be higher. Maurath and Willenbacher (2017) revealed that by enhancing the rheology and uniformity of the ink-printing process and optimized sintering, a honeycomb structure with higher specific strength and greater dimensional stability may be created. Powder bed fusion (PBF), paste extrusion, inkjet, and stereolithography (SLA) are the most common methods for 3D printing ceramics. Inkjet is considered to be the most common technology for producing solid ceramic samples that don't require post-processing (Travitzky et al. 2014). Ceramic powders may also be 3D printed using selective laser sintering (SLS). Another method called selective laser gelation (SLG), which combines SLS with the solgel method, also has been developed for printing ceramics (Liu et al. 2011).

Applications of AM

In recent years, the development of novel, sophisticated AM processes has accelerated, resulting in a growing number of commercial applications. AM, as opposed to subtractive manufacturing, is particularly well suited to making low-volume items, particularly components with complicated geometry.

In Construction

In recent years, automated building construction using 3D printing technology has gotten a lot of attention. It allows for significant time and manpower savings during construction (Wu et al. 2016). It has the potential to transform the building sector and make development on the moon easier for astronauts (Labeaga-Martínez et al. 2017). In the sector of construction, 3D printing can be used in areas with limits, such as geometric complications and hollow constructions. In 2014, the FDM process was used to create the first 3D-printed residential construction in Amsterdam (shown in Fig. 1) (3D Print Canal House – DUS Architects). The project was initiated by DUS Architects, who intended to demonstrate the printer's mobility with low material waste and transportation expenses, opening the way for it to enter the construction industry (Fig. 6).

Lim et al. represented three large-scale 3D printing procedures for the construction sector, each of which differs in terms of materials used and application process. The production procedure for D-shape and concrete printings is normally done

Fig. 6 First 3D-printed house made by DUS Architects (3D Print Canal House – DUS Architects)

off-site and is frame-mounted and gantry-based. On the other hand, the robot or crane-mounted contour crafting technique can be used for on-site applications (Lim et al. 2012). Because the raw materials and manufacturing technique used in 3D printing differ from traditional building methods, competent individuals with the capacity to combine robotic and civil work remain a challenge for AM in the construction industry. Although additive manufacturing (AM) is still in its early stages in the construction business, it is clear that it has the potential to improve traditional construction methods. A new study into and development of this technology is predicted, to result in more opportunities and problems in the construction sector.

Automotive Industry

The automobile industry has adopted AM technology as a vital tool in the development and design of automobile parts because it has shortened the development process and reduced manufacturing and product costs. Small amounts of structural and functional pieces for luxury, low-volume autos, such as driveshafts, gearbox parts, engine exhausts, and brake systems, have also been created utilizing AM technologies. Unlike passenger automobiles, racing vehicles are often made of lightweight metals (such as titanium) with very complicated construction and limited manufacturing numbers. AM methods have also been successfully used to create functioning components for racing automobiles by companies and research organizations. CRP Technology (Italy) has successfully developed and produced many components for motorsports using AM processes such as SLM, SLS, and EBM. F1 gears (titanium), MotoGP 250R air boxes, motorcycle dashboards and supports, F1 suspension systems, camshaft covers for MotoGP engines, reed valves, and other parts are among the items manufactured. Vilaro et al. created a water pump for racing vehicles by using SLM utilizing aluminum alloy (AlSi10Mg). Their tests revealed that the components generated had mechanical qualities that are comparable to heat-treated AlSi10Mg (Vilaro et al. 2008). Using LENS, Optomec created Ti6Al4V components for the Red Bull racing vehicle, including suspension mounting brackets and driveshaft spiders, which results in a $>$ 90% material reduction, as well as considerable time and cost-savings (Optomec). Concept Laser used SLM to make a variety of steel and aluminum automotive parts, including wheel suspensions, engine blocks, oil pump housings, exhaust manifolds, and valve blocks. Many studies have shown that AM can build complex components for the automotive sector utilizing casting patterns, molds, and cores created by SLA, SLS, 3DP, FDM, and LOM.

Aerospace Industry

Complex geometries are common in aerospace components, which are typically comprised of sophisticated materials such as nickel superalloys, titanium alloys,

special steels, ultrahigh-strength steels, and high-temperature ceramics, which are difficult, expensive, and time-consuming. For small quantities, AM is more cost-effective than traditional approaches since it doesn't need costly types of equipment like molds or dies. Concept Laser used SLM to create an engine housing. In the aircraft sector, AM-built plastic components, like vents and ducts, also have been employed. In the meantime, flame-resistant polymers, like PEEK, were developed for AM techniques to suit aircraft standards. Aeroengine components, turbine blades, and heat exchangers are examples of metallic and nonmetallic items that may be made or repaired using AM. For quick prototyping of components and manufacturing fixtures and interiors composed of ceramics, plastics, and composite materials, nonmetal AM technologies such as stereolithography, multi-jet modeling, and FDM are employed. In conjunction with several aerospace firms such as Piper Aircraft, Bell Helicopter, and NASA, Stratasys embraced FDM for fast prototyping, manufacturing tooling, and part production. NASA, for example, used Stratasys FDM technology to print 70 components of the Mars rover, resulting in a lightweight and sturdy construction (Stratasys|3D Printing Solutions for Aerospace). Another aerospace use of AM is the creation of wind tunnel testing models for airplanes, missiles, airfoils, and other designs to evaluate their aerodynamic properties. The use of additive manufacturing technology reduces the time and cost of producing these models, which typically have complex geometry. Daneshmand et al., for example, used SLS to construct a wing-body-tail launch vehicle configuration model out of glass-reinforced nylon (Daneshmand et al. 2006). In addition to directly producing functional components for aerospace applications, AM methods are also utilized to repair aircraft engine parts like compressors, housing parts, turbine and combustor castings, and blades to minimize the cost and prolong the lifetime of such parts. LENS has been shown to effectively repair elements used in gas turbine engines such as vanes, stators, seals, and rotors, as well as geometrically difficult parts including airfoils, ducts, and diffusers, according to Optomec. As a result, AM technology is particularly well suited to aircraft applications.

In the Medical Field

Since every individual is unique in the medical arena, AM offers a lot of promise for tailored and customized medicinal applications. There are several fields such as bio-fabrication, dentistry, surgery, and pharmaceutics in which there are a huge number of applications of AM.

Bio-Fabrication

The production of vascularized organs is a major problem in bio-fabrication (Murphy and Atala 2014). For large organs to maintain their metabolism, they require blood vessels. Therefore, strategies for creating complicated vascular networks and innervation will be required. 3D bioprinting of blood arteries and efficient vascularized tissue had made significant development recently (Zhang et al. 2017). The existing limitations of printing at fine resolutions at a microscale, along with the

absence of mechanical qualities for vascularized tissues, indicate that further study and progress are needed in this field to manufacture 3D-printed tissues. However, breakthroughs in adaptable bio-inks highlight additive manufacturing's promise in tissue engineering of delicate human components (Lee et al. 2010). Bioreactors are being investigated in conjunction with substances that stimulate angiogenesis and innervation to produce mature bioprinted components with the required properties. The use of a mix of bio-inks and advanced manufacturing methods to create human-scale tissue structures is yielding promising results (Kang et al. 2016). In situ bioprinting for tissue regeneration is also a cutting-edge concept that will transform the biomedical business.

In Surgery

In maxillofacial and oral surgery, AM is a widely used process. It is the procedure of connecting materials to items constructed from virtual model data (Levi et al. 2012). Oral and maxillofacial surgeons face a difficult task in managing missing craniofacial tissues due to congenital defects, trauma, or cancer therapy. Many approaches to treating such deformities have been developed, but autogenic bone transplants endure the gold standard in rehabilitative bone surgery (Petrovic et al. 2012). However, cell-based therapies combining adipose stem cells with osteoconductive polymers or scaffolds have emerged as a viable alternative to autogenous bone transplants. Customized 3D scaffolds that meet functional and cosmetic needs, provide appropriate blood supply, and meet the load-bearing necessities of the head are frequently required in such treatment procedures. Presently, such personalized 3D frameworks are being manufactured using 3D printing technology.

Pharmaceutics/Drug Delivery

The pharmaceutical industry's future is shifting away from mass manufacturing and toward tailored dosing for distinct groups of patients based on metabolic uniformity, except for direct energy deposition and sheet lamination deposition. Fused deposition modeling and inkjet printing are the most used advance manufacturing technologies in medicine delivery and pharmaceutics. Although these technologies give more precision at cheap cost, fast drug release, patient-personalized medications, and higher drug dose loading, poor productivity when compared to traditional medicine manufacturing processes. Furthermore, because 4D printing is a novel idea in the pharmaceutical business, only restricted technologies have been applied, such as direct ink writing for intravenous drug distribution systems (Durga Prasad Reddy and Sharma 2020). Similar 3D printing processes may find their way into the pharmaceutical business in the future. Another issue with AM in the pharmaceutical business is the scarcity of biomaterials. Sterilization procedures for polymer-based pharmaceuticals, for example, can't be strict or employ a temperature greater than the temperature of biopolymer's glass. Shape recovery hydrogels, on the other hand, showed significant promise for future medicinal uses. Finally, the most significant issue that

prevents AM technology from providing mass manufacturing of personalized medications is the inability to scale up innovations in this sector.

Dentistry

Patients in dentistry have a variety of needs, such as crowns, implants, and bridges. Dentistry can benefit from a variety of AM technologies. Dental prostheses are made using binding jet technology. The dried particle level, binder quantity, drying period, and powder spreading speed are all taken into account. The outcome demonstrates that it gives a precise implant at a reasonable cost with increased strength (Miyanaji et al. 2016). Patient-specific eruption guiding appliances are made via additive manufacturing, which improves patient comfort while also lowering the model's overall cost (Barone et al. 2018). Jet binding metallic powder is used to create partial dentures using 3D printing technology. To produce a 3D-printed model, micro-computed tomography is employed to scan the current framework. The results demonstrate that it can reach a density of more than 99% while controlling shrinking at a lower cost. It is extremely suitable for the creation of complex-shaped dental implants with precise dimensions (Kunrath 2020). The precision of dental restorations made utilizing additive manufacturing versus subtractive manufacturing methods such as wax or zirconia milling has yet to be determined. The results reveal that dental restorations made using additive manufacturing techniques are more accurate than those made using subtractive methods. AM is also a digital way of storing inventory in digital form, which has the added benefit of lowering inventory costs (Mostafaei et al. 2018). For teeth manufactured using the FDM process, an experimental investigation for dimensional correctness is performed. Three distinct layer thicknesses are employed to build a virtual 3D model and constructed model using the intraoral 3D scanner. GOM Inspect program evaluates the model's dimensional correctness, revealing that the lowering layer thickness readily reaches a high degree of precision (Bae et al. 2017). AM allows dentists to meet their unique needs in less time and at a lower cost (Milde et al. 2017).

Challenges and Future Scope in AM

Although 3D printing's benefits, like design freedom, customization, and the capacity to create complicated structures, some disadvantages would need more study and technical advancement. High prices, restricted uses in big constructions and mass manufacturing, poorer and anisotropic mechanical qualities, material limitations, and flaws are only a few of the disadvantages. In comparison to conventional processes like casting, fabrication, extrusion, or injection molding, AM of a part often takes longer. The long time taken and the greater cost of 3D printing are the key barriers to large-scale production of any repetitive components that can be readily produced using other traditional technologies in a fraction of the time and price. However, AM can be more economical when it comes to a personalized product with a complicated structure, such as a 3D-fabricated

scaffold for bone tissue creation (Duta and Caraiane 2017). One of the most significant disadvantages of 3D printing is the creation of voids between successive layers of materials. Because of the reduced interfacial adhesion between printed layers, the extra porosity induced by AM can be rather considerable, lowering mechanical performance (Hollister 2005). The production of voids is more prevalent in processes that employ filaments of materials, like FDM or contour crafting, and is regarded as one of the primary faults that result in weaker and anisotropic mechanical characteristics. After printing, this gap creation might cause delamination between layers (Wang et al. 2017b). Due to complete contact between succeeding layers, Paul et al. found that rectangular nozzles produce fewer voids than cylindrical nozzles. Rectangular nozzles, however, make 3D printing of complicated objects, particularly at joints, more challenging (Gibbons et al. 2010). One of the most difficult aspects of AM is anisotropic behavior. The microstructure of the elements within each layer differs from that at the borders between layers due to the nature of layer-wise printing. The addition of successive layers reheats the borders of preceding layers in metals and alloys 3D printed by heat fusion (SLS or SLM), resulting in distinct grain morphology and anisotropic behavior owing to thermal gradients (Paul et al. 2018). The laser beam's heat penetration into each layer is critical for managing the sintering process as well as minimizing anisotropic behavior. The main tool for designing an item that may be 3D printed is computer-aided design (CAD) software. Because of the constraints of additive manufacturing, the printed item may have a few faults that were not anticipated in the planned element. Solid geometry and boundaries are combined in the CAD system. To approximate the model, it usually uses tessellation ideas. Transferring CAD to a 3D-printed object, on the other hand, frequently results in mistakes and faults, especially on curved surfaces (Carroll et al. 2015). Although a very fine tessellation may be able to alleviate this problem to some extent, the computational processing and printing would be time-consuming and complex. As a result, post-processing (heating, laser, chemicals, or sanding) to remove these flaws is occasionally contemplated. Due to the nature of additive manufacturing, layer-by-layer appearance is also an issue. If the 3D-printed object is buried in the end use, such as scaffolds for tissue engineering, the look may not be significant. A flat surface, as opposed to a layer-by-layer look, is desirable in various applications such as structures, toys, and aircraft. Sintering, for example, is a physical or chemical post-processing procedure that can eliminate this fault, but it adds to the manufacturing time and expense (Oropallo and Piegl 2016).

Future Scope

Even while AM has advanced significantly in recent years, it is still not universally recognized by most sectors. The main goals for the next 5–10 years are to improve technology to the point where it can change people's thinking and acquire industry acceptance, as well as widen, develop, and find industrial uses that are only conceivable with AM methods. Novel AM methods, such as those for bioapplications

employing cells, biologics, or biomaterials as building blocks, as well as for micro/nano-engineering, must be explored and developed to widen and create new applications. AM technology and its applications will require a substantial amount of research and development in terms of materials, designs, new procedures as well as machines, process modeling and controlling, bio-additive manufacturing, and energy sustainability applications to reach these goals.

Conclusion

The key advantages of 3D printing include design flexibility, product customization, and the capacity to build complicated structures with minimal waste. A detailed assessment of 3D printing technologies, materials, and the present status of trending applications in a varied range of fields was conducted. Also, the primary challenges associated with 3D printing were explored. 3D printing has the ability to replace traditional technologies since it is a sustainable technology. In addition to being cost-effective, AM is also environmentally benign and hence can assist to minimize the negative environmental impacts of industrial growth. Based on studies, it can be concluded that a variety of 3D printing technologies have emerged, each of which is compatible with a particular material. Different advantages and cons are linked with each 3D printing method. Aside from being able to handle complicated and elaborate designs, 3D-printed items need relatively little posttreatment. FDM is the most prevalent 3D printing process; however, it works best with polymeric materials. SLS and other powder-based methods have several drawbacks, including difficulties in manufacturing. Powder-based technologies like SLS encounter several challenges, including powder transport and storage.

Abstract

The potential of additive manufacturing (AM) to build products in a layer over layer basis from a digital three-dimensional model with tremendous variability in accordance with the criticality of design has propelled it to the forefront in the manufacturing technology sector. Furthermore, AM requires no extra tooling equipment and can make parts with little to almost no material wastage. Even after having these technological benefits, AM has still yet to realize its full potentiality, owing to a dearth of proper knowledge of all AM procedures and coordinated efforts in the area of standardizing, metrology (measurement science), qualification, as well as certification. Consequently, AM manufactures products with greater complexity and characteristics but with lower dimensional accuracy, precision, requisite tolerances, and desired material characteristics. Method-specific standardized metrology and inspection procedures for AM parts, in particular, play a critical role in achieving the requisite quality and, as a result, simplifying the AM product certification process. This chapter offers a brief introduction to the metrology of AM, its need, and the challenges associated with it along with a detailed evaluation of general metrology methods as well as for AM-specific metrology methods.

Keywords

Additive manufacturing · Challenges · Inspection and qualification · Metrology

Introduction

Additive manufacturing (AM) also known as 3D printing, unlike various manufacturing techniques, has developed as a feasible technology for the creation of engineering components, as it is an additive process. Despite traditional manufacturing subtractive methods, where a tool has been used to remove undesirable material from a workpiece to form a product, AM is a method of fabricating components from a 3D model information by joining materials layer-by-layer (Standard 2012). When low manufacturing numbers, significant design complexity, and regular design changes are necessary, AM proves to be useful. Overcoming the design limits of traditional manufacturing processes, AM allows for the production of complicated parts. As AM does not require fixtures, tools, or coolants, it enables more efficient and quicker component manufacture. It also eliminates material waste, provides design freedom, and can print difficult structures with a greater resolution and surprising flexibility (Ngoa et al. 2018). In the aerospace, defense, automotive, biomedical, and construction industries, AM methods are widely employed (Pham and Dimov 2003; Campbell et al. 2018). AM processes have been mainly classified into seven categories – powder bed fusion (PBF), material extrusion, binder jetting, vat photopolymerization, sheet lamination, material jetting, and directed energy deposition (DED) (Astm 2015). Most commonly used 3D materials are polymers, metals, ceramics, and concrete. Although AM has numerous benefits, still AM

technology has not yet reached the point where it can be used in applications in the real world. There have been downsides and obstacles, along with advanced technological developments, that need to be investigated. The limitations of part size, and the construction of overhang surfaces, as well as high costs, anisotropic mechanical properties, low manufacturing efficiency, scalability limitations, top layers gaps, misalignment of layers, poor accuracy, over-extrusion, under-extrusion, elephant foot, warping, mass production, and material limitations, are all challenges that have been faced in AM (De Jong and De Bruijn 2013; Chen et al. 2017). Despite its enormous popularity, the lack of common metrology, inspection, and standards criteria has hampered AM's implementation (NIST 2012). Until the generated things were confirmed as appropriate and acceptable, AM's great potential would be intangible (Everton et al. 2016; Leach et al. 2019). This is one of the most significant obstacles to overcome until AM can be used extensively in industrial and military applications. Metal powder AM components are frequently characterized by high surface roughness values and might have undesirable material qualities. Furthermore, while a component cannot be made using subtractive methods without even a dimensional consistency system, it is currently unknown how to use tolerance concepts for AM parts. AM isn't any different than subtractive manufacturing in terms of metrology. However, existing AM equipment and procedures lack integrated metrology, which makes the commercialization of the produced items difficult (Berglund et al. 2018; Mani et al. 2017; Seifi et al. 2016). To supplement present AM technologies for manufacturing components with desired properties and accurate dimensions, new measurement techniques should be developed (Slotwinski et al. 2012; Stavroulakis and Leach 2016a). In this regard, metrology is a critical tool for analyzing and optimizing AM performance. Metrology in AM is crucial for identifying and then executing mitigation strategies to obtain dimensionally accurate products with the appropriate surface smoothness and material properties.

Background: Metrology – Measurement and Inspection Methods

Metrology is far more common than one may assume; practically everyone uses it unintentionally in their daily lives. Any conclusion that may be expressed numerically and in terms has been included. Metrology includes the establishment of units, the development of measurement techniques, the creation of artifacts that act as measuring norms to allow measurement traceability, and the analysis of uncertainties and accuracies (Raghavendra and Krishnamurthy 2013). Metrology and inspection are important and economical ways to improve AM quality. Testing would have to combine both developing and current methodologies for AM capabilities to keep growing. Different classifications for measuring and inspection methods include contact/contactless, destructive/nondestructive, in situ/ex situ, and real-time/off-time depending on the type of the method. Contactless, nondestructive, real-time, in situ measurements, as well as precise and time- and cost-effective technologies that are reliable and assist process control, are more suitable for AM. Different state-of-the-art metrology and inspection techniques are as follows:

Dimensional Metrology

Dimensional metrology deals with geometric characteristics, such as size, length, angle, shape, or coordinates. It is extremely crucial for controlling and measuring production processes when mechanical equipment interactions cause geometry deviations. Physical measuring equipment range from simple scales and rulers to advanced optical measuring and interferometry devices.

Linear Measurement

Linear measurement is performed with a variety of measuring equipment developed for industrial use. The majority of linear measuring tools are advanced versions of simple rulers and scales. Depending on the measurement needs, these are either precision or non-precision and graduated or non-graduated. Verniers, calipers, and micrometers are some of the most common linear measurement devices.

Angular Measurement

For alignment reasons, angular measurements are required not just to measure the angle, but also to determine straightness, flatness, and parallelism. The most commonly used instruments for this type of measurement are Vernier, micrometer, and protractor.

Comparators

Comparators use relative measuring principles instead of absolute measurement, with the sole distinction that seems to be that the sizes are assessed and compared to established measurements or standards. Electrical, mechanical, pneumatic, and mechanical-optical are the four major categories they fall under. Electrical, mechanical, pneumatic, or optical principles drive its fundamental working mechanism, as the name indicates.

Surface Metrology

Surface metrology tends to refer to the measurement of variation inside a surface or between two places on the same area. Surface qualities (such as topography, surface polish, or roughness) are crucial in the manufacturing industry. That's because the qualities of the mating surfaces have a considerable influence on the successful production of the entire system in terms of friction, corrosion, stress, dependability, aesthetic appearance, and so on when the components are put together. A careful examination of any surface shows surface abnormalities like waviness and roughness, which are usually related to the manufacturing process. Surface roughness measurements are mainly of two types: contact and contactless.

Coordinate Metrology

Coordinate metrology is the most sophisticated approach for accurately measuring three-dimensional (3D) coordinate values (Vora and Sanyal 2020). The information

regarding the coordinates of the specific position is critical for 3D measurements. Only coordinate metrology tools provide for the present capacity to produce things with the utmost accuracy (micro to nanoscale). Electronics, mechatronics, optics, mechanics, and computer science developments have all aided in the creation of coordinate metrology systems. These measurements give not only 3D surface data but also GD&T data, allowing for the rapid and precise detection of exterior (surface finish, etc.) and interior (porosity, etc.) faults in the 3D arena. Overall, coordinate metrology delivers great measurement precision and accuracy, although the equipment is more costly and measurements take longer.

Coordinate Measuring Machine

A coordinate measuring machine (CMM) is a device that comprises the contact probes that contact the test object's surface, a mechanical system that allows the probe to travel in three directions (X, Y, and Z), and a control system, either manual or automatic that keeps track of data of each axis' three-dimensional coordinates. Nowadays, different types of CMMs are available which have variations in mechanical structures, drive controllers, and configurations in the probe (Sładek 2016).

X-Ray Computed Tomography

X-ray computed tomography (CT) is mostly employed as a medical diagnostic instrument in the health industry. It has become increasingly popular for measuring the dimensions of engineering components because this process can measure the outer and inner geometry of a part without destroying it. It may be utilized to collect information on product internal structures for wall thickness examination, dimensional measurement, and component size and voids (Villarraga et al. 2015).

Magnetic Resonance Imaging

Paul C. Lauterbur devised magnetic resonance imaging (MRI) (Lauterbur 1973). Noncontact coordinate measuring and scanning systems are MRI systems. MRI systems are commonly employed in medical diagnostic procedures. The concept of nuclear magnetic resonance underpins MRI. A strong magnetic field region gradient is formed by the operation of large magnets, which impacts hydrogen atoms. A computer captures these changes to build a cross-sectional picture (Gao et al. 2015).

Geometrical Dimensioning and Tolerancing

The theory and measuring procedures of geometrical dimensioning and tolerancing (GD&T) are briefly discussed in this section. It is generally recognized that just supplying the tolerancing (plus/minus) and dimensioning of the design drawing is insufficient in production. To assess components and process capabilities, data on GD&T factors such as flatness, parallelism, straightness, roundness, squareness, cylindricity, and runout are required.

Measurement of Material Properties

Material qualities must be measured to evaluate part performance. Material characteristics can be evaluated through in situ metrology and mechanical testing. Mechanical testing is an important aspect of the examination process for determining the parts' functional and mechanical characteristics. Manufacturing process advancements provide several metrological difficulties, which may be efficiently addressed by employing in situ metrological technologies. Furthermore, the utilization of these approaches for real-time monitoring systems is one of the key advantages of in situ metrology.

In Situ Metrology

In measurements, in situ refers to taking a measurement using the system while maintaining the original test circumstances. In situ measurement is critical for ensuring the quality of produced parts. As machines become more complicated, new obstacles to standardizing procedures for modern in situ operations arise. In-process control and monitoring algorithms for the operation of the machine are always being improved.

Role of Metrology in AM

Metrology, or measurement science, comprises the equipment used to measure the dimensions, or even the measurements themselves and data processing (Musgraves et al. 2018). Some of the main reasons we invest so much effort into measuring what we produce are:

1. To determine if a part is suitable for its intended use; for example, would a shaft fit through a hole while still providing sufficient space for the passage of lubricating fluids?
2. To allow the gathering of complicated parts; without acknowledging the sizes of objects as well as their corresponding tolerances, fitting one component to the other becomes nearly impossible – this is especially true when assembling components produced by different companies or various parts of the same company.
3. Metrology is important for quality control because it allows us to try things like net-shape production and get it correctly the first time.
4. To provide control of a production process; there seems to be little control without measurement. For example, we may wish to adjust the speed of a cutting tool based on the surface texture it produces – we must measure the texture during the machining operation.
5. To reduce energy consumption; the fewer repetitive manufacturing processes necessary, the less energy is needed to make a product.

6. Customers' trust in a product ("customers" in this sense may be another manufacturing concern that has to utilize your components) – without tolerances and quality assurance, there will be a loss of faith in assembly procedures down the track.

Metrology is a very important and low-cost way to improve AM quality. Some of the applications are (1) validating whether components are within necessary tolerances, (2) characterizing various AM methods, and (3) developing standard techniques that assist decrease inspection costs and maximizing measurement accuracy. When different new materials and component geometries are continually introduced, form metrology, or the measurement and characterization of a component shape, is crucial for quality standards of AM components and AM machine makers to efficiently characterize and optimize their AM methods. Metrology for AM is critical in discovering and then implementing mitigation methods to achieve dimensionally correct products with the desired surface finish and material attributes. The present AM literature clearly states that metrology is required for many AM technologies, yet there are currently just a few solutions and guidelines available (Monzón et al. 2015; Seifi et al. 2016; Lane et al. 2016).

Challenges in Metrology of AM

As AM is comparable to conventional machining in terms of metrology. Therefore, the existing AM equipment and techniques lack integrated metrology, which makes commercializing the resulting parts very difficult. To provide the customer's faith in a product, the customer could be other manufacturing firms that have to utilize the product so without providing the quality control and tolerances, assembly operations will lack confidence. For instance, an aircraft company would not use a turbine blade created with additive manufacturing unless its metrology can provide a high level of assurance.

Advancements in metal AM equipment and procedures resulted in direct manufacturing of functional parts. This direct manufacturing of parts, particularly parts having complex structures, necessitated shared understanding between the one who designs, manufactures, and the end users concerning (a) the intent of the design, (b) specifications of material, (c) part testing and inspection essentials, and (d) procedures and part qualification and certification concerns. Numerous technical roadmaps have been developed in the past decade to highlight the major technological challenges to the mainstream adoption of AM (Bourell et al. 2009; NCMS Report 0199RE98 1998; NIST 2013).

All such roadmaps agree that AM-specific specification standards are needed to bring uniform and consistent methodologies for establishing requirements and testing the final components, by lowering the risk of implementing this technique. The first organization for developing standards to recognize the necessity and possibilities of AM standards was the American Society for Testing and Materials (ASTM International). The standards are defined at three levels according to the framework of ASTM and ISO: first is the basic standards (e.g., shared concepts and

requirements across all applications); second is standards for materials, processes, types of equipment, and finished items in general; and the last is standards for a particular material, procedure, or application. Based on their range, norms for geometrical specifications and measurements of AM components may correspond to all three levels of this system. However, there are currently just a handful of developed standards in this area. This shortfall is primarily due to the more immediate requirement to select materials and procedures for this developing technology. The most significant ISO and ASTM recommendations for geometric requirements and metrology standards produced so far are linked to designing for AM (ISO/-ASTM 52910 2017) and some basic concepts concerning quality attributes of AM components, with accompanying suitable test techniques (ISO 17296-3 2014). Part geometry and properties are mentioned specifically in the AM design standards (ISO/ASTM 52910 2017). The dimensions of the component, the surface texture, the maximum aspect ratio, the minimum spacing of feature, the minimum feature size, the maximum part size, and the maximum unsupported feature characteristics are all detailed. Part dimensions, surface texture, minimum feature size, maximum aspect ratio, minimum feature spacing, maximum part size, and maximum unsupported feature attributes are all stated in detail.

When it comes to the quality of AM products, a variety of measuring and inspection obstacles must be addressed. Among them, some are mentioned below.

Shape Complexity

Metal AM products have unique properties, such as complex shape and surface roughness, which make coordinate measurements of surface form and dimensions difficult. However, shape complexity is critical, particularly for interior holes as well as channels, porosity, and undercuts. They all can be printed readily by utilizing AM, but they cannot be measured or inspected easily. Consequently, product complexity has an inverse relationship with quality inspectability and measurement.

Effect of Post-Processing on Metrology and Inspection

The post-processing methods have an adverse effect on metrology and inspection. The post-processing of components in AM is unavoidable and preferred to fulfill the application's demands for metals, polymers, and composites. Shrinkage and cracks can also occur in AM components (Shahzad et al. 2013). Support structures are an important component of AM sections with overhanging components. Support structures must be eliminated before final use to avoid warpage in the AM component (Dimitrov et al. 2006). Removing the support structures leaves the component with a poor surface quality, which can be addressed with post-processing techniques (Svensson et al. 2010). Sintering-based AM techniques are an example of this approach. AM component shrinkage during solidification is a problem that may be mitigated by allowing for shrinking allowances. As a result, these post-processing procedures must be integrated into the component design to guarantee proper GD&T

(Islam et al. 2013; Seepersad et al. 2012). Before the slicing procedure, these size compensations are integrated into the CAD model (Limaye and Rosen 2006). This stresses the need for metrology in additive manufacturing.

Surface Texture Metrology

Metal AM surfaces are frequently complex, and uneven, due to which the texture measurements can reveal considerable variations in measuring technology. In the case of surface texture metrology, particularly the majority of measurement problems are connected to the topographies of the produced surfaces rather than material attributes. PBF procedure produces rougher surfaces than grounded surfaces, although not being as abrasive as other AM procedures like DED and FDM (Thompson et al. 2017). Because of vertical walls, many discontinuities, and reentrant characteristics, PBF surfaces pose considerable measuring issues (Townsend et al. 2016).

Powder Measurement

Besides, it is well recognized that environmental conditions such as relative humidity can affect powder measurements, particularly bulk density and flow measurements.

Internal Feature Metrology

As AM reaches the application arena of high-quality functional parts. The metrology issues associated with internal and hidden details are also rising (De Chiffre et al. 2014). Internal characteristics comprise internal cooling channels, which can already be expressed using old GD&T symbology, but not infill patterns and lattice structures, which are presently being developed using new GD&T symbology. Furthermore, though AM's process variability isn't as high as subtractive methods, inspection for internal material defects like cracks and pores is still required (Thompson et al. 2016).

Metrology and Inspection Methods for AM

AM can manufacture items with the utmost complex geometry and a wide range of materials, posing the same challenging metrology methods for measuring the performance of AM (Brown et al. 2013; Russell and Fielding 2014). Recent research has focused on not just the design and manufacturing of the component, but also on the requirement for metrology to assess the part's dimensions and functional quality.

Nondestructive Testing and Evaluation

The ubiquitous requirement for nondestructive testing (NDT) and evaluations (NDE) for AM is generally established based on the outcomes of numerous

conferences, meetings, and journal articles supplied by academia, industry, and government (Waller 2018). According to studies, AM technology is capable of creating a large variety of parts when especially in comparison to the component quantity, and it is recommended to NDT and NDE techniques to reuse the tried components. To develop real-time process monitoring, measurement, and control of AM technology, the National Aeronautics and Space Administration (NASA) and National Institute of Standards and Technology (NIST) have advised employing NDT/NDE techniques for AM parts and artifacts using in situ, contactless, and real-time metrological instruments for dimensional and materials characteristic measurement (Waller et al. 2014). Owing to the difficulty of the dynamic of AM techniques and the absence of formal predictive methods required for process control, some commercial AM systems are not provided with the in situ process and attribute evaluation with closed-loop process control systems. Internal flaws and surface texture monitoring in AM-specific products are currently the subjects of less investigation (Stavroulakis and Leach 2016b). It is suggested to check the industry criteria for component dimensions and measurement concerns before deciding on the optimal inspection technique for AM. Most of the inspection methods used for AM are nondestructive methods. The most commonly used NDTs for inspection purposes of AM are as follows:

Computed Tomography

The usefulness and feasibility of employing computed tomography (CT) (Ferrucci et al. 2015; Carmignato et al. 2014; Ontiveros et al. 2012) to both subjectively and statistically analyze AM-generated components has recently aroused attention. Using CT for the metrological assessment of AM components and artifacts has been a focus of study in recent years. For dimensional metrology, CT may be utilized to give information on the interior structures of products (Saint John et al. 2014). As a nondestructive technology for obtaining structural characterization of both internal and exterior geometric shapes of AM components, CT offers various advantages, and it is sometimes the sole feasible choice for extracting component dimensions of internal or hidden characteristics (De Chiffre et al. 2014; Villarraga-Gómez et al. 2014). As a result, CT technology is a partner in the "3D printing revolution" for AM product research and inspection. CT seems to have been beneficial in real-time process monitoring, in situ in AM.

Coordinate Measuring Machine

Coordinate measuring machines (CMMs) are commonly used to gather and assess three-dimensional metrological geometry data on a product. With sub-micrometer precision, they can determine the dimensions of spatial locations on the sample surface (Park et al. 2006). CMMs are commonly utilized as semiautomated to fully automated inspection techniques that are best suited for the production environment. CMMs are increasingly being utilized to help in AM inspection. Controlling both geometry and characteristic fluctuation is difficult with complicated components produced by AM machines. Tactile CMMs have been utilized in a variety of industrial applications for decades and can determine form and measures with

more precision than noncontact CMSs. Tactile CMM is contact equipment that takes many points with a probe to measure the surface of an element. An operator can manage the probe's position manually or automatically using a computer (Kupriyanov 2018). They are, however, slower and frequently sample a smaller number of spots on the measured area. Principles and features of tactile probing methods are presented elsewhere (Weckenmann et al. 2004), and interest in this area has dwindled since then. Metal AM methods and associated error factors are frequently studied using tactile CMMs as reference measurements. An optical CMM is a noncontact equipment that uses pictures to do measurements, relatively similar to measuring microscopes and optical comparators. Depending on whether or not they employ their means of illumination in contrast to ambient light, optical coordinate measurement techniques may be divided into two categories: active and passive (Carmignato et al. 2010). Active sensors, on the other hand, give superior measurement uncertainty and performance (Se and Pears 2012). Passive sensors are frequently less expensive, lighter, and more compact. As a result, active optical sensors are often the most accurate optical sensors for monitoring AM metal components. Both give high precision, but only optical CMM is used for smaller characteristics. Both give data of few points, are expensive, are slow, and also require post-processing.

Structured Light Testing

Controlling both geometric and characteristic variation is difficult with complicated products manufactured by AM methods. Laser scanning and structured light are optics-based methods for evaluating the surface of an AM component, along with dimensional analysis and the identification of residual stresses caused by warping (Mandache 2019). Structure light testing (ST) approaches enable real-time imaging performance and are widely employed in a variety of 3D imaging applications (Nguyen et al. 2015).

Ultrasonic Testing

Ultrasonic testing (UT) is an NDE method for identifying and analyzing surface and internal issues. UT can detect flaws as deep as several meters from most metals, although the component thickness is a severe constraint for other NDT techniques (Cerniglia et al. 2015). In AM, ultrasonic testing (UT) can identify voids or inadequate deposition layers. It is one of the most capable NDT technologies for industrial component testing (Fathi-Haftshejani and Honarvar 2019; Shakibi et al. 2012). Many new sophisticated ultrasonic methods have been introduced and deployed in a variety of industrial applications in recent years. It is a nonhazardous process and can also detect deep flaws. But it requires experienced technicians, and the surface must be smooth and accessible.

Interferometry

Interferometry is an NDT, contactless method which has been accomplished for surface topology measurements. Surface shape interferometric measurements are comparative measurements in which the form of a defined surface is compared to

that of an unknown surface. The difference is shown as a sequence of interference fringes on the surface (Abdelsalam and Yao 2017). Interferometry can measure smooth surfaces and provide high contrast and resolution. It has disadvantages like high cost and causes errors while measuring rough surfaces.

Scanning Force Microscopy

Scanning force microscopy (SFM), also called atomic force microscopy (AFM), is a kind of scanning probe microscopy (SPM) that has attained nanoscale resolution, which is 1000 times better than the optical diffraction limit. It makes a 3D surface profile and also works in both liquid and ambient air environments. It has a higher resolution than scanning electron microscopy (SEM).

Optical Profilometry

Optical profilometry is a surface metrology technology that is fast, nondestructive, and contactless (Fainman et al. 1982). An optical profiler is a microscope that divides light from a bulb into two paths using a beam splitter. In one direction, the beam is guided at the region under test, while in the other, it is directed toward a reference mirror. The two surface reflections are merged and then projected upon an array detector. When the path difference between the recombined beams is smaller than a few light waves, interference can occur. This interference provides information on the test surface's surface contours. It is an automated process and easy to use but has a limited surface slope.

Neutron Diffraction

Neutron diffraction is the application of neutron scattering to determine a material's atomic and magnetic structure. A specimen is immersed in a stream of hot or cold neutrons, which produces a diffracted that gives structural information about the material. It provides atomic structural information with great precision. Because of the irregularities in the neutron beam, the measurement accuracy may suffer.

Laser-Ultrasonic Testing

Laser ultrasonics is a cutting-edge NDT approach in which ultrasonic waves are generated and then measured in a material using lasers. When a laser beam is directed onto a sample surface, a thermal shock occurs, enabling the sample surface to quickly expand. As a result of the rapid expansion, the test piece generates ultrasonic waves. Generally, LU is performed in one of two ways: ablation or thermoelastic (Scruby and Drain 2019). Laser-ultrasonic testing can create ultrasound in objects without contacting them, has a tiny footprint that allows it to be deployed to asymmetrical shapes, and uses fiber optics to get access to inaccessible regions. It is a contactless method and remote examination of samples at high temperatures, such as during welding with limited access, is possible. The footprint is small and customizable. Inspection of tiny and complicated geometries is possible. It can detect flaws that are undetectable by ultrasonic testing. It has few disadvantages as efficiency is a function of material absorption qualities, which is somewhat costly and necessitates preventative precautions against probable laser risks.

X-Ray Computed Tomography

When it comes to interior geometry, X-ray computed tomography (XCT) is the sole viable option for product inspection in AM (Hiller and Hornberger 2016; Villarraga-Gómez et al. 2018). It employs X-rays to generate the virtual 3D representation of the inspected object without damaging it. Due to various benefits of tactile and optical measuring technologies, XCT is widely being employed to coordinate dimensions of AM components (Thompson et al. 2017). Furthermore, XCT may give surface texture measures, internal feature geometry assessment, and material quality inspection all at the same time. Different research areas are presently available in metrology to evaluate XCT as a referencing device for quality assurance of AM components. It provides information on interior flaws that other AM approaches cannot correctly deliver. If a part has complicated free-form geometries, high-roughness surfaces, difficult-to-access areas, or components with varied optical and surface qualities, XCT can benefit (Sbettega et al. 2018). A vast variety of influencing variables increases the uncertainty in XCT coordinate determinations. When scanning metal components, the metal and its penetrating thickness, which affects X-ray attenuation directly, have a significant impact on dimensions and form measurements (Carmignato et al. 2018). It is somewhat costly, and operational safeguards are necessary.

Conclusion

In real-life applications, AM technology shows great promise and has the potential to transform design, fabrication, logistics, maintenance, and acquisitions. Nevertheless, there are still a number of obstacles to conquer before AM becomes a viable tool in the industry's tool kit. "If you can't measure it, you can't enhance it," as stated by Lord Kelvin, and this simple phrase encompasses a tremendous discourse on why measuring is important and serves as a necessary component of the manufacturing system. That is why as AM progresses, the only strategy to assure that this new technique emerges as a viable production capability is to prioritize the development of suitable measurement methods and calibration regimens.

The present state of metrology for AM has been examined in the chapter, as well as its requirements. Present AM specifying standards and the need for wide usage of AM procedure have considerable gaps. Due to a variety of factors, including the existence of internal deformities and complicated surface topography, additively made parts are characterized by metrological problems and complications. Specific properties of metal AM products, such as complicated shapes and surface characteristics, with typically significant roughness, make coordinate measurements of surface form and dimensions challenging.

A broad analysis of general metrology and in situ real-time inspection techniques utilized in traditional production methods has been discussed. In order to use the stated approaches for components generated by AM methods, a full description of metrology and in situ real-time inspection methods is offered.

Abstract

Today, additive manufacturing (AM) is used in many industries, including aircraft, transportation, medicine, architecture, toys, arts & design, and construction. The 3D model is created in a computer-aided design (CAD) software, and this model is converted into a standard translating language (STL) and then transferred to a 3D printing machine, creating a physical model via a material joining process into a layer-by-layer pattern. AM is expected to have a tremendous impact on the industry and, eventually, every aspect of our life. To make the manufacturing revolution a reality, though, there needs to be an ongoing research effort into AM metrology. AM processes require the implementation of tolerance and quality control techniques, starting with offline metrology and moving toward closed-loop control using inline metrology. The several significant capabilities of AM are covered in this chapter, along with their metrological implications. Additionally, several significant challenges of AM for measurement systems are briefly explored.

Keywords

Additive Manufacturing · Metrology · Standardization · Measurement · Quality

Introduction

Additive manufacturing (AM) has proliferated over the past decades. The American Society for Testing and Materials F-42 classified the AM process into seven different processes based on the powder, liquid, and solid forms of material (as shown in Fig. 1). In terms of general operation, all AM technologies use the same base. The procedure begins with the 3D modeling, converting the CAD model into a standard

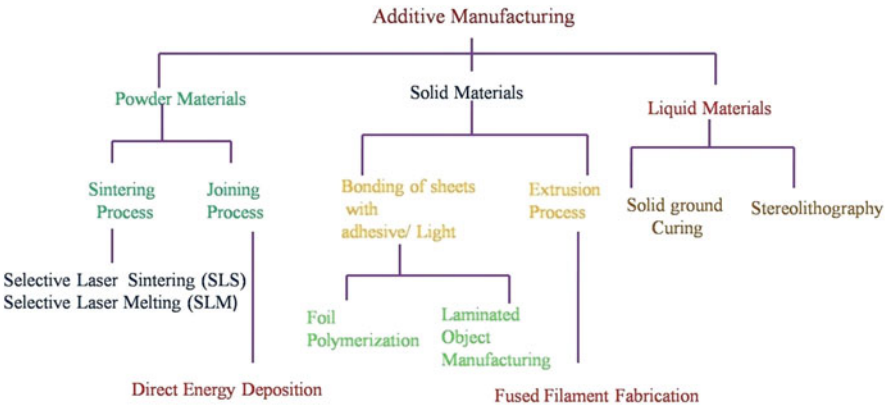

Fig. 1 Classification of AM processes (Gardan 2017)

translating language (STL) or AMF file format. Usually, STL file format is preferred as compared to AMF because it is heavier and requires more storage. This file was transferred to a 3D printing machine where slicing of the model was done based on printer slicing software; then ultimately final part was fabricated. It has the unique feasibility of design freedom, efficiently fabricating complex and customized parts without any constraints for mold, dies, or prerequisite tool preparation. The manufacturing industry has been attracted toward incorporating AM into the production system entirely or in hybrid mode. Despite many benefits, it is still not feasible to see AM-produced parts as finished, ready-to-use parts and for mass production, especially when it comes to metal additive manufactured parts. Metal AM part still has many discrepancies such as dimensional inaccuracy, surface roughness, warpage, porosity, and defects. Although industries have partially adopted the AM industry, however, it cannot replace the conventional manufacturing process entirely due to a lack of standardization, metrology (measurement science), dimensional inaccuracy, and qualification and certification issues in AM (Pant et al. 2021, 2022a; Tofail et al. 2018; Paul et al. 2018). Since the inception of manufacturing, metrology has been indispensable for the manufacturing industry because it provides valuable input for process control and post-process troubleshooting. It is strenuous to build up production processes and maintain production tolerances to reduce the number of scrap components without quick and precise metrology. In the field of AM, where many machines are employed on the same production floor to scale up output, metrology is important in every phase. To obtain precise tolerances on the products being created, each machine could be considered an individual production process or manufacturing line that requires process feedback. Although various authors have noted hurdles to the widespread adoption of AM in the industry, the following may be highlighted as examples of these challenges:

1. The link between material qualities and powder properties is not precise, and this must be recognized.
2. Machine-to-machine or day-to-day variability is caused by underlying variables that are not fully understood.
3. Traditional methods for material qualification and certification of AM materials are largely impracticable in terms of time, effort, and expense. Standardized procedures for qualifying and certifying AM components materials are absent or insufficient.
4. There is a lack of AM material data, including both generic and high-quality, pedigreed, reproducible data required for design-allowable databases.
5. Limited build volumes/part sizes, poor part accuracy, and surface finishing.
6. There are no established, uniform techniques for analyzing AM materials across laboratories.

AM is a multidisciplinary field that necessitates tight collaboration between information and communication technologies (ICT), design, material, and technology. The adoption of AM principles will make it possible to move from mass production to the future specialized, demand-driven, and environmentally friendly

manufacturing needs. This chapter discusses the metrology role of AM. The different methods needed during the preprocessing, in-process, and post-processing are discussed. It also discussed the present organization working on the standardization and developing a road map of measurement science for AM industry.

Metrology Need for Different Phases of AM

AM has been widely used to produce parts with internal cavities in free-form geometries, typically impractical or prohibitively expensive with traditional machining techniques. The use of modern technologies, which model, simulate, and store every step of the manufacturing process (i.e., the whole life cycle of a product, from its design to production, assembly, testing, and maintenance), increases productivity and quality. The function of metrology, and its application, has altered substantially due to countless advancement. The inconsistent geometric dimensioning and tolerancing (GD&T) of 3D printed objects is one issue preventing the widespread usage of AM industry. Traditional inspection techniques, such as tactile coordinate measuring machines (CMM) and contact measuring devices used for castings or forged components, are also utilized to measure system and material properties on a specific combination of additive machine and alloy. The limitations on its wider acceptability are variances in part quality concerning material qualities, dimensional tolerances, surface roughness, and defects. Today's process control methods, which rely on heuristics and experimental data, only slightly increase part quality. The measurement standard was required in the following areas (Javaid et al. 2022; Pant et al. 2022b).

Preprocess Measurements

Powder bed fusion (PBF) is the most common process in the metal AM process, where the material is used in powder form. Hence, it is critical to quantify and measure the powder properties to predict the final quality of components. The literature reported that if the two powder particles show the same behavior, their dynamic behavior is still a variation. It demonstrated how various batches of AM steel powders can operate differently in a metal AM system despite having similar particle size distributions and dramatically varying flow characteristics. Undoubtedly, the technologies employed to analyze AM powders are not sensitive enough or appropriate to do so accurately, given the importance of particle properties to AM process. The shear, dynamic, and bulk properties measurements should be included in best practices to understand powder flow behavior in AM systems fully. Hall flowmeter measurements frequently used to characterize metal powders also have limits. The final quality outcomes can be influenced by particle characteristics such as morphology, surface roughness, surface chemistry, size distribution, and environmental factors (Forster 2020; Slotwinski and Garboczi 2015; ASTM International 2010).

Process and Equipment Measurements

3D design is the foundation for ensuring that parts are accurate, fit correctly into a functioning assembly, and line up with other essential features and components. Specialized software has been created for design, simulation, feasibility, and costing solutions. Materials with various pricing ranges are required for fabrication, including composites, carbon, stainless steel, aluminum, brass, and copper. The 3D model is examined for scale and manufacturability before any material is created, which increases the process efficiency. The digital thread that connects computer-aided engineering (CAE) manufacturing and metrology solutions is centered on the CAD model. The activities of CAD-based inspection software are based on a 3D model. A metrology tool, such as a portable arm and integrated scanner, collects 3D point data or scanned point clouds from the manufactured part connected to the digital model. The scan set and primary component are compared in the inspection program to determine whether the part passes or fails after the data has been aligned to the CAD model using key reference points. The temperature and melt-pool shape were measured using the charged-coupled-device (CCD) camera. It resulted in mapped photos of the entire build area with more precise and localized melt-pool signals. Scientists could identify part deformation and overheat close to overhanging structures by measuring variations in the photo detector output (Dunbar et al. 2016).

Modeling and Simulation

Modeling and simulation are crucial for evaluating the characteristics of AM products before the start of actual production. It aids in the optimization of input variables to produce products with the desired features and attributes. Real-world metrology results assist in validating the outcomes of modeling and simulation. Usually, a range of physical factors controls the metal AM process, including powder layer creation, laser-powder particle interaction, and heat transfer, fluid dynamics of the melt pool, phase transitions, and microstructure growth. Any deviation in these systems could impact the final component's quality. Inconsistent product quality is a significant obstacle to the metal AM technology's broad adoption. Investigating the sources of variability, quantifying the uncertainties that arise at various stages of the process, and figuring out how much they have impact on crucial output values will all help to improve the quality of the final result. Computational models and simulations are potential techniques to comprehend the dynamics, complicated phenomena, and variability present in the process because undertaking uncertainty quantification via physical tests is frequently expensive (Seif et al. 2016; Moges et al. 2018).

Post-process Measurement

The post-process measurements are often focused on the part quality and based on dimensional accuracy, surface texture, and mechanical properties. The parts made with AM can potentially crack and shrink. The support structures are an essential

component of the overhanging structure AM components. Support structures must be taken down to prevent the warpage of the AM component before final use. When these support structures are removed, the component has a poor surface finish, which is improved by post-processing processes. Coordinate metrology of the exterior form is essential for metal AM product quality assurance and for providing input for AM process optimization. Metal AM items eventually exhibit form defects due to intricate interactions between the material and the energy source, warpage brought on by thermal gradients, and residual stress inside the part. Tactile CMMs are commonly used as reference measurements for the assessment of metal AM operations and related error sources. There is so much literature that has been reported on various materials to check the tensile, fatigue, density, porosity, and residual stress properties to correlate with AM machine parameters and compare with conventionally manufactured parts (Leach et al. 2019; Chen et al. 2022).

Qualification and Certification

An industrial insight analysis of the AM market estimated that the AM market would increase at an average annual rate of above 20% over the next 5 years. Due to the superior overall performance of toughness, strength, hardness, and wear and heat resistance of metallic products as compared to those of polymeric and ceramic counterparts, metal AM, which includes directed energy deposition (DED), powder bed fusion (PBF), binder jetting, and sheet lamination techniques, plays an increasingly important role in the AM industrial market. The primary purpose of certification is to satisfy a certifying authority or organization. Most of the time, certification and qualification are interchangeable because they attempt to fulfill predetermined requirements. However, certification emphasizes whether the authority meets deliverables (such as products). In contrast, qualification focuses more on whether a product is created or manufactured following industry criteria. According to the technical requirements and the specification of the product manufacturing process, the operation, technique, and process parameters should be evaluated. A series of production qualification for sample testing, consistency, and reliable production performance validation could be required throughout metal AM operations and post-processing. Qualification and certification organizations play a crucial role in driving the commercialization into different sectors by offering a range of services, including feasibility assessments, training, consulting, accreditation of quality management systems, testing, and audit, as well as surveys (Seifi et al. 2017; Chen et al. 2022) (Table 1).

Advanced Measurement Methods

The function of metrology within the manufacturing system has evolved dramatically due to advancement like intelligent multisensor systems, virtual metrology, and metrology-driven operations. In the past, measuring solutions were typically used for

Table 1 Several advanced techniques for quality control and inspection (Vora and Sanyal 2020)

Factor	Property	Measurement approach	Measurement technique
Material characterization	• Powder, wire filament liquid feed morphology	Off-line/at-line	X-ray photoelectron spectroscopy, energy-dispersive X-ray analysis, atomic force microscopy
In-process monitoring	• Dimensional inspection • Surface chemistry, macrostructure, and porosity microstructure • Internal surface inspection • Thermal management	Off-line/in-line On-line/in-line On-line/in-line On-line/in-line	CMM, gauges, light scanners, Raman spectroscopy, scanning electron microscope, transmission electron microscope Ultrasonic, radiography, tomography IR: infrared
Post-build processing	• External surface inspection • Internal stress • Grains, grain boundaries, cracks, and defects including dislocations • Surface finish	Off-line Off-line Off-line Off-line	Visual, penetrate, E-magnetic X-ray diffraction visible light microscopy Atomic force microscopy, Profilometry

quality checks at the end of verifying a product's compliance or as post-processing activities. The most recent industrial revolution has resulted in the availability in real time of a wide range of measurable data needed for management, monitoring, and diagnostic activities that can be used to speed up inspections and analysis. Feeler gauges, micrometers, slide calipers, checking fixtures, and a coordinate measuring machine (CMM) equipment are used for quality control (QC) and inspection. Measurement science has made considerable strides in the previous ten years and now provides the technology and software required for inspection. With an emphasis on accessibility and software modification, it has enabled the broad use of high-precision measurement for vehicles, aircraft, consumer goods, electronic enclosures, and other production applications. As mechanics, technicians, tool makers, and other nonprofessional metrologists employ portable metrology devices today, the person who 10 years ago used feeler gauges to check a part does so without hesitation. Modern manufacturers are discovering the value of feedback from metrology data during production, so they may change the procedure and stop spending time inspecting the items. Robots, laser trackers, sensors, software, and hardware, all of the technology needed to make these notions possible, are all readily available now. Manufacturers are placing metrology procedures on the shop floor directly adjacent to the production of parts at the OEM level (McCann et al. 2021; Santos et al. 2020). Robotic and metrology-based automated cell systems can take apart, load it into a scan cell, start the cycle, and produce a report at the conclusion. Many nondestructive (NDT) methods have been reported to evaluate the quality of additive manufactured parts, which are discussed below.

X-Ray Computed Tomography (XCT)

AM can fabricate complex and intricate parts; however, these parts require a delicate measurement method to measure the dimensional accuracy, surface texture, and internal and external features. Sometimes, it is difficult to measure such delicate components using conventional measurement methods. XCT is an optical measurement tool used to measure porosity, volume density, dimensional accuracy, and internal structures. In the XCT method, an X-ray cone beam scans an AM part repeatedly from various angles, enabling a 3D reconstruction of the part to expose the 3D complex volume without causing any damage. This method offers fantastic advantages over conventional inspection methods. It can observe the internal and exterior properties simultaneously. By quantitatively sampling and reconstructing the intricate lattice structures, flaws and porosity can be found, and their distribution can be determined (Matsushima et al. 2006; Garboczi and Bullard 2017).

In-Line Metrology

Modern in-line/on-line machine measuring facilities should adhere to all the features and observe the geometric related flaws and other internal features of the additively created components during the production. In-line metrology involves taking measurements while a process is in progress and has several benefits over conventional approaches, which treat inspection as a specific activity for manufacturing operations. Using in-line metrology concept, it becomes easier to take quick action and detect the flaws immediately. Previously, the additional setup and transport activities needed to move the items to an inspection department can cause delays. In-line inspection speeds up the process and enables the elimination of some processes. Because early problem detection of measuring items in-process can help to reduce rework and scrap (Everton et al. 2016; Fieber et al. 2020).

Robots

In today's workplaces, robots assist in creating and calibrating complex measuring devices; nevertheless, robots frequently rely on these same sophisticated measuring devices to complete their tasks. The requirements of robots have occasionally served as an inspiration for the creation of sensors, although robots perform poorly in poses, which restricts their usage for high-precision tasks, particularly for measurement applications. They provide six degrees of freedom (DoFs) of movement, a fast rate of execution, and a considerable deal of versatility. These qualities continue to be very desirable and may enable the 3D digitization of complicated parts produced by AM while utilizing the ongoing reorientation offered by robots. The surface quality of the AM parts is still challenging because it does not meet the requirements for final use. To resolve this problem, measuring the form and dimension variation is vital to thoughtfully plan the post-processing processes. Additionally, the advanced measurement phase should be wholly integrated into the production line near the AM

process. Robots enable quick access to the majority of orientations and positions required to digitize complicated parts (Tankova and da Silva 2020; Bhatt et al. 2020).

Laser Trackers

The development of novel optical measurement techniques, including laser trackers, structural light sensors, and optical sensors, is a result of the advancement of production processes. These techniques are utilized in manufacturing, metrology, and reverse engineering. Since laser sensors enable the generation of more than 100,000 points in a matter of seconds, they are distinguished by having a quick measuring time. When the proper scanning approach is used, they can perform measurements accurately. Therefore, the proper scanning strategy configuration might improve accuracy while utilizing measurement speed and the dense point cloud. In general, quality indicators often assessed by artefact measurements are used to indicate the measurement quality of a laser sensor. Most often, noise and trueness are used to describe the caliber of measurement data. A parameter that assesses the dispersion of the measured points concerning a related theoretical feature is referred to as noise. In contrast, trueness is defined as the difference between a reference distance and a measured distance between two measured characteristics (Macy 2015; Chesser et al. 2022).

Present Organization in AM

The rapid prototyping community first became interested in standards for AM in the 1990s, even though these technologies were not frequently used to create actual parts for direct production. At the time, rapid prototyping technology was still primarily focused on formal/functional prototypes. The National Institute of Standards and Technology (NIST) in the United States held a workshop for the industry on "Measurements and Standards Issues in Rapid Prototyping" on October 16–17, 1997. Numerous organizations and specialists have urged the establishment of particular standards for additive manufacturing over the past decades. However, the most significant advancements have been made in the last few years, mainly via the efforts of international organizations like the International Organization for Standardization (ISO) and the American Society for Testing and Materials (ASTM), with the assistance of technical groups and projects aimed at the standardization (Jurrens 1999; Musgraves et al. 2018). Standards are instruments that eventually increase the user confidence in a product. Different measurement techniques, standards, procedures, and terminology are applied correctly and consistently. The Society of Automotive Engineers (SAE), Aerospace Material Specifications (AMS), American Society of Mechanical Engineers (ASME), and American Welding Society (AWS) are examples of organizations working on standards for metal AM that cover materials, processes, post-processes, and inspections. The corresponding AM committees are ISO Technical Committee (TC) 261: Additive Manufacturing and ASTM F42: AM Technologies. Currently,

ASTM F42 is working on about 20 work items for proposed new standards, with ten of those being approved standards. Additionally, ASTM F42 has developed a strategic plan for standards creation that specifies the fields in which high-level, particular, and technical standards are required in the future (Mani et al. 2017; GovTrack HR 1988; U.S. Congress 1988). The National Science Foundation (NSF) and NIST both contribute to defining the technical difficulties preventing the more general deployment of AM technology. The academic community, business, and governmental groups all participated in both organizations. The NIST project proposed broad industry strategies for tackling those technological problems, particularly on demands related to metal-based AM systems.

Challenges

The widespread use of AM is hampered by problems with part quality, including dimensional inaccuracy and form flaws, undesirable porosity, layer delamination, and unclear or inadequate material characteristics. The setup of the AM process parameters, which is currently commonly done via a trial-and-error manner for each material, might be attributed to part quality difficulties. With AM, many new challenges have emerged from a metrological point of view:

1. However, there are not enough adequate and pertinent metrological instruments and methods. Due to that, AM has not yet established a sustainable quality assurance system.
2. The lack of material data still necessitates a deeper analysis of the materials' issues relating to AM-built items.
3. Internal faults can significantly impact the quality, mechanical properties, and safety of finished products such as powder agglomeration, balling, porosity, internal cracks, and thermal/internal stress. Defect inspection techniques are therefore essential for removing manufactured flaws and improving the surface quality and mechanical properties of AM components. To convey information more clearly and from different angles, three-dimensional multicamera modeling objects need to be investigated. It will increase the accuracy of defect identification.
4. AM processes must be controlled for tolerance and quality, first with offline metrology and then with closed-loop control using inline metrology. The advancement of AM also requires concurrent research activities and global standardization.

Conclusion

This chapter summarized and identified the measurement science requirements essential to real-time AM process control. The study is structured to show the measurement role during the different phases of AM to manufacture better quality

products. Metrological characterization is required for AM not just from a technological aspect but also due to the market's requirement for products with consistent and dependable performance. The future manufacturing industry is built on more innovative, faster, actionable metrology. The automated control systems used in factories with industrial robots and automated material handling are based on rapid feedback and verification. Manufacturers need to adapt their inspection processes to overcome physical barriers and close the gaps in the metrology information between different value chain stages to support autonomous digital production.

Abstract

Additive manufacturing (AM), commonly known as 3D printing, is gaining popularity in academia and business due to its distinct benefits over old-fashioned subtractive manufacturing. However, its processing parameters are challenging to control since they can significantly influence the printed parts, microstructure, and subsequent product performance. Building a process-structure-property-performance (PSPP) connection for AM is a complex undertaking. Understanding the combined effects of strain, strain rate, and temperature is essential for understanding the crashworthiness of the AM components. This can be done using numerical-analytical models and topology optimization. This chapter reviews the progress made in using topological optimization and numerical-analytical models for several parts of the am whole chain, including

Introduction

In contrast to conventional manufacturing, which comprises subtractive manufacturing technologies and formative manufacturing procedures, additive manufacturing (AM) is the "process of combining materials to build things from 3D model data, usually layer upon layer" (ISO/ASTM 52900-15) (A Short History of 3D Printing). AM offers significant advantages over conventional manufacturing processes, such as the capacity to create intricate structures, drastically reduced resource usage, and quicker product development cycles. Since freeform manufacturing enables the construction of novel structures with greater strength and less weight than conventionally manufactured components, metal additive manufacturing (AM) has gained appeal. Powder-based metal additive manufacturing (AM) has advanced from quick prototyping to quick production during the past 20 years. The two main process types are powder bed fusion (PBF) and directed energy deposition (DED). Some powder bed AM processes go by historical or branded names like direct metal laser sintering (DMLS), selective laser melting (SLM), electron beam melting(EBM), selective laser sintering (SLS), etc. Directed energy deposition techniques are also referred to as laser-engineered net shaping (LENS), direct metal deposition (DMD), and laser-melted deposition (LMD). Some of the significant milestones for the development of AM are listed in Table 1.

The Additive Manufacturing File Format

The 3D file format known as AMF, or additive manufacturing file Format, is used to store and describe things that will be manufactured via additive manufacturing. The stereolithography (STL) file standard is what AM machines utilize to create the slices needed to make the part. As seen in Fig. 1, the STL format approximates the part surfaces using planar triangles. The component representation is erroneous due to this piecewise planar approximation, especially for strongly curved surfaces (Zhao and Luc 2000; Zhao et al. 2009; Pandey et al. 2003; Jamieson and Hacker 1995). The AMF format, which is based on XML, was created to include native support for file specifications including scale, geometry, lattices, color, material, and orientation.

The main body of the part can be colored in accordance with a function from the original design by using nested color assignments. Vertices, triangles, volumes, objects, or materials can be colored in red, green, or blue and have a certain amount

Table 1 (continued)

Additive manufacturing milestones	Year	Reference
With the introduction of the first prosthetic limb in medicine, 3D printing acquires more recognition	2008	Manero et al. 2019
The patents protecting the fused deposition modelling (FDM) printing method expired in 2009. This made it possible for new companies to begin making commercial FDM 3D printers	2009	Monclou Chaparro 2017
The development of the first printed aircraft and prototype car demonstrates the scalability and potential	2011	Molitch-Hou 2018
The specification for its additive manufacturing file formats was made available by the ASTM international committee F42 on additive manufacturing technologies	2011	Lee et al. 2019; Krueger 2017
SLS patent of Carl Deckard expires. The high-resolution, low-cost technology offers new potential for 3D printing businesses to grow. The first 3D printer with zero-G technology is sent to orbit by NASA	2014	Bayraktar 2022; Werkheiser et al. 2014
Introduction of 4D printing	2014	Tibbits 2014
The Swedish company Cellink releases the first commercial bio-ink that can be used to create cartilage tissue. This development benefits researchers worldwide as 3D bioprinting becomes more accessible	2015	Jose et al. 2016
Additive manufacturing for high-strength alloys	2016	Mukherjee et al. 2016
The first household to reside in a 3D-printed house. The house took 2 days to print and is now fully habitable	2018	Hossain et al. 2020
Self-healing elastomer materials with free-form designs produced using additive manufacturing	2019	Yu et al. 2019
World's first human cells-based 3D-printed heart created	2019	Noor et al. 2019
Introduction and implementation of aerial additive manufacturing with multiple autonomous robots	2022	Zhang et al. 2022

of transparency added to them. Because clear components can be produced by various AM methods, including vat photopolymerization, the transparency value may not be useful. Color values could be used in conjunction with other material-based factors to control an AM process in a variety of ways.

Regarding the picture data assigned to objects, the color assignment is inapplicable. The texture operator, however, can be used to accomplish this. First, a texture is assigned geometrically by scaling it to the feature, which ensures that each pixel applies to the object uniformly. These pixels will have intensity, and that intensity will be given a color. It should be noted that this is not a physical texture, such as ridges or dimples, but rather an image texturing process like computer graphics. It is possible to allocate different volumes to be made from various materials. Multiple

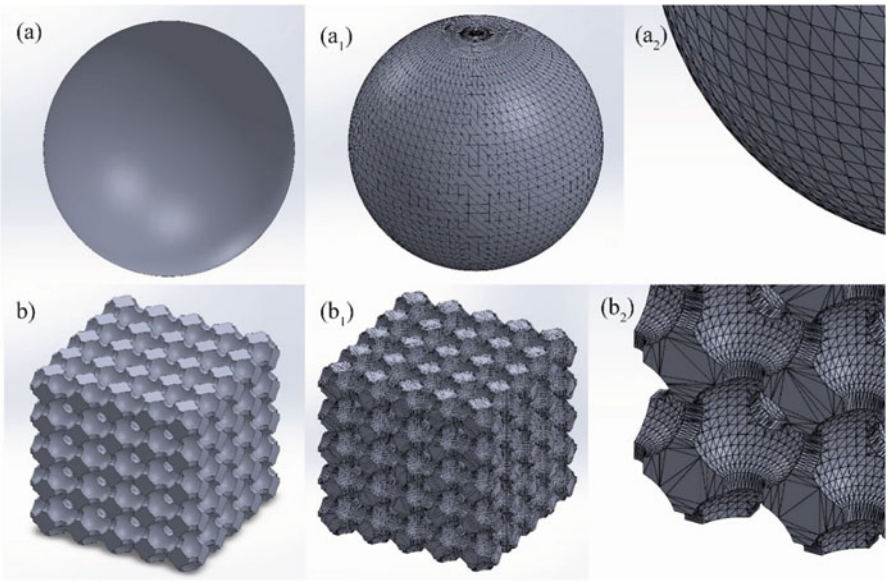

Fig. 1 CAD part (**a**, **b**) and STL file (**a1**, **a2**, **b1**, **b2**)

material parts can now be produced using the Connex machines from Stratasys and a few other extrusion-based systems. The operating system of the machine must now go through a laborious redefining process before designing parts. It is feasible to continue this from the design stage onward by having a material specification within AMF. The fundamental structure of the component to be manufactured can be altered using AMF operators.

The parts produced by AM machines using the STL file representation as a guide are inaccurate as a result of this approximation (Navangul 2011). By using smaller triangles and increasing the tessellation in the STL file, the approximation can be lessened. However, the number of triangles in the file grows exponentially as a result, leading to huge file sizes. Vertex translation algorithm (VTA)-based selective modification of the STL file depending on the error threshold of various surfaces has been suggested by Navangul et al. (2011). The amended file still employs planar facets even though this technique has been shown to be effective in decreasing the approximation error while regulating the growth in the number of facets. Consequently, there is a limit to how much better the tessellation may be made using this method.

The STL format has a lot of issues, despite being effective, as has already been mentioned. An alternative format will probably be needed as AM technologies advance to accommodate various materials, lattice structures, and textured surfaces. In May 2011, the ASTM Committee F42 on Additive Manufacturing Technologies published ASTM 2915–12 AMF Standard Specification for AMF Format 1.1, and ASTM also proposed a whole new additive manufacturing file (AMF) format.

(de Normalización 2013). Second-degree Hermite curves are used in this AMF format to depict curved triangles that split back into planar triangles by the AM machines as they read the AMF file to produce the slices.

Although it is still in its early stages of development, some commercial and beta-stage software has already adopted this file format. AMF, which is much more complicated than STL, intends to incorporate a wide range of new part descriptions that have impeded the advancement of current AM technology. These have the following characteristics: triangles that curve: in STL, the surface normal and the triangle vertices to which it is connected are on the same plane. The normal vector's starting point does not need to be in the same plane in AMF, though. If so, a curved triangle must be used in its place. This method of describing the triangles allows for far less triangle usage in a normal CAD model. This solves the issue of big STL files for high-resolution systems due to complicated geometry models. Since there is a limit to how much curvature may be applied, the curved triangle method is still only an approximation. However, there has been a significant improvement in overall accuracy in terms of cusp height deviation.

Santosh et al. (Allavarapu 2013) have developed a curved format for AM machines that piecewise approximate the CAD surfaces using modified rectangular biquadratic Bezier surfaces. Although the Bezier format can considerably reduce mistakes, cutting the Bezier patches to generate the contours cannot be done analytically, necessitating the use of numerical or optimization methods, which introduces flaws in the solution.

A new file format that uses curved Steiner patches rather than flat triangles for both approximating the part surfaces and creating the slices is introduced by Paul and Anand et al. in a research paper (Paul and Anand 2015). Bounded Roman surfaces called Steiner patches can be parametrically expressed by rational Bezier equations. This new Steiner file format will be more accurate than the conventional STL and AMF formats due to Steiner surfaces' greater order, which will also result in fewer geometric dimensioning and tolerancing (GD&T) mistakes in components produced by AM procedures. The slicing of the Steiner format can be done with relatively low processing complexity because the intersection of a plane and the Steiner patch is a closed-form mathematical solution. The Steiner representation is also generated using an error-based adaptive tessellation approach that minimizes the number of curved facets while enhancing the Steiner format's correctness. The adaptive Steiner, STL, and AMF format representations are used to digitally construct the test components, and the GD&T errors of the fabricated parts are calculated and compared. The findings show that, in comparison to the STL and AMF formats, the modified Steiner format can greatly reduce the chordal and profile defects. The aim of this chapter is to provide an overview of modelling and simulations. The modelling is organized as follows:

(a) *Heat source modelling*
(b) *Residual stresses and distortion*
(c) *Melt pool characteristics*

(d) *Surface characteristics modelling*
(e) *Microstructure modelling approaches*
(f) *Porosity modelling*
(g) *Material properties modelling*
(h) *Topology optimization*

Modelling Considerations in AM

To evaluate the build quality, process modelling offers first-hand data (such as temperature evolution and stress evolution). A strong computational method should contain both microscale and macroscale models due to the nature of layer-by-layer production. The microscale modelling objective is to investigate the basic operations of an AM process at short lengths and time scales, such as the interaction of an energy beam with a material in a microsecond, transient melting pool dynamics in a single scan, temperature evolution in a few scans, or the building of multiple layers. Macroscale modelling adopts the outcomes of microscale modelling to anticipate the surface integrity of the manufactured component, such as residual stresses, part deformation, and surface roughness. Utilizing multiscale modelling methods at the process level not only provides essential information for future microstructure prediction but also makes it possible to optimize the process and product design for higher component quality. This section describes the advancements and modern computing techniques in macroscale and microscale modelling. Metal AM processes have been facing various challenges in terms of quality-wise component production (Rezayat et al. 2015). These challenges primarily include the framing of defect remedies and their in situ/post-process minimization/mitigation.

Hit-and-trial experiments and numerical modelling are the two methodologies needed to address the physical phenomena involved in the occurrence, correction, and prevention of these problems. Therefore, to prevent this from happening, an analytical and numerical modelling technique is required. This approach offers a proper set of process parameters for component manufacture with the fewest possible flaws. Finite element, boundary element, and finite difference methods (FEMs, BEMs, and FDMs) are mesh-based numerical modelling techniques. Smoothed particle hydrodynamics (SPH) is a mesh-free numerical modelling technique (Dao and Lou 2021; Liu and Liu 2010).

The mesh-based finite element method (FEM) was developed by Turner et al. (1956). In every area of engineering, FEM-based numerical analysis has been a proven vital tool to tackle boundary difficulties, initial and eigenvalue problems (Hughes et al. 2014). To avoid wasting time and money on hit-and-trial testing, the usage of FEM has been expanded for modelling and parametric optimization (Mehboob et al. 2018). In light of this, FEM has emerged as the most popular modelling technique for predicting flaws, such as porosity, residual stress, and distortion. A few noteworthy evaluations in the areas of technologies, development, and long-term interests and qualities, defect, and problems in material processing and quality improvement.

Numerical Modelling in AM

The use of finite element analysis (FEA) techniques to forecast how various manufacturing processes will perform as process parameters, geometry, and/or material parameters change is becoming more and more common. To forecast the results of welding, forming, molding, casting, and other processes, manufacturers employ commercial software programs like SYSWELD, ANSYS, COMSOL, Mold Flow, and DEFORM (Vanderploeg et al. 2017). Predictive finite element methods have an especially difficult time simulating AM technology. For instance, utilizing physics-based FEA to accurately mimic the multiscale nature of metal powder bed fusion techniques like metal laser sintering and electron beam melting would take a very long time.

Due to the intrinsic multiscale nature of AM processes, it is necessary to use fine-scale finite element meshes with a size of 10 μm or less in order to fully represent the solidification physics surrounding the melt pool. Several academics are seeking for methods to establish assumptions that would allow them to copy and paste solutions from simplified geometries to construct a solution for big, complicated geometries using existing FEA tools. The advantage of this method is a quicker solution time, but for large, complex geometries, these predictions fall short of fully capturing the impacts of shifting scan patterns, intricate accumulations of residual stresses, and localized thermal properties.

Additionally, the simplified solutions may become invalid due to slight adjustments to the input conditions. Therefore, the objective of a predictive AM simulation tool is to create a simulation infrastructure that can swiftly build up a "new" response for every given shape, input condition, and scan pattern. In order to speed up FEA analysis for AM, researchers have recently started employing dynamic, multiscale moving meshes (Greco et al. 2015; Neugebauer et al. 2014; Luo and Zhao 2018). These multiscale simulations move along at speeds that are many times quicker than those of conventional FEA simulations. This section now moves on to overviews of modelling and simulation that take into account many aspects that affect the quality and use of parts made using additive manufacturing.

Heat Source Modelling

A number of process variables, including heat source power, deposition rate, thermal history, etc., affect how well AM components work. The numerical modelling reduces the failure rate of the designed structure, enhances the structure's quality, and aids in understanding the intricate phenomena that control the success of the AM. During metal AM procedures like selective laser melting (SLM) and directed energy deposition, the same high-energy heat source is used for material deposition. Around the melt pool, a significant temperature differential is produced by the high-energy concentric heat source. The manufactured structure of AM parts will

therefore always have residual stress and thermal distortion. Residual stresses can impair the designed structure's strength, fatigue life, and dimensional accuracy and are frequently linked to unexpected failures. This demonstrates that a significant component affecting the quality of the formed structure is the thermal history and temperature distribution during deposition.

The definition of the heat source is an essential component of thermal modelling. The melt pool's temperature distribution is determined by the thermal heat source. The volumetric heat source concept is frequently used in welding and additive manufacturing. The 1940s saw the beginning of research on the heat source model. A detailed characterization of the heat source is crucial to calculate the fusion zone (FZ), heat-affected zone (HAZ), temperature distribution along the deposition track, and peak temperature. For this model to precisely quantify the magnitude and distribution of the heat flux, it needs to know several crucial melt pool parameters.

Thermal Model

The melt pool generated by the laser heat source was defined using a transient heat input approach. The analysis is influenced by the activated parts at a particular spot in the model. For computations, the inactive elements are not considered. The controlling equation for the analysis of transient heat transfer is given by

$$\rho c \frac{\partial T}{\partial t}(x, y, z, t) = -\nabla . \vec{q}(x, y, z, t) + Q\,(x, y, z, t) \tag{1}$$

In the Eq. 1, ρ is the density, c specific heat capacity, T is the temperature, (x, y, z) are coordinates, t is the time, $\nabla$is special gradient, $\vec{q}$ is the heat flux, and Q is the heat generation.

Heat Source Models

The interaction between the arc and the metal material in a numerical simulation of the arc additive manufacturing process frequently corresponds to the heat source model. The numerical simulations in this research (Goldak et al. 1984) use the Goldak double ellipsoid model as the heat source model. Two semi-ellipsoids with the same minor axis but separate major axes are used to approximate this model, which accounts for the molten pool's actual geometry. Figure 2 displays the model's schematic diagram.

As per the Goldak double ellipsoidal model, the heat source model is expressed as:

$$Q = \frac{6\sqrt{3}}{\pi\sqrt{\pi}} \frac{\eta P f_i}{abc_i} \exp\left[-\left(\frac{3x^2}{a^2} + \frac{3y^2}{b^2} + \frac{3z^2}{c_i^2}\right), (i = 1, 2)\right] \tag{2}$$

where Q is the heat flux, P is the heat source power, η is the energy absorption rate, f_1 and f_2 are the energy distribution coefficients of the front and back ellipsoids, respectively, and a, b, c_1 and c_2 are the heat source shape parameters.

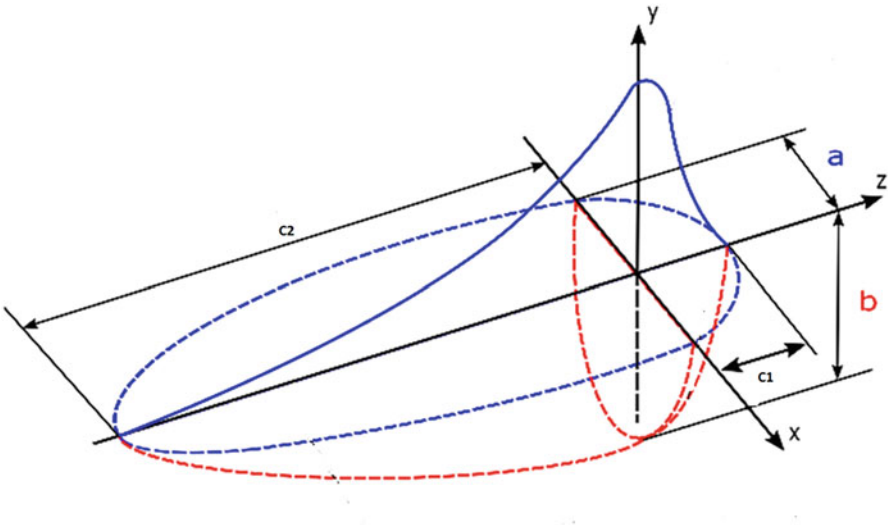

Fig. 2 Goldak double ellipsoidal model schematic diagram

Residual Stresses and Distortion

Distortion and residual stresses are two common and significant challenges that impact the manufactured part's performance and dimension accuracy when using primary AM technologies. Distortion refers to how the part created using additive manufacturing deviates from its intended dimensions or shape. It can happen during the additive process or after the created part has been detached from the substrate, resulting in a reduced precision that is difficult to recover. In the AM processes, significant variability of distortion and residual stress are caused by a long history of temperature cycles, a variety of processing factors, and complex structural designs. As illustrated in Fig. 3, the three aspects of structure, material, and processing comprise key influencing variables of residual stress and distortion.

Material shrinkage occurs often in different AM techniques. In the case of metal AM, the metal contracts and turns from liquid to solid. The resin also shrinks during the light curing procedure. In contrast, because the preheating temperature was so close to the glass transition temperature of the sintered material, the part produced by the selective laser sintering (SLS) technique was somewhat distorted. The SLS material experiences low contraction, which limits the built part's distortion. Thus, in various AM techniques, material shrinkage is a major contributor to distortion and residual stress.

Mode of Residual Stress in AM

The stresses that remain retained in the material after thermomechanical treatment are known as residual stresses. The three different types of residual stresses are

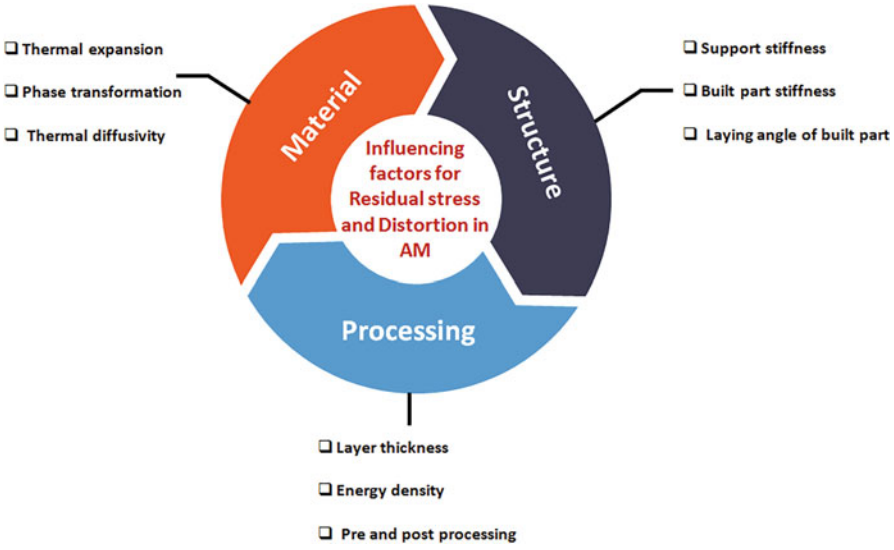

Fig. 3 Influencing factors for residual stress and distortion in AM

type I, type II, and type III. Long-range stresses of type I balance across macroscopic dimensions. Continuum models are used to calculate these types of stresses, which overlook a material's multiphase or polycrystalline nature. Type II residual stresses rely on the size of a material's grain, whereas type III dislocations exist spanning atomic dimensions. Residual stress is a type of long-range stress that continually varies over a length scale that is comparable to the macroscopic dimension of a component. On the other hand, thermal stress indicates the state of stress at high temperatures, making measurement procedures difficult. Thermal stress collected throughout the AM operations leads to residual stress, which is typically evaluated at ambient temperature. Cracks can emerge during the AM process and during the separation from the substrate when the heat stress is higher than the material's tensile strength.

Mode of Distortion in AM

In AM processes, when a small bit of material is heated to its melting point on an otherwise much cooler entity, distortion is an inevitable effect. While the top layer is still blazing hot, the material in the heat-affected zone (HAZ) naturally experiences thermal expansion, which causes the part to suddenly bow downward as the cooler material is pushed to bend to accommodate the expansion of the top. Thermal contraction occurs at the top of the part as the molten material solidifies during cooling, stretching the lower regions of the part and causing it to bend upward. Because of the high stresses experienced during expansion and contraction, the component is forced to give, which causes irreversible deformation.

By optimizing the model based on morphology and dimension, the stiffness of the deposited structure can be increased. Additionally, because it can change the slice of

the model and the related structural stiffness layer by layer, a part's laying angle in an additive process allows for adjustment in the stiffness of the deposited structure. Additionally, it is thought that the distortion is significantly influenced by how stiff the support system is. To lessen distortion, proper processing parameters, including heat input, are required. It is thought that excessive heat input will raise the constraining coefficient and the resulting distortion. Invar and other materials with low thermal expansion coefficients deform less than materials with high thermal expansion coefficients. Next, the part produced by additive manufacturing must be accurate and of high quality (particularly if it uses SLM or LPBF). It is claimed that distortion should take precedence over part quality because the latter can be enhanced through parameter optimization and post-processing techniques such as hot isostatic pressing, polishing, and remelting.

Melt Pool Characteristics

The processes that take place in the temporary melt pool that forms when a laser or electron beam contacts a metal powder bed are considered in models of the melt pool in powder-bed processes, as well as in the neighborhood (often within about 1 mm) of the melt pool. On a microsecond time frame, the beam melts the powder, which is typically made up of metal particles of 20–50 μm and generates a liquid melt pool that later cools and solidifies (Cook and Murphy 2020; Li et al. 2022).

The melt pool has been modelled using a variety of computational techniques, but regardless of the specifics of the formulations employed, the same fundamental set of physics equations must be solved. The formulation presented in the following sections is given from the viewpoint of computational fluid dynamics (CFD), the most popular technique for modelling fluid flow in general and melt pool modelling (Zhang and Zhang 2019).

The majority of CFD codes either employ a FEM (Zienkiewicz et al. 2005) or FVM (Ferziger et al. 2002) strategy. Both discretize the model domain into a mesh of tiny elements or control volumes, allowing the physics equations to be solved in more straightforward linearized forms before being assembled to reconstruct the entire domain. FEM has traditionally been regarded as having better handling of complex geometry and occasionally greater accuracy, whereas FVM has been regarded as being quicker and more user-friendly for developing novel physics. However, in contemporary codes, there is no obvious favorite, and these distinctions are highly hazy.

Melt pool simulation has been carried out using LBM and SPH (Liu and Liu 2010), two more computational techniques. In LBM, fictive fluid particles are produced at a lattice of sites rather than directly solving the Navier-Stokes equations. Realistic fluid behavior develops because of tracking their subsequent impacts and movement. With SPH, the material is represented by a sizable collection of imaginary Lagrangian particles, each of which is specified by a local kernel function. The common physics equations are used and then broken down into interactions between nearby "particles." Few LBM and SPH applications for melt pool simulation have

been made to date. Additionally, some crucial physics, such as temperature-dependent surface tension and intricate boundary conditions, are challenging to integrate in commercial software due to their lack of development. However, both approaches have potential in the long run because they implicitly handle complex interphase boundaries and can simulate the whole-body motion of solid metal particles.

The main requirements of the melt pool model are to predict the melt pool geometry and temperature distribution. Porosity, spattering, and other phenomena that are closely related to what happens in and around the melt pool can be predicted to arise. To compute the initial evolution of the microstructure surrounding the melt pool, temperature information is required. To improve the global model's approximations, mesoscale processes must be understood. Provide a global model of the thermal and residual stress in the part with an averaged melt pool temperature or a heat source.

A linked solution for heat transfer and fluid flow underlies the simulation and incorporates several physical processes, such as the melting and heating of powder particles. The coalescence of molten material has a wetness and surface tension effects. Flow occurs in the melt pool. Porosity development, expansion, and freezing, the motion of the liquid's free surface, heat transfer via convection and radiation, and the development of recoil pressure on the liquid's surface during evaporation are all factors. Metal that is changing from a liquid to a solid while also releasing or absorbing latent heat.

Surface Characteristics Modelling

As was previously discussed, AM is widely used in large applications due to its capacity to generate yet lightweight components. Despite its widespread use, AM has not completely supplanted conventional techniques, with poor surface quality being one of the major causes. Surface texture is vital to a component's operation and, if neglected, can lead to major issues with the manufactured parts. Therefore, to establish control over the surface quality, it is required to properly understand surface behavior and modelling regarding the factors affecting it. Furthermore, complex surface metrology issues are prevalent in all forms of additive manufacturing, but especially in metal AM. Nevertheless, given the process' enormous potential, these challenges must be overcome. Processes can therefore be comprehended, enhanced, and optimized with the correct surface modelling and advanced tools and techniques.

Surface measurement tools offer topographic data that can be utilized directly for qualitative characterization. The measured surfaces typically contain geometrical data regarding the surface's shape and surface texture relied on by the manufacturing process. Surface texture is recognized as the roughness features of the surface topography, and surface shape is frequently referred to as form and waviness. The primary surface is derived from the raw surface data in accordance with ISO 25178-2 (2012) following the use of an S-filter that eliminates all of the small-scale lateral components. The S-F surface is the surface that is generated from the primary surface after the form has been removed using the F-operator. The S-L surface is

the surface that is generated from the S-F surface by employing an L-filter to remove the large-scale components. Roughness or surface texture refers to the S-L surface, while waviness surface refers to the residual surface left over after applying the L-filter to the S-F surface.

The surface wavelength determines how the shape, waviness, and roughness of a surface vary. The waviness can be caused by manufacturing-related disruptions including vibrations, temperature effects, or in some cases, the nature of the manufacturing process itself. The form describes the low-frequency or long-wavelength component of the surface topography. The existence of the form may be caused by the sample's geometrical shape, tilt errors, or rotary form when measured on cylindrical, cone-shaped, or spherical samples. Wavelengths of the waviness components on the surface topography are often much shorter than those of form.

Microstructure Modelling Approaches

Only a small amount of research has incorporated microstructural characterization, despite the fact that it provides an understandable relationship between the method and the ensuing mechanical, physical, and even chemical properties. For their use in service, the mechanical property variability of metal parts produced via additive manufacturing is a major concern. The texture of the solidification, which is influenced by scan patterns and other process variables, is one of the parameters determining the feature. An avenue to regulate these features, which ultimately determine the final structural material qualities, can be provided by an understanding of how these textures emerge throughout the AM process. It is presented and qualitatively compared with reported literature by numerous researchers who have investigated grain evolution in multilayer depositions using different scan patterns in directed energy deposition (DED), metal laser sintering/selective laser melting (MLS/SLM), and electron beam melting (EBM). Metallic materials processed using SLM and EBM showed variation in grain size and orientation evolution, which was directly influenced by exposure to various cooling rates and temperature gradients. It is possible to anticipate continuum-level structural features at both the global and local length scales using CA-based modelling for forecasting grain orientation and size in metal AM processes. The general conclusion for the development of grain structure from various studies is as follows:

(a) Due to the heat source moving perpendicular to and parallel to the plane, cross-hatching scans include two different grain orientations.
(b) The grain morphology is unidirectional and bidirectional, when rotating an island scan pattern at 45°.
(c) Even when utilizing zigzag scan patterns (Fig. 4 shows different patterns), the morphology changed from zigzag to unidirectionally oriented grains by lowering the cooling rate and thermal gradient.
(d) In the vertical and horizontal parts, respectively, low cooling rates and temperature gradients are the main causes of large columnar and equiaxed grains.

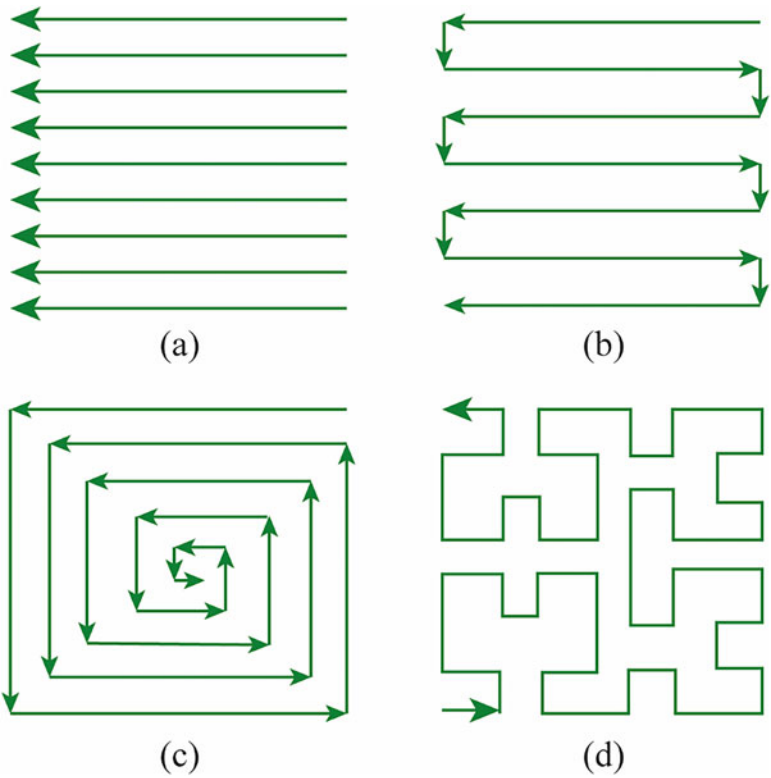

Fig. 4 Different deposition patterns: (**a**) raster, (**b**) bidirectional, (**c**) offset-out, and (**d**) fractal (Saboori et al. 2017)

(e) Curved columnar grains are seen in single-line scans at slower laser (energy source) speeds than straight columnar grains, which are seen at faster laser speeds. This finding explains why the grain morphologies produced by welding and additive manufacturing techniques differ.

If cooling rates and thermal gradients are known, it is possible to forecast grain evolution for many different processes (including SLM, DED, and EBM). It is possible to mimic the grain size of a material by entering the appropriate nucleation parameter for an alloy. Predicting the ultimate mechanical properties of components made via additive manufacturing will be much easier with the modelling, which includes grain size and orientation.

Porosity Modelling

The world is experiencing a rapidly increasing demand for mimics of natural geometry and physical structure, e.g., biomedical implants, biomedical scaffolds,

fractal-shaped microchannels in the electronic industry, filtration, and purification. In the same context, the application of porous parts has increased exponentially in recent years (Bayraktar 2022). This section aims to discuss only the development of porous structures in AM technologies and the related sciences. To argue in the favor of porous parts that can be developed easily by additive manufacturing, we may have a case of bone (implants due to an expanding and aging population, which increases both the rate and number of such incidents as trauma, bony tumors, and skeletal deformities) (Werkheiser et al. 2014). The AM process is used for various porous applications such as dental or orthopedic parts, batteries, electrodes, sensors, pharmaceuticals, fuel cells, etc. Figure 5 shows various porous applications.

The majority of AM research focuses on creating high-density parts with porosity values ranging from 0.1 to 5%, depending on the application. The AM approaches for porous parts were divided into two categories by Stoffregen et al. (2011) (i) geometrically defined lattice structure porosity (GDLSP) and (ii) geometrically undefined porosity (GUP). In contrast to GUP, where the required porosity and pore size are produced by optimizing the process parameters of AM technologies, in GDLSP, porosity and pore size are dictated by different lattice structures and strut thickness, respectively. GUP pores typically range in size from 1 to 100 nm, while GDLSP pores are between 100 nm and 1 mm. The porosity is at its highest point and the pore size is in the 10–30 m range when this technique is used (Abele et al. 2015).

There are different methods used to measure the porosity, as follows:

(a) Archimedes
(b) Bulk density measurement
(c) Mercury intrusion porosimetry
(d) Microscopy analysis
(e) X-ray computed tomography (XRCT)

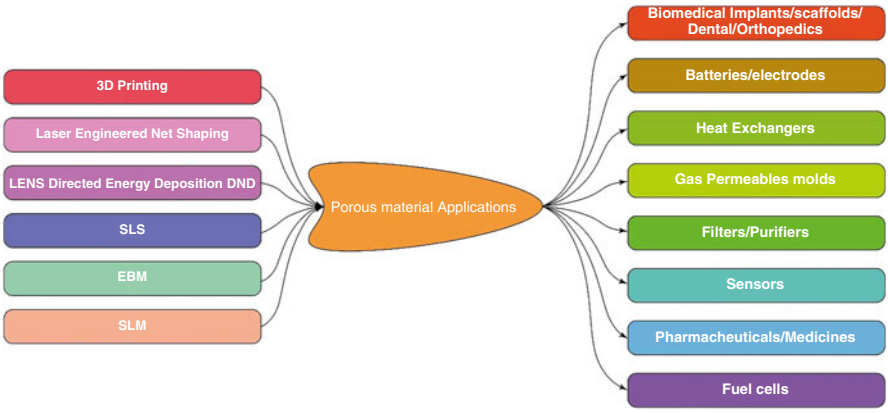

Fig. 5 AM process for various porous applications

(f) Mass and volume
(g) Ultrasonic wave speed measurement technique

Material Properties Modelling

Paper laminates, waxes, and polymeric materials were initially used to develop AM technology, some AM components may contain voids or anisotropy depending on the part orientation, process conditions, or how the design was fed to the machine (Gibson et al. 2015). With these questions, the study moved forward and observed that the prediction of deformation, residual stress, and thermal stress of a structure is crucial in determining its structural properties. This is particularly true when it comes to 3D printing concrete, which, due to its time-dependent rheological qualities, calls for accurate deformation forecasts and exact process parameters to ensure that the fabricated object stays within the tolerances given in the design. Furthermore, the accuracy of the process parameters guarantees that limitations on manufacturing, like the total amount of printing time, are not broken. Concrete additive manufacturing techniques using extrusion are highlighted by finite element analysis (FEA), which reveals the intricate relationships between process and material factors (Ekanayaka et al. 2022; Kruger and van Zijl 2021).

In a typical structural FEA, the deformations and stresses of a fixed input geometry are computed, but in AM simulations, the input geometry changes over time as new layers are built on top of older ones, adding another level of complexity to the simulated model. A variety of AM technologies can be used to simulate structures using current commercial FEA tools. Similar general procedures apply when utilizing commercial software to run typical FEM simulations, where the target CAD geometry is initially supplied together with the appropriate boundary conditions, material properties, and external forces. The governing physical equations are discretized and solved to determine nodal displacements after the structure has been constructed. Secondary factors like stress and tension can be subsequently determined.

Topology Optimization

In addition to the modelling discussed above, topology optimization is another numerical modelling technique used to develop parts for the metal 3D printing process. To identify the best material distribution in a part's design for a specific set of loading and boundary constraints, topology optimization is a mathematical technique (Fernández et al. 2021). FEA is the model's foundation. By eliminating the material from the area where it is not required to support the load or boundary condition, this procedure is carried out. The final topological structures produced by this procedure, which resemble tree branches and bones, are not uniform in cross-section (Orme et al. 2017). Making a rough 3D model and breaking down the specific load and boundary conditions into components are the first steps in the

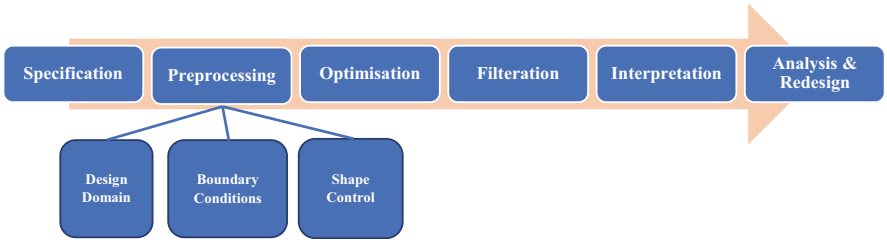

Fig. 6 Topology optimization process

topology optimization modelling process. Then, all the applied constraints are calculated by the optimization software. Then, the regions that are unnecessary will be removed. The final geometry will satisfy the mechanical and design criteria (Walton and Moztarzadeh 2017). The process stage of part modelling topology optimization is shown in Fig. 6.

Conclusion and Future Scopes

The modelling approaches that have been put forth in the literature primarily aim to represent the phenomena of heat, residual stress, distortion, microstructure modelling, and porosity creation in AM parts. These characteristics will determine whether the part can meet the design criteria. Insight into AM processes can be gained through computational modelling. This overview discusses and examines a number of numerical models used in AM. The modelling approach that predicts thermo-mechanical models most frequently is FEM. Similar to this, the PF modelling approach shows excellent promise for predicting microstructure during AM operations. Other researchers' modelling approaches have taken into account surrogate models, whose inputs either comprise a sizable amount of modelling experimental data or data produced by other modelling models.

It should be anticipated that mathematical advances will happen more frequently in the future as computational modelling sources become more widely available and mathematical techniques become more refined. This is especially true if the amount of experimental data also increases, creating a "big data" database. The main goal of AM modelling research is to develop a computational model for a certain phenomenon. Examples of this include modelling the Marangoni effect in the creation of melt pools or modelling aimed at understanding the mechanisms driving various occurrences. It is still necessary to fully incorporate modelling – modelling that takes into account the links between processes, structures, and properties – into the entire engineering design process. It is important to keep in mind that modelling requires a feedback-based strategy, where simulation results from modelling provide data that are processed to produce the next simulation until the modelling successfully fulfills all the necessary parameters (low distortion, desired microstructure, high cycle modelling fatigue, etc.).

Disclaimer The information on several companies in the area of 3D printing is only supplied for general informational reasons. The authors do not in any way recommend the companies or their products for a specific use or level of quality.

Abstract

The growing population of the world has pressurized today's agriculture sector for more production with less available resources. The advancement in technology paved the path for the induction of new techniques replacing the age-old traditional methods in the agriculture sector. The internet of things (IoT) along with its components like wireless sensor network, big data analytics and cloud computing have contributed in transforming the traditional agriculture to smart precision agriculture. In smart precision agriculture methods, we are monitoring the field parameters like soil moisture, temperature, humidity, pH level etc. via different sensors available in real-time condition and supplying the optimum resource required to the field. This method avoids excessive use of resources and increases the production as well. This data generated can be stored in the cloud and future decision can be taken based on the analytic results. So, IoT can enable us to guide in smart farming in a way to save resource, optimum resource utilization, increase production, real-time monitoring, future decision and many ore

Keywords

Internet of things (IoT) · Smart precision agriculture · IoT agriculture architecture · Agriculture application

Introduction

The word "Agriculture" is a Latin word that means "Land Cultivation." In a wide sense, agriculture is the practice of cultivating plants and livestock. It is the most essential part of human civilization which leads to the production of food, and food supports the life system on the earth. The population of the world is growing at a very fast rate and is expected to touch about 8 billion by 2025 and 9.5 billion by 2050. So, to feed such a large population, agriculture production must be increased. However, in the twenty-first century, agriculture will face many challenges like the production of more food to feed such a large population with less available resources, smaller labor force, climate change sustainable crop, etc. (Accessed 2020; [1] Food and Agricultural Organisation of United Nations 2022).

In India, with a population of 1.27 billion, the agriculture sector is the largest source of livelihood. Here more than 70% of rural livelihood depends on agriculture. India still accounts for a quarter of the world's hungry people and is home to over 190 million undernourished people. Increasing stress on water resources of the

country would need a realignment and rethinking of policies. Desertification and land degradation also pose major threats to agriculture in the country. Water scarcity and falling water tables have been a key concern in recent years. Fortunately, the importance of judicious use of water is being increasingly recognized. India also needs to improve its management of agricultural practices on multiple fronts. So, one aspect is strengthening agriculture diversity and productivity (FAO 2022). At the same time, the percentage of food lost after harvest on-farm and at the transport, storage, and processing stages stands at 13.8 percent globally, amounting to over USD 400 billion a year (FAO 2021). To achieve the sustainable development goal of the United Nation along with the Government of India, information and communication technology can play a crucial role. It can be used to improve agricultural productivity to feed a large growing population and effective management of crop and natural resources.

The traditional methods of agriculture are slow and not sufficient to cope with the increasing demands of food. The application of the most advanced technology in agriculture is growing day by day. With this, the application of IoT in the agriculture sector cannot be left behind. As internet of things (IoT) itself implies interconnection of things that can communicate and exchange information. Therefore, things can be used to monitor agricultural parameters continuously. IoT can be useful in agriculture in some areas like precision agriculture, early disease detection, climate monitoring (Ma et al. 2020), crop management, data analysis, field monitoring, natural resource management, etc.

IoT is important in agriculture for the following reasons (Sharma et al. n.d.; Elijah et al. 2018):

(a) It can solve the problem persisting in the current scenario regarding water shortage, resource management, cost management, and productivity challenges to achieve the food security for all.
(b) The valuable resources can be utilized in a judicious manner with increase in the crop production or in other words well organized scheduling with available restricted resource.
(c) IoT can act as a predictive system for the control of pests and insects. It monitors the growth and development of weeds, pests, and other harmful insects in the crop via GPS-enabled devices. If left unmonitored, then the application of pesticides and fungicides will incur extra costs to the farmer and also pollute the environment.
(d) The traditional agriculture system is converted to data-driven services with decision tools and automation system.
(e) Due to declining in number of manpower, IoT can automate the agriculture field which may require a smaller number of labor and minimal chance of error.
(f) The field can be monitored from around the world in a real-time and predictive analysis can be done by smart decision tools to maximize the profit.
(g) Agriculture machinery connected via IoT with GPS can operate in auto-pilot mode at precise and accurate location. This can increase the efficiency of the system.

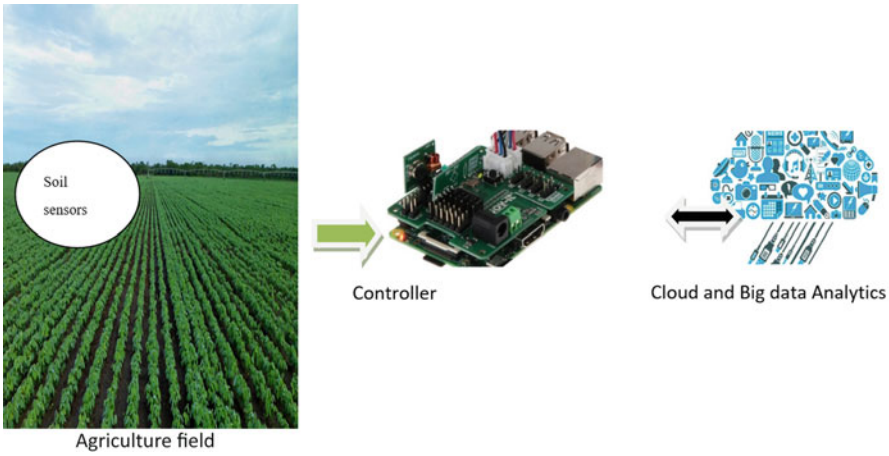

Fig. 1 Smart agriculture using IoT

(h) It can be useful in asset tracking in the field of supply chain and logistics for agriculture companies which may lead to reduction in loss after production stage.
(i) IoT can monitor the micro-environment in greenhouse by reducing human efforts, energy saving, and efficient farming and can provide customer connectivity.

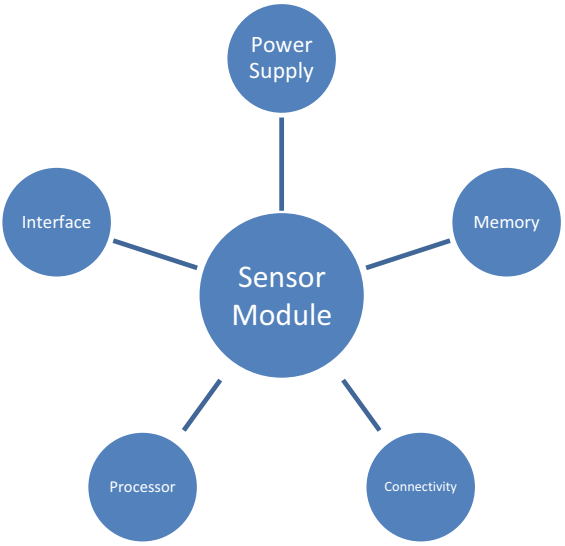
Besides these, a large number of the agricultural parameter can be monitored, sensed via different sensors, and the information from these sensors can be stored in the cloud server and analyzed via big data analysis, and action can be taken based on the outcomes. These data help us to understand the course and development of the farming system. The IoT has the capability to reduce human efforts and saves natural resources in a broader sense.

The general overview of the implementation of IoT in agriculture sector has been shown in the Fig. 1.

Sensors

Sensor is a device which measures physical parameters. In agriculture application, sensors can be used in a number of applications, viz., precision agriculture, disease detection, etc. A sensor transmits the output voltage proportional to sensed parameter in the form of binary information generally. The main components of a sensor module are power supply which powers the module, processor that acts like a brain of module, memory for data storage, connectivity for sending sensor data over wireless or wired medium to the Internet, and interface to connect nearby sensors or actuators. These can be shown in Fig. 2.

Fig. 2 Sensor components



In precision agriculture, sensors are used to monitor the agriculture parameters at different growth stage of the crop. Precision agriculture means supplying the optimum parameters at optimum time and at optimum amount for the growth of a healthy crop. Therefore, the actual growth stage and its required parameters are monitored by a variety of sensors. The sensors generate data from the parameters like soil moisture, temperature, weather condition, soil nutrients, humidity, air pressure, soil salinity level, CO_2 level, plant wetness, hydrogen level in plant, etc. The sensor information is sent to the controller which transmits it to the cloud for storage and analysis. Data analytics is used to give certain decision based on the analysis, and actuator is used to control the amount of water, pesticides, fertilizer, etc. in the field (Shafi et al. 2019). So, the correct information at the right time is provided which results in cost saving and increase in yields. In other words, the data received via sensors play a crucial role in smart crop irrigation (Table 1).

The various types of sensors are shown in Fig. 3.

Sensor Associated with Smart Agriculture

The various types of sensor with its application are illustrated in the following sections:

Table 1 List of sensor and parameters measured (Shafi et al. 2019)

S. No	Name of the sensor	Parameter measured
1	ECH2O soil moisture sensor	Soil temperature, soil moisture, conductivity
2	EC sensor (EC250)	Soil temperature, salinity level, soil moisture, conductivity
3	107-L temperature sensor (beta Therm 100K6A1B thermistor)	Plant temperature
4	237 leaf wetness sensor	Plant moisture, plant wetness, plant temperature
5	YSI 6025 chlorophyll sensor	Photosynthesis
6	SHT71, SHT75 (humidity and temperature sensor)	Humidity and temperature sensor
7	CM-100 compact weather sensor	Air temperature, air humidity, wind speed, air pressure
8	Cl-340 hand-held photosynthesis	Photosynthesis, plant moisture, plant wetness, CO_2, plant temperature, hydrogen level in plant
9	LW100, leaf wetness sensor	Plant moisture, plant wetness, plant temperature
10	Sense H_2 ™ hydrogen sensor	Hydrogen, plant wetness, CO_2, plant temperature

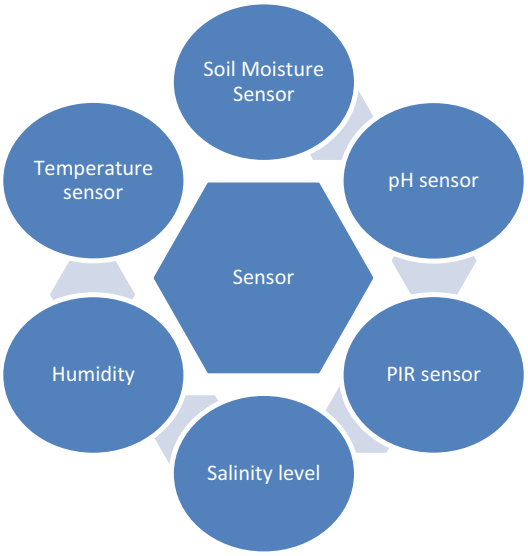


Fig. 3 Types of sensors used in agriculture field

Unmanned Aerial Vehicle

In agriculture, unmanned aerial vehicle (UAV) integrated with sensors can be used to detect disease and crop management. UAV can act as an eye of the farmer to view the entire field from a height very close to the surface. High-resolution images captured by the camera sensors can be analyzed to detect the presence of disease, pest, weeds, and growth stage of the crop from the field in a real-time situation. Images captured

by satellite are useful in identifying distributed shrublands and grasslands with an accuracy of 79% and 66%, respectively (Saha et al. 2018). Optical and multispectral techniques are being used via UAV drones equipped with RGB-D cameras or laser cameras to identify the presence of chlorophyll in the field. Based on the outcome of the image processing applied on the images, various measures can be taken like supplying the water to the soil; measures to protect against weeds, insects, and fungi; or any other countermeasures which seem fit depending on the situation. This early detection can protect the crop damage and farmer loss (Tripicchio et al. 2015). The pesticides can also be sprayed to exact location which have pests using UAV and thus save the crop and cost incurred by farmer.

Intrusion Detection

There is a significant loss in the production due to theft by human being or unwanted entry of animals in the field. Hence, IoT can be helpful in reducing this loss gap. The detection system employs PIR and ultrasonic sensor to record this event. The sensor, employed at the boundary of the field, can sense the motion of intruder and sends the information to the controller which in turn generates an alarm or informs the farmer in the form of text message. Thus, timely action can save the crop and increase the production efficiency. The sensors can communicate via single or multi-hoped connectivity in wireless sensor network which is a part of IoT (Roy et al. 2015).

Livestock Monitoring

Livestock is a part of agriculture system. Livestock monitoring helps the farmer to know about the real-time position, location, and health of the livestock. Farmers can track the body temperature, humidity level, and heartbeat rate of their cattle using different sensors. Body temperature sensor can inform about indigestion, milk infection, and disease like Influenza and anthrax in the cattle. Humidity level measurement can inform about the stress level faced by the cattle. A heartbeat sensor can predict the low and high blood pressure level found in the cattle. A high heartbeat rate signifies a pain with several disease. The sensed information is sent to the farmer via IoT using WSN who can monitor it even from outside the farm. An action can be taken in advance before the situation worsens for the cattle. Hence, the role played by the IoT in livestock monitoring cannot be undermined (Shah et al. 2019).

Greenhouse

The greenhouse or polyhouse is a polythene-covered house which protects the crops from outside uncontrolled environment parameters like harmful sun rays, extreme weather condition, excess rainfall, high speed wind, etc. Here, the farming is done in

a fully controlled environment to increase the production and quality of the crop. In the indoor greenhouse system, all the parameters can be monitored and controlled with IoT via different sensors. The sensor can check the variables like temperature, fan, soil pH, soil moisture, lighting, water, motion detector sensor, and openings for their timely supply and send the information to the server for appropriate action (Dagar et al. 2018).

Network Architecture

It plays an important role in the implementation of IoT in agriculture sector. It facilitates data transfer and reception between the devices. It sets some guidelines and rules on how data can be sent over the network, that is, path to be followed for lossless delivery to the intended receiver. Hence, it basically consists of network topologies, specification, and set of rules for IoT to be used in agriculture. IoT agriculture network consists of four layered architecture, namely, link layer, network layer, transport layer, and application layer. Each layer has its own protocols, and various technologies are available that work under particular layer.

Link Layer Protocols

This layer is responsible for implementing methods and process related to actuating and sensing different agricultural parameters. It decides on ways of the data transmission over physical medium like wireless or wired medium (Boursianis et al. 2020). As the field lies in the remote location, so wireless medium is most popular. IEEE 802.15.4 operates in ISM band having 2.4 GHz and is the most energy efficient physical layer protocol used in agriculture IoT. It is also low cost and a less complex protocol. Other standard wireless protocols available are Zigbee, Z-wave, and RFID. Cellular technology such as 2G/3G/4G/LTE is also used in some application due to its high data rate and Internet connectivity. The field agricultural parameters are transmitted to the nearest server storage or cloud via 4G LTE network. However, it consumes high power (Zhang et al. 2017). Some of the protocols are listed as follows:

IEEE 802.11

It is a bunch of wireless Local Area Network communication standards. It includes 802.11a having a bandwidth of 5GHz, 802.11b operates in 2.2 GHz, 802.11 g operates in 2.4/5 GHz, 802.11n operates in 60 GHz, and 802.11 ac operates in 5GHz. It has an overall frequency band of 5–60GHz with a data transfer rate varying from 1 Mbps to 7Gbps (Hiertz et al. 2010). It has high energy consumption with high cost. Its range varies from 20 to 100 m.

LoRAWAN

LoRAWAN stands for long range wide area networking, and it is a long range communication protocol. LoRAWAN has data rate of about 27 Kbps with a range of less than 30 KM. It is meant for battery-powered application as it has very low energy consumption (Adelantado et al. 2017) (Dias and Grilo 2020).

WIMAX 802.16

IEEE 802.16 is a bunch of wireless broadband standards. It has a frequency range of 2–66 GHz with a data rate of 1.5 Mbps to 1Gbps. It has a range of about 50 Km and medium energy consumption.

Zigbee

It is based on wireless 802.15.4 standard and developed by Zigbee alliance. It operates with the frequency of 2.4 GHz, and its range is low, i.e., 10–20 m. its data rate is 20–250 Kbps. It has low energy consumption and low cost. It has a characteristics of network resilience and interoperability. It is less secured than Wi Fi system and very commonly used in agriculture system (Ngangue Ndih and Cherkaoui 2016).

Bluetooth

It is based on IEEE 802.15.1 standard. It has a frequency band of 24 GHz with data rate of 1–24 Mbps. It has a very low energy consumption and low range personal area network. It has a range of 8–10 m. Many sensors used in agriculture are Bluetooth enabled.

Cellular 2G/3G/4G Mobile Network

Cellular network like 2G/3G/4G is available in most of the region of our country. Hence, IoT devices in agriculture can communicate over this cellular network area. It has a frequency of 865 MHz and 2.4 GHz. It has a data rate of 50–100 Kbps for 2G, 200 Kbps for 3G, and 0.1–1Gbps for 4G network. It has medium energy consumption and medium cost.

NB-IoT

Narrow band IoT (NB-IoT) is a cellular technology. It has long range, low data rate, and low energy consumption and is cost efficient. It consumes less power compared to cellular 2G/3G/4G cellular network. It promises long battery life for energy-constrained devices. It employs GSM frequency band and best suits for agricultural application as agriculture field lies in remote location in the rural area (Valecce et al. 2020).

Network Layer

This layer has the responsibility of sending data from source network to destination network. The packet contains both the senders and destination address, and this layer

performs packet routing to reach the intended network. The unique addressing is provided via IPv6. As the number of devices is increasing day by day, so IPv4 was not sufficient to provide unique addressing to all the connected devices over the network.

IPv6

It is an upgraded version of IPv4. With large number of devices being connected to the internet, it became difficult to uniquely identify in IPv4. Hence, IPv6 is being used. IPv6 uses 128 bit for addressing different devices. The total number of distinct devices that can be connected goes to 2^{128} devices.

6LoWPAN

When we talk about IoT in agriculture, we mean the things or devices which are generally energy constrained. Hence, 6LoWPAN, i.e., IPv6 over Low Power Personal Area Network is being used as Internet protocol in power-constrained devices. It operates in the frequency range of 2.4 GHz with a data rate of 250 Kbps. It is an IP-based communication protocol (Suryady et al. 2011).

Transport Layer

This layer supports end-to-end message delivery irrespective of underlying network. It is called host-to-host transport layer. The sensor data is obtained and encapsulated in this layer, i.e., data transferred from IP to IoT domain. It has two types of protocol, i.e., transmission control protocol (TCP) and User Datagram Protocol (UDP).

Transport Control Protocol (TCP)

TCP is a connection-oriented protocol. It is also a stateful protocol, i.e., each request from client to server does not contain all the information. It supervises ordered data packet transmission from sender to receiver in a reliable manner. It uses handshaking for reliable delivery. It also supports error detection and correction techniques in which lost data packet is resent and duplicity avoided. The flow control mechanism synchronizes the sender and receiver speed of data packets. It has higher overhead so consumes more power compared to UDP. TCP has lower packet sending speed.

User Datagram Protocol (UDP)

UDP is the connectionless protocol. Hence, there is no overhead for opening a connection, maintaining a connection, and terminating a connection. UDP is known as stateless protocol. It does not acknowledge the send packets been received or not. UDP is very fast compared to TCP. As it does have overhead, so it consumes very less power and an ideal choice for some application in IoT. UDP is also efficient for broadcasting and multicasting. It only has basic error checking mechanism.

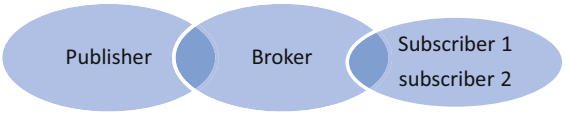

Fig. 4 Publish subscribe model

Application Layer Protocol

This layer involves the ways of how to interface with lower level in order to send data. The data files encoded using application layer and encapsulated using transport layer protocol are transmitted using network layer to reach the destination address. The different application layer protocols used in the IoT are MQTT, CoAP, AMQP, XMPP, and HTTP (Bansal and Kumar 2019). These protocols are light weight as it requires to work in energy-constrained environment. It works on different communication model like request-response or publish subscribe or web-socket (Al-Fuqaha et al. 2015).

Message Queue Telemetry Transport (MQTT)

MQTT is a communication model widely used in IoT. It is bandwidth efficient and consumes less power and is suitable for energy-constrained device. It works on publish-subscribe model over TCP/IP protocol and has one to many distribution. Publisher acts like a source of data which transfer the data to the subscriber subscribed to a topic managed by broker. Whenever a broker receives any information on a topic, it forwards to the subscriber. Neither is publisher aware about the subscriber nor vice versa. It is managed by a broker (Eurotech, IBM 2022) (Fig. 4).

Constrained Application Protocol (CoAP)

It is an application layer protocol which is best designed for constrained device. It is web transfer protocol based on User Datagram Protocol (UDP) and works on request-response model of communication. It is more suitable for IoT application as it reduces overhead of handshaking.

Extensible Messaging and Presence Protocol (XMPP)

This protocol is used for sending data in real-time environment. It uses client server architecture. It can deal with large and small file such as text, image, or video.

The overall architecture of IoT in agriculture sector is shown in Fig. 5.

Technologies in Agricultural IoT

Various technologies that are associated with IoT can be specifically used in agriculture IoT to modernize this sector. These technologies will give boost to age old traditional agricultural system that prevailed in our country. The various

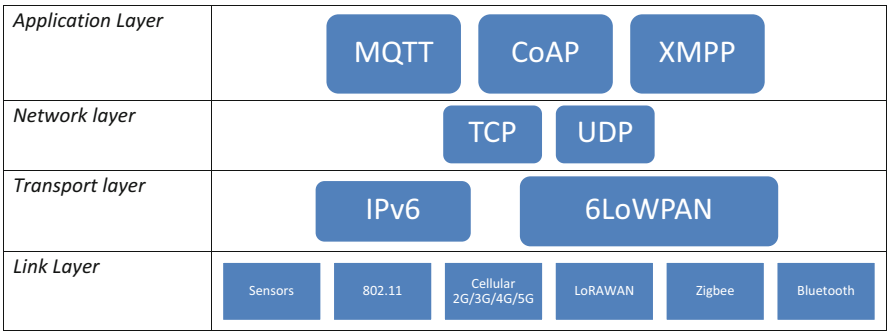

Fig. 5 IoT architecture in agriculture

technologies are cloud and edge computing, wireless sensor network, robotics, big data analysis, and communication protocols.

Cloud and Edge Computing

A cloud computing may be considered as an on-demand service like data storage, access, and cloud application available on the Internet. IoT can provide access to shared resource in agriculture. Application and architecture on the cloud can process and retrieve the agricultural information. A sensor data from the field can be sent to cloud for storage as it has large storage capability (Botta et al. 2016). Edge computing facilitates the computing at the source of data generation like sensors and actuators to reduce the burden at the cloud. These computing can used in smart farming as one of its features (Zamora-Izquierdo et al. 2019).

Big Data Analysis

Big Data refers to large volume of data. In agriculture, when the fields are connected with sensors via IoT, a wide variety of massive data is generated. This data are captured and stored in a huge storage space or in the cloud for further analysis and decision making. The decision can be predictive in nature or for real-time decision making or may be useful to design future business model (Wolfert et al. 2017).

Wireless Sensor Network (WSN)

A wireless sensor network is a network of large number of sensor nodes with each nodes having sensor to detect physical parameters. For monitoring large field size, WSN proved to be an optimal solution. WSN can be useful in different farming-related activities like irrigation scheduling, early stage detection and prevention of a

crop disease, real-time field monitoring, etc. It can also be used to control the microclimate within the greenhouse at different location. It has the capability to increase the farm production as well as optimum utilization of resources like water and pesticides. WSN can be useful to monitor the field parameters such as temperature, air humidity, soil pH level, soil humidity, wind speed and direction, etc. (Kalaivani et al. 2011; Khan et al. 2018). WSN has low power and very low data rate so it is an energy-efficient technology (https://www.cropin.com/iot-internet-of-things-applications-agriculture/ n.d.).

Robotics

Labor shortage in the agricultural sector causes a loss of 3.1 billion USD in the USA alone. So, focus is given to automation in this sector. The application of robotics like wedding robots, machine navigation, harvesting robots, material handling, and drones, etc. supports automation in this sector. Drone is a device which is equipped with camera and sensors for surveying, mapping, imaging, etc. There are two types of drones, viz., ground based and aerial. Ground based used robots for its work, whereas aerial drones use UAV for its operation. Drones can be remotely monitored to collect information like crop health, irrigation, spraying, planting, soil and field, etc. The collected data then can be analyzed to predict about events in agricultural sector (Sharma et al. 2021).

Machine Learning

AI and machine learning can be applied in the agricultural sector to analyze the operational data and improve decision making to enable smart farming. Based on the data available, AI and machine learning algorithm are useful in training the system so that they can take decision automatically and reduce human effort. This technology can be useful in predicting the pest breeding well in advance so that measures can be taken beforehand to save the crop (Al-Sarawi et al. 2017).

Communication Protocol

An IoT system relies on its network and communication protocol to transmit the information from sender to receiver. Various available wireless communication technologies and protocols that are useful in IoT are Internet Protocol version 6 (IPv6), Low Power Wireless Personal Area Network (6LoWPAN), Zigbee, Bluetooth Low Energy (BLE), Sigfox, Near Field Communication (NFC), etc. Some are low powered, and some are short range network. Based on the requirement and suitability, different protocols can be applied to transfer data over the network (Sreekantha and Kavya 2017).

Application of IoT in Agricultural Sector

IoT can be applied in agriculture sector in a number of ways. It can be used in smart precision farming, farm management, greenhouse monitoring, livestock monitoring, field fire detection system, etc. IoT is capable of revolutionizing the traditional agriculture system. Some of the applications are as follows:

Precision Farming

It is a method of farming in which agriculture parameters are utilized in a best suitable way so as to save the resources as well as to increase the yield. This can be achieved by monitoring the agriculture parameters via different sensors. The different parameters are soil quality, soil moisture level, weather condition, temperature, moisture, humidity, wind direction, etc. The information sent to the server are used for analysis, and decision taken is conveyed to the actuators via controller for appropriate actions.

Crop Monitoring

In this method, IoT can be used to monitor the growth stage and field crop condition in field crop so as to increase the productivity and cost reduction. Every growth stage is monitored, and water and other nutrients are supplied according to its need in appropriate quantity via controlled instruments. When the crop is ready to harvest, the sensors provide information. So this increases the productivity by timely harvest and reduces cost by supplying optimum required nutrients (Kour and Arora 2020).

Disease Detection

Pest or disease infection can destroy the standing crop in the field resulting in loss to the farmer. IoT can be beneficial in preventing this damage. Sensors and image processing play a crucial role in the early identification of the pest. Images of the crop can be taken via camera from the field directly, UAV drones, or satellites. The preventive measures are taken well in advance before the pest damages the entire crop by spraying pesticides. It prevents the crop from damage and loss to the farmers.

Greenhouse Monitoring

Greenhouse is a method in which we grow plants inside a covered transparent house. Greenhouse is generally used to provide healthy and necessary environment for the growth of protected cultivable plants like fruits and vegetables. Here plants are

Fig. 6 Greenhouse monitoring

grown in a controlled environment, so intense monitoring of parameters is required within it. IoT can be used to monitor the microclimate inside it via WSN with minimal human interference. A large number of sensors can be used in water management, plant monitoring, and microclimate monitoring inside greenhouse. Microclimate includes maintaining proper ventilation, balance of CO_2 and O_2 level, temperature, and humidity inside greenhouse. Different location has different parameter level. All the sensory modules are interfaced or connected to the controller to share the information for further processing. The controller is programmed to act based on the defined threshold value via actuators. For example, when the soil moisture falls below critical value, the controller turns on the actuator water pump and turns it off when the soil moisture level exceeds the limit. Sensor information are stored, analyzed, and used to take appropriate action in the future (Pahuja et al. 2013) (Fig. 6).

Fertigation Monitoring

The application of IoT in agriculture can be beneficial for the optimum use of fertilizers in the field. Excess application of fertilizers not only increases the salinity of the soil but also affects the fertility. The nutrients like nitrogen (N), potassium (K), phosphorus (P), and pH of the soil can be monitored via sensors with IoT for optimum use of fertilizers in the crop field to save the soil and production cost (Cambra et al. 2014).

Farm Machine Monitoring

Nowadays, due to scarcity of labor force, heavy automatic machines are used in the big as well as small farming. The sudden failure of these machinery can cause loss to the farmers. So, in order to have a smooth supply chain, all the equipment and machinery can be monitored via IoT to avoid sudden breakdown and real-time monitoring from remote location (Kaloxylos et al. 2012). Any problems can be diagnosed well in advance, and necessary action can be taken to failures.

Livestock Monitoring

Livestock are considered as a part of agriculture system in our country. The health status and position of the livestock in the field can be monitored via sensors using IoT. The heartbeat sensors can be useful in monitoring the health condition of the livestock. The unusual behavior can be tracked, and necessary action can be taken well in advance. This can be useful to prevent some communicable disease by isolating the infected livestock and taking proper care. In other ways, the position of some livestock can be monitored in real-time manner. In both these ways, sensors attached to livestock via wireless sensor network connected to IoT can transmit information to the server (Kumar and Hancke 2014).

Field Fire Detection

Sometimes during summer season naturally or accidentally, standing field crop catches fire. This can cause huge loss to the farmer. So, the temperature sensor and fire sensor connected to the Internet can sent alarm signal or alert to the farmer so that necessary action can be taken (Nesa et al. 2018).

Drip Irrigation

Drip irrigation is the best available technology for the efficient use of water for growing horticultural crops in large scale on sustainable basis. Drip irrigation is a low labor-intensive and highly efficient system of irrigation, which is also amenable to use in difficult situations and problematic soils, even with poor quality water. Irrigation water savings ranging from 36 to 79% can be affected by adopting a suitable drip irrigation system. Drip irrigation or low volume irrigation is designed to supply filtered water directly to the root zone of the plant to maintain the soil moisture near to field capacity level for most of the time, which is found to be ideal for efficient growing of horticultural crops. This is since at this level the plant gets ideal mixture of water and air for its development. The device that delivers the water to the plant is called dripper. Water is frequently applied to the soil through emitter placed along a water delivery lateral line placed near the plant row. The

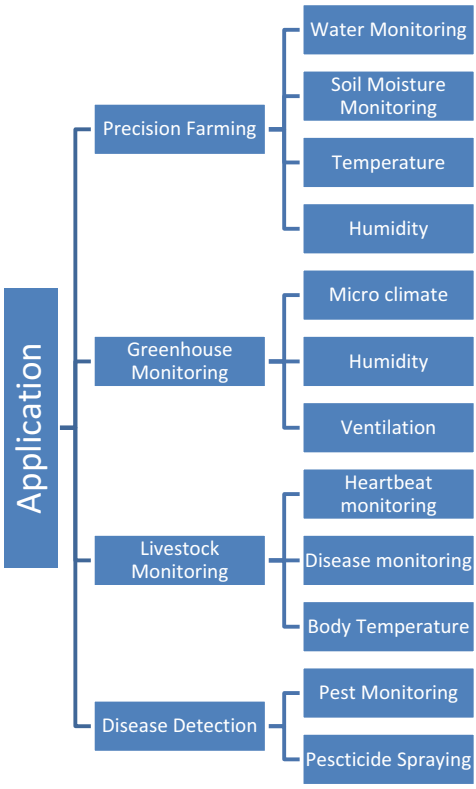

Fig. 7 IoT application in agriculture

principle of drip irrigation is to irrigate the root zone of the plant rather than the soil and getting minimal wetted soil surface. This is the reason for getting very high-water application efficiency (90–95%) through drip irrigation. The area between the crop rows is not irrigated; therefore, more area of land can be irrigated with the same amount of water. Thus, water saving and production per unit of water is very high in drip irrigation (Fig. 7).

Case Study

Smart precision agriculture uses different sensors and IoT devices for communication and control in the IoT network system. This system monitors different low-cost sensors which collect data from soil, air, water, pests, and other agricultural parameters. The controller makes the decision of irrigation, fertigation, pesticide spraying, and others automation based on the analysis of data.

The whole system has been divided into three layers. The first layer includes the sensors, hardware, and controller. Actuators. The second layer consists of database

Fig. 8 Smart irrigation layer architecture

operation, communication protocols, artificial intelligence, cloud services, other software related services, etc. The third layer comprises of web-based dashboard, mobile application, weather application, data analytics and decision-making commands, scheduled irrigation, and fertigation system decisions, etc. The different layers can be represented in Fig. 8.

Various sensors for parameter measurement like soil moisture sensor, pH measuring sensor, air pressure sensor, temperature and humidity sensor, and related actuators like water pumps, solenoidal valves, and fertigation system are spread out in the field which communicates with the controllers via wireless communication protocol IEEE 802.11. The controllers used are raspberry Pi which also acts as gateway and servers in this case. Raspberry pi can be programmed via different programming language like python to communicate and convert different sensors messages into common configuration. The server also acts as an interface and sends data to web-based dashboard or mobile application. The data are stored in the server or cloud space in case of large data for future analysis and decision making. The server can give command to actuators based on the sensor values. When connected to cloud or Internet, this sensor can be read, and actuators can be accessed from worldwide. This system performs smart precision irrigation using connected sensors and other data available about current weather. In the next phase, it irrigates field with appropriate water quality which can be checked with pH and turbidity sensor. If the water quality is not good, this system prevents it and sends and alerts message to the user. To conserve the precious water resource, this system employs drip irrigation technique. The drip pipe must be checked if there is any leakage or not. In case of leakage, the flow sensor will send an alert to the user with location and will cut the water supply through that route. This system also cleans the pipe and removes an unwanted sand particles through filtering technique. A variety of filters available to remove contaminants from irrigation water are gravity filter, wire screens, sand separator, screen filter, and gravel filter. This system also employs fertigation system as a system with drip irrigation; no additional pumps or any other device is required. The same tank is useful for mixing water and soluble fertilizers. Fertigation is done

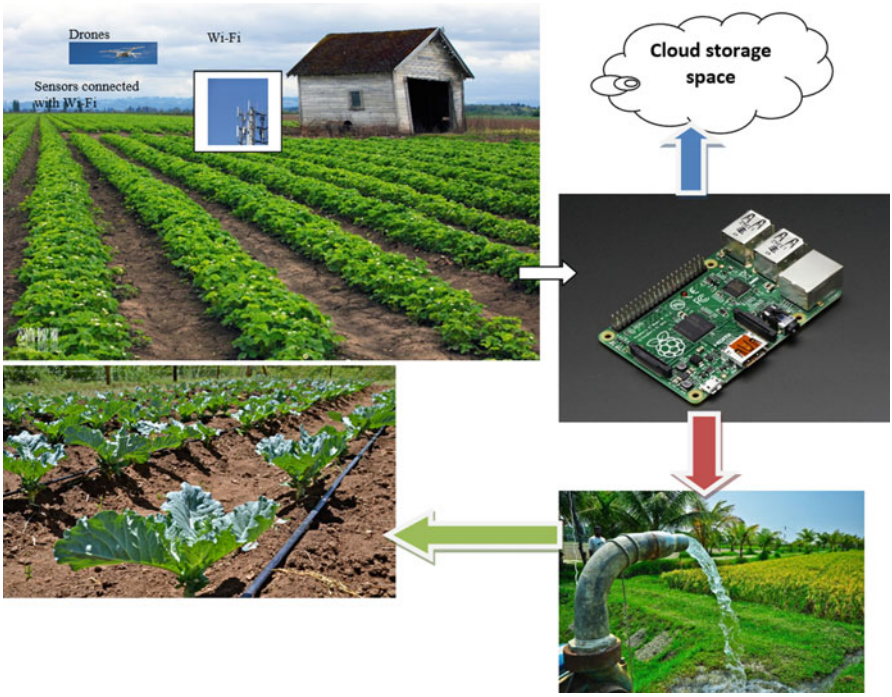

Fig. 9 Case study – smart precision agriculture

by the system after monitoring the soil nutrients, database related to the corresponding crops, and irrigation scheduling. The nitrogen-phosphorous-potassium (NPK) solution is supplied to the crop in various proportion based on the parameters obtained via sensors through drip irrigation (Jani and Chaubey 2021). In this system, a drone camera collects the image of the pests in the field with location. So, pesticide can be applied to accurate location with less cost and reduced health hazards. The whole smart irrigation system has been shown in the pictorial form in the diagram 9 as shown Fig. 9.

Challenges of IoT in Agriculture

Besides the benefits of IoT, it also posed some of the serious challenges in the country like India for its proper implementation (Elijah et al. 2018). Some of them can be listed as follows:

(a) In our country, 86.2% of the farmers are marginal farmers with land holding below 2 hectares. These are low-income farmers. They cannot afford costly automation system using IoT. So, our aim is to design and develop very low

cost IoT integrated system for the welfare of this large section of farmers and conservation of large natural resources.

(b) These marginalized farmers are not so educated. The farmers in the rural areas have lack of knowledge about IoT and its technology. So, we must provide training and awareness program to them for its efficient implementation.

(c) The policy of the government will play an active role in its successful implementation and creating an environment beneficial for the private players to invest on the development of low-cost products. More number of competitors will automatically lead to low-cost products.

(d) Besides these, the general challenges are security and privacy issues, cost factor, un-interoperable IoT devices, reliability of the hardware system, etc.

(e) There is need for resource optimization due to varying field size and available sensor types for profit margin.

(f) Ultralow-power devices and long-range connectivity for its sensors will give boost to its implementation in the agriculture field.

Conclusion

Thus, we can see that information and communication technologies with Internet of things (IoT) help to make our agricultural system smart, i.e., Agriculture 4.0. It is the future of our farming system which is the need of the hour to avoid wastage of agriculture resource and to tackle the climate change effect. The overall architecture and components required for smart precision agriculture has been discussed. The different possible applications are also explained in brief to give a wide view of its uses in agriculture sector. A case study about the application of IoT in the smart precision agriculture has been discussed which implements the smart irrigation, fertigation, pesticide spraying, and data analysis in the real-time in the field. IoT can be a game changer and offer several benefits in the agriculture sector if implemented with low cost devices for small and marginalized farmers. There are immense scope for the growth and implementation of IoT in agriculture in the future. IoT also has the potential to grow a new business model in the agriculture sector. Thus, IoT paved the way for resource utilization, production improvement, and future prediction for better decision making in the current scenario by utilizing the data for research and management. This technique will boost the food security requirements and conserve and utilize the available natural resource of the earth efficiently with less human labor requirement.

the development of routines that objectively quantify magnitudes that are subjective, difficult, or expensive to measure. (As shown in this chapter, soft metrology measures quantities related to human perception or those derived from abstract representations, and this is a new conceptual paradigm for comprehending metrology in contrast to the well-known basic measurements directly associated with the International System of Units (SI).) However, despite the increase in the use of soft metrology systems, it is a developing area, and there are still many issues related to ensuring the validity of results, as there are no standardized uncertainty estimation procedures for these kinds of applications, and there still are open discussions about the uncertainty propagation through blocks of measurement processes made up by computer routines. This book chapter discusses the state of conceptual development and the proposed general structure for soft metrology systems, focusing on challenges involved in uncertainty estimation. Lastly, some discussions and final considerations are presented where epistemic and aleatory uncertainties are contrasted and associated with the representation quality and learning capability for inference, regression, and/or forecasting models in the framework of measurement processes and soft metrology.

Introduction

One of the main challenges of metrology in the context of Industry 4.0 is the development of measurement systems that allow more accurate and efficient manufacturing processes, maximizing quality and minimizing costs. Measurement is a key factor in engineering as it allows the quantification of important attributes in monitoring, analysis, and control of processes. This has led to the development of multiple sensors, designed to measure every imaginable magnitude in a wide variety of contexts. However, increasing complexity in industrial processes and in the requirements related to production efficiency, product specification compliance, and environmental constraints according to laws and regulations have resulted in increasingly more complex measurement systems.

One of the current challenges is the fact that there are many processes in which the relevant variables that need to be monitored to have a good comprehension of the system are difficult or expensive to measure or impossible to determine in-line. However, with current data analysis techniques, several strategies have been developed in which the available information of other easier, or less expensive to measure, variables in the process can be used to create models to infer the value of those that cannot be directly measured (Souza et al. 2016; Kullaa 2017). These techniques, developed since the 1970s, have been referred to as soft sensors, virtual sensors, inferential sensors, virtual metrology, and soft metrology.

Regardless of the term used to designate a soft metrology system, the main idea behind all these developments is that it is possible to find system variables that are more easily measured and that have a phenomenological relation with the difficult to measure variables, thus allowing the creation of a variety of indirect measurement models which can express the linkage between inputs and outputs corresponding to the measurand estimation. In Vallejo et al. (2020), all the terms used in the literature for indirect measurement systems and their application contexts are presented, and the term soft metrology is proposed as a global designation suitable to gather all other terms. Previous definitions were considered (Rossi 2016) and a wider one is proposed, which encompasses the concepts related to all the different cited terms, as follows: "A set of models and techniques that allows the objective quantification of magnitudes that are subjective, difficult, or expensive to measure, such as those related to human perception and/or to process dynamics. This quantification is intended as the process of experimentally obtaining one or more quantity values that can be attributed to the variable that needs to be measured by building a model that correlates it with other quantities, such as available measured variables from the same process, or physiological, operational, and psychological response in the case of human perception" (Vallejo et al. 2020).

Although there are several approaches to developing soft metrology systems, most of them rely on modeling tools based on machine learning algorithms to create the measurement model. In the literature, we find important challenges in the development of soft metrology systems (Vallejo et al. 2020), especially in terms of ensuring the validity of results, since there are no standardized methods to estimate the uncertainty in measurement models based on machine learning.

The remainder of this chapter is organized as follows: Section "Soft Metrology Systems: Approaches, Structure, and Applications" presents the structure and applications of current soft metrology systems, section "Challenges in Soft Metrology Applications" presents challenges for future developments, and section "Discussion and Final Considerations" discusses final considerations.

Soft Metrology Systems: Approaches, Structure, and Applications

There are two main approaches for developing a soft metrology system: model-driven and data-driven. The model-driven approach is based on the construction of a measurement model using the phenomenological knowledge of the studied system (Arpaia et al. 2015; Ferrari et al. 2017); this means that it is important to have a deep understanding of the process dynamics condensed in a series of equations that can be used to correlate the available measurements with the magnitude that needs to be inferred. On the other hand, the data-driven approach uses a structured database to generate a measurement model using machine learning techniques (Kadlec et al. 2009). The database can be obtained from an experimental design or from historical data. Given the complexity of most of the processes that require a soft metrology system, the data-driven approach has been widely researched and used in practical

applications (Kano and Ogawa 2010), and this chapter will focus mainly on this kind of soft metrology system.

Structure of a Soft Metrology System

The structure of a typical soft metrology system is depicted in Fig. 1, where physical sensors are used to acquire the magnitude of the system variables that are easy or unexpensive to measure, and that will be the input for the inference model, which consists of a machine learning algorithm that captures the relationship between inputs and the desired measurand.

Essentially, the idea of using machine learning is to create a measurement model without using phenomenological knowledge of the process. Instead, a database containing examples of the system behavior is used to make an initial model and adapt it until the system intrinsic dynamics is achieved, following the examples in the database. Thus, the learning algorithm is a program developed to help the dataset "learn" the behavior of the system. It means that the designer will define a certain initial structure for the measurement model and the algorithm will iteratively adapt the structure and/or its parameters until the model is able to express the dynamic represented in the database with a minimum error or bias.

The process for developing the machine learning algorithm depends on the technique chosen to model the process, and there are many machine learning routines that can be used in a soft metrology system. However, there is a common workflow for designing solutions, independent of the specific technique chosen, as illustrated in Fig. 2. The rest of this subsection will describe characteristics of this workflow and some approaches for each step in this design process.

The design process begins with database construction and preprocessing, where the goal is to collect the data that will be used in the following stages to build the measurement model. The structure of the database depends on the model choice. If a supervised method is chosen, the dataset must have an organized structure containing labeled samples, where the values of the inputs are registered for each value of the output (measurand); but with unsupervised methods, it is possible to

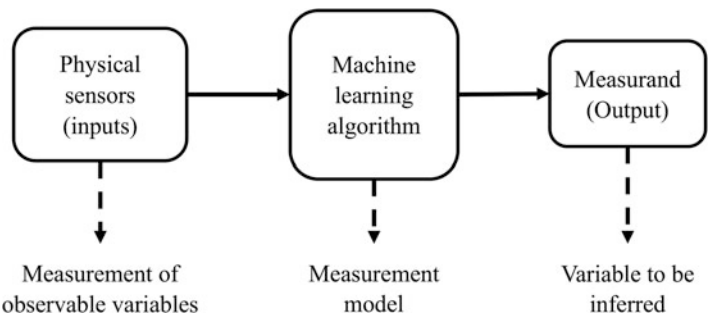

Fig. 1 Typical soft metrology system structure. (Source: Authors)

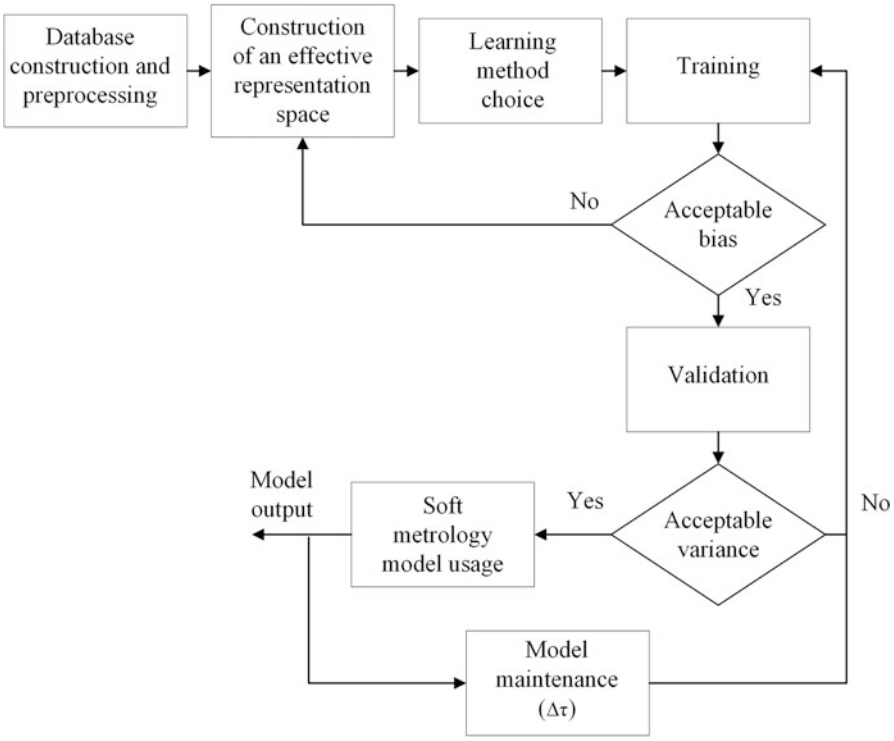

Fig. 2 Design of a data-driven soft metrology system. (Source: Authors)

have unlabeled samples, where only the inputs are stored. Later on, we will briefly discuss supervised and unsupervised learning methods.

To be able to train the models in the following stages, the database must be built keeping the following considerations in mind (Vallejo et al. 2020):

- It is important that the database includes values that cover the entire dynamic range that is to be modeled, as the system will not be able to model the process behavior in input or output values not included in the database.
- The representation quality of a soft metrology system depends on the reliability of the measurements embedded in the representation space for optimizing routines of prediction, regression, or inference of dynamic states. Additionally, the representation quality is deeply influenced by the amount of data in the database, i.e., the larger the database, the better the representation will be.
- The database must be preprocessed to find outliers and/or missing values. Also, normalization and noise filtering are usually performed.

However, building a database entails challenges (Susto et al. 2015) that sometimes make it unviable to achieve an optimal REsult. For starters, it is not always easy to obtain labeled samples, as the output is usually a difficult or expensive

variable to measure. It is also possible that some of the available input variables in the system may be irrelevant for the inference or several of them may be redundant. Likewise, some processes have delays between inputs and outputs that must be characterized in order to determine the concordance among the points in the database.

For these reasons, the following stage in the design process is the construction of an effective representation space. This stage is devoted to improving the quality of the representation, by mapping the points in the database to a proper representation space made up of features that capture the intrinsic information embedded in the measurements acquired with the physical sensors (Terzi et al. 2017). This is achieved by means of feature selection and/or feature extraction techniques, which do not only allow a better representation of the information but can also help reduce the dimensionality, thus improving the computational complexity in the model development. Feature selection techniques are essentially intended to eliminate irrelevant and/or redundant variables, which do not contain useful information for the inference process, while feature extraction techniques involve a functional transformation of the available variables to build a new space of features that better represents the information.

There are essentially four approaches to this stage (Chandrashekar and Sahin 2014):

1. Filter approaches, in which a relevance criterion is used to rank the input variables according to a correlation coefficient between inputs and outputs, such as Pearson correlation coefficient (Bidar et al. 2018), average mutual information (AMI) (Wang and Liu 2017), or variable importance in the projection (VIP) (Wang et al. 2015), among others. Filter approaches have the advantages of being simple and they avoid overfitting; however, they do not consider the performance of the following stages of the design process in the choice of the relevant variables.
2. Wrapper approaches, where subsets of the input variables are analyzed, and the inference error of each subset is used in an objective function to optimize the combination of variables. A common way of implementing a wrapper approach is the use of sequential selection algorithms, such as stepwise regression (SR), sequential forward selection (SFS), and sequential backward selection (SBS), where variables are added or removed according to the inference error (Kim et al. 2017). Another option for wrapper approaches is least absolute shrinkage selection operator (LASSO), which favors simple models by penalizing the complexity of the model reducing the coefficients of irrelevant variables to zero (Susto et al. 2015). Unlike filter approaches, wrapper approaches do consider the performance of the following stages, supporting an optimal representation. However, these methods are more complex and can suffer from overfitting.
3. Embedded approaches, in which the training of the learning method chosen to model the system and the obtainment of the effective representation space are performed at the same time. Therefore, there is no need for a separate stage involving feature selection/extraction procedures. Currently, the most commonly used method in this kind of approach is deep learning (Zeng and Spanos 2009).

These approaches also consider the performance of the following stages, but they are computationally less expensive than wrapper methods. Also, these methods can suffer from overfitting.

4. Transformation approaches, where the original variables are transformed to obtain new features (i.e., latent features), seeking a better representation of the underlying information. A widely known example of transformation approaches is principal component analysis (PCA) (Yuan et al. 2015; Maione et al. 2019). An important advantage of this technique is that it allows dimensionality reduction without the loss of information caused by eliminating features. Also, it helps avoiding overfitting. However, the new features can be difficult to interpret, and they are not chosen according to the performance of the following stages.

The effective representation space obtained from these procedures is then used as an input for a learning algorithm, which is used to model the system dynamics. In the following stage, a specific technique is chosen that will be used to create the model and that will essentially define the measurement model structure. However, there are several options in this step and the choice depends on many aspects. The most relevant elements that must be considered are the nature of the variable that needs to be estimated, the database structure, and the process linearity.

- *The nature of the variable that needs to be estimated is related to the objective of the model.* If the goal is to estimate a continuous numerical value (e.g., infer the value of a flow rate using information about the vibrations on the pipe (Vallejo et al. 2021)), the model can be created using a regression algorithm. The specific choice also depends on the linearity of the process. If the behavior is linear, it is possible to use techniques such as multiple linear regression (de Morais et al. 2019) or principal component regression (Slišković et al. 2011); but if the process is nonlinear, artificial neural networks (Hirai and Kano 2015), support vector regression (Popli et al. 2018), or extreme learning machines (Wang et al. 2019b) are more appropriate. However, if the objective is to obtain a discrete value that may correspond to a state, class, or type (e.g., inferring from electromyographic signals whether a patient suffers from myopathy or amyotrophic lateral sclerosis or is a healthy subject (Vallejo et al. 2018)), this requires a classification algorithm, such as linear discriminant analysis (LDA) (Wang et al. 2019b), K-nearest neighbors (K-NN) (Rajasekar and Sharmila 2019), support vector machines (SVM) (Haq and Djurdjanovic 2016), or artificial neural networks (ANN) (Ruiz-Gómez et al. 2018).
- *The database structure is also an important factor to keep in mind as it is the main element used to train the chosen method.* If the database consists of a collection of labeled samples, where every example of input values has a correspondent value for the output, supervised learning methods may be used. However, sometimes it is impossible to obtain labeled samples, and in these cases, it is necessary to choose a method that allows unsupervised learning. The difference between supervised and supervised learning will be discussed below.

Once the method has been chosen, it is necessary to train the model. The training process consists of an iterative transformation of the values and/or the structure of the model, until it has learned the system dynamics represented by the database. As mentioned before, there are two main approaches for this stage: supervised and unsupervised learning.

Figure 3 illustrates the supervised learning scheme, where the model starts with initial values for its parameters (this may be random), which are then updated according to the error between the model output and the expected value contained in the label. This updated procedure will be iteratively repeated until a desired minimum error has been reached.

On the other hand, if the database does not contain labels, it is necessary to use an unsupervised learning algorithm, where structures in the representation space are found according to some criteria (e.g., finding trends, patterns, or clusters). Figure 4 illustrates the scheme of an unsupervised method, were the model starts with initial values for its parameters, that may be random, which are then updated according to

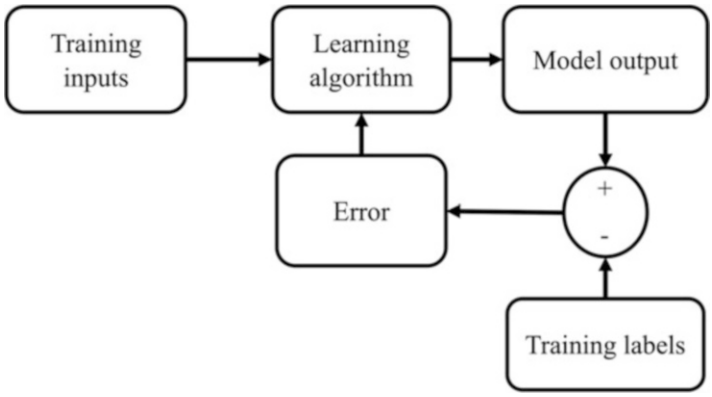

Fig. 3 Supervised learning scheme. (Source: Authors)

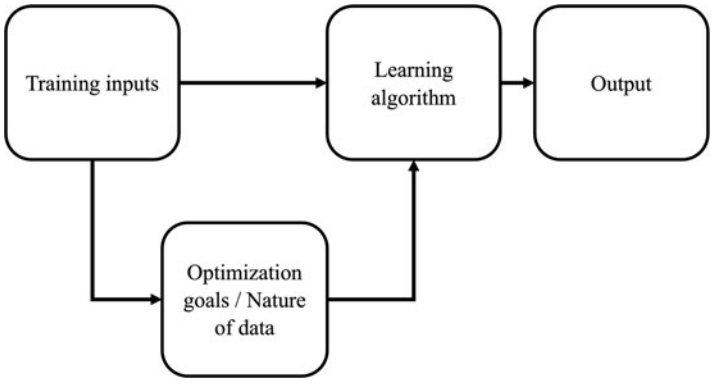

Fig. 4 Unsupervised learning scheme. (Source: Authors)

the nature of the data and the optimization goals, defined by the previous conceptualization that the designer has established for the system.

It is important to clarify that, before training, the database is separated in two portions (generally using a random split algorithm), and only one of them is used in the training procedure. The remaining portion is reserved for validating the model after training, as is explained below.

Training is successful if an acceptable model is obtained that represents the relationship between inputs and outputs with a relatively low bias, that is, with an acceptable error between the output given by the model and the target value contained in the database. If the training process does not yield a low bias, the structure of the representation space and/or the learning method choice must be reconsidered before attempting a new training procedure.

On the other hand, if training is successful, then the model must be validated. This means that the model is presented with the data contained in the remaining portion of the database. The error between the model output for this new data and the target value in the database will show if the model can generalize a good behavior in the presence of previously unseen data, with an acceptable variance in the results. If the system does not have generalization capabilities, it is necessary to go back to the training process.

Once the soft metrology model is successfully validated, it is possible to use it as a measurement model to infer the output value in the presence of new inputs. However, it is important to consider a periodical model maintenance, where the system is retrained with a certain periodicity ($\Delta\tau$), to ensure that the method adapts to changes in the process dynamics over time due to elements such as deterioration of pieces and changes in environmental conditions, among others (Lu and Chiang 2018; Souza et al. 2016).

Soft Metrology System Applications

As mentioned previously, soft metrology systems have been used in a variety of contexts and applications, although, sometimes, they are referred to with different terms. The first expression used for this type of indirect measurement strategy was "inferential sensor," which became popular in the 1970s with the development of inferential control for industrial applications, and it continues to be used in chemical and process industries (Mojto et al. 2021; Wang et al. 2021; Khatibisepehr et al. 2013).

However, in the 1990s, the term "soft sensor" was popularized in the literature, becoming a synonym of inferential sensor, and it was extensively used in many applications (Kano and Ogawa 2010). Some of the fields that have used the term soft sensor more frequently are in chemistry, process industries, and oil refineries, where it is possible to find works such as the one presented by Chen and Ngu (2023), who investigated the predictive performance of soft sensors based on locally weighted partial least squares (LW-PLS), illustrating the potential application in several processes related to chemistry such as the predictive control of a wastewater

treatment process and the polymerization of methyl methacrylate. Another example is reported in Beiroti et al. (2023), where a model was trained for estimating the biomass of *Pichia pastoris* yeast, which is used to express hepatitis B surface antigen for vaccine production. In an industrial context, there are many applications, such as the work by Vemulapalli and Venkata (2022), which describes a method to estimate the correct output of an orifice flow meter in the presence of disturbances such as plate contamination, flow density changes, pipe corrosion, or incorrect insertion of the plate, and the work by Amini et al. (2021), who used an artificial intelligence model to predict water flow. In oil refineries, a benchmark application is the measurement of the butane content on a debutanizer column (Guo et al. 2020; Yuan et al. 2018). However, the above are not the only application areas of soft sensors; for example, in the medical field, this type of technology has also been applied to the continuous monitoring of pressure and temperature, to minimize the potential harm of pressure injuries in hospitalized patients (Oh et al. 2021). In aquaculture, some studies have proposed water quality monitoring using soft sensors (Inderaja et al. 2022).

In some cases, the development of soft sensors can be assigned to different fields of application simultaneously. An example is reported in Jo et al. (2022), where a multifunctional soft sensor capable of simultaneously detecting six stimuli (pressure, bending stress, temperature, proximity, ultraviolet light, and humidity) was developed. Thus, there are many potential applications in the industrial, medical, and military fields.

Another designation frequently used is "virtual sensor," which is usually implemented in automotive and aircraft applications, such as the estimation of vehicle's unsprung mass (UM) vertical velocity in real time (Kojis et al. 2022), the estimation of vehicle roll angle (Sieberg and Schramm 2022), or the implementation of virtual angle of attack (AOA) sensors in aircrafts (Mersha and Ma 2022). Virtual sensors are also used in applications for intelligent buildings, for energy or ventilation systems (Koo et al. 2022; Torabi et al. 2021), as well as in air quality measurements for estimating the concentration of black carbon (Fung et al. 2020; Rovira et al. 2022).

There are also terms related to a very specific domain of applications, such as virtual metrology, which is used in semiconductor manufacturing (Chien et al. 2022; Choi et al. 2022; Shim and Kang 2022), and electronic tongues, used in the characterization of flavors in the food industry for many products like edible fungi (Yang et al. 2022), milk (Salvo-Comino et al. 2022), tangerine peel (Li et al. 2022b), honey (Lozano-Torres et al. 2022), peaches, and so on. Likewise, the food industry has used electronic noses for characterizing flavors and odors (Zhang et al. 2022; Li et al. 2022a), but this application can also be found in other contexts, such as breath test analysis for the detection of silicosis in miners (Xuan et al. 2022), the detection of pests and diseases in agriculture (Zheng and Zhang 2022), and the discrimination of pure biofuels (Mahmodi et al. 2022), among others.

As mentioned before, the term soft metrology has been proposed to encompass all designations, although initially it was specifically used to refer to measurement

systems that characterize human perception with the five senses (Bergman et al. 2020; Iacomussi et al. 2016; Fanton 2019; Rossi 2016; Pointer 2003).

In addition, many measurement applications use machine learning tools to model the corresponding process but do not use any of the aforementioned terms. An example is reported in X. Wang et al. (2022), where the system characterization in terms of product quality in an oil refinery is accurately estimated through a model and a parameter optimization process. In the same way, in Wen et al. (2022), deep learning algorithms are used to measure and differentiate movement features and joint positions in the human body.

Challenges in Soft Metrology Applications

Although nowadays soft metrology systems (soft sensors, virtual sensors, virtual metrology systems, etc.) are extensively used in many contexts, there are still many challenges in their development, especially in two aspects:

- The development of a soft metrology system for a specific application requires a careful assessment of the process under analysis and an experimental design to obtain the appropriate database. Each application may entail specific complexities and challenges. In subsection "Soft Metrology System Implementation: An Example of Flow Rate Measurement," an example is presented to illustrate this point.
- There is a lack of quality metrics associated with measurement for soft metrology systems. Particularly, there are no standardized procedures to determine the uncertainty associated with an indirect measurement system that has a machine learning-based inference process. This issue is further analyzed in section "Measurement Uncertainty in Soft Metrology Systems."

Soft Metrology System Implementation: An Example of Flow Rate Measurement

Flow rate measurement is an essential task in industrial processes and urban water supply systems (Dinardo et al. 2018), among others. For this reason, a wide variety of measuring instruments has been developed. However, these devices can be expensive (Campagna et al. 2015) and usually intrusive (Medeiros et al. 2015, 2016). These are critical disadvantages in cases where many sensors must be installed, when portable measurement systems are required, or when measurements are taken in adverse conditions. Hence, indirect measurement systems based on pipe vibration analysis have been developed with the aim of achieving less expensive, portable, and nonintrusive flow rate measurement devices (Vallejo et al. 2021).

Since the 1990s, the correlation between vibrations and flow rate in a pipeline has been studied. In 1992, the INEEL (Idaho National Environmental and Engineering Laboratory) led a series of analysis and found a direct correlation between the

standard deviation of the signal produced by an accelerometer attached to the pipe and the flow rate, which led to further studies intended to characterize this correlation with metrological purposes (Evans et al. 2004), so different techniques have been proposed for indirect flow rate measurement.

In the literature, the correlation between the fluid flow rate through a pipe ($\dot{Q}$) and the acceleration affecting the pipe wall in the radial direction is described by a series of linear relationships ($\propto$) expressed by Eq. (1) (Dinardo et al. 2018; Campagna et al. 2015):

$$\dot{Q} = A\overline{U} \propto u' \propto \tau_w \propto \frac{\partial^2 r_w}{\partial t^2} \tag{1}$$

where A is the pipe cross-sectional area, $\overline{U}$ is the average flow velocity, u' is the flow velocity fluctuation along the axis, τ_w is the shear stress in the pipe, and $\left(\frac{\partial^2 r_w}{\partial t^2}\right)$ expresses the acceleration in the radial direction.

However, there is no precise and unique phenomenological equation that can express this relationship, and several studies have shown that there is a wide variety in aspects such as the sensor used to measure vibrational features, the machine learning routines used to create the model, and the range of flow rates studied, among others.

In order to acquire signals that contain the vibratory characteristics of a pipe, three types of sensors have been used: accelerometers, which register the acceleration in several axes and are attached to the wall of the pipe (Medeiros et al. 2015, 2016; Evans et al. 2004; Kim et al. 2008; Venkata and Navada 2018; Pirow et al. 2018); laser Doppler vibrometers (LDV), which measure the amplitude and frequency of the vibration using a laser and an interferometer (Dinardo et al. 2013, 2018; Campagna et al. 2015; Fabbiano et al. 2020); and acoustic sensors, which focus on the vibrations associated with acoustic dynamics (Göksu 2018; Jacobs et al. 2015; Safari and Tavassoli 2011).

Each type of sensor exhibits specific advantages and disadvantages:

- Accelerometers measure vibrational characteristics in three axes, increasing sensor accuracy by improving the inference space (Mohd Ismail et al. 2019).
- LDVs do not require direct contact with the pipe surface, but this feature is problematic in cases with limited access or without line of sight (Rothberg et al. 2017).
- Acoustic sensors are contactless too, but they may be more susceptible to background noise.

The acquired signals must be filtered to reduce noise in the representation space (for any type of sensor), using several types of filters such as Butterworth filters, “notch comb” digital filters (Medeiros et al. 2015, 2016), median filters (Hu et al. 2014), and filters based on wavelet transform (Dinardo et al. 2018).

To improve the representation space, frequency analysis has been proposed, which relies on the fact that the natural frequency of a fluid moving through a pipe decreases when the flow rate increases (Evans et al. 2004). Frequently, the power spectrum is used as an input for the inference algorithm and the amplitude of the first harmonic (Dinardo et al. 2013, 2018; Fabbiano et al. 2020; Jacobs et al. 2015; Safari and Tavassoli 2011), or the center frequency of the first harmonic (Evans et al. 2004) as representation features. Time analysis has also been used, where flow rate is characterized in terms of the signal amplitude (Jacobs et al. 2015) or statistical parameters such as the statistical moments (Medeiros et al. 2015, 2016), the frequency domain average time series (Evans et al. 2004; Pirow et al. 2018), or the root mean square (RMS) value (Dinardo et al. 2018; Fabbiano et al. 2020; Jacobs et al. 2015). Lastly, some studies report approaches that use decomposition techniques that simultaneously analyze the signal time-frequency features, using wavelet transform (Göksu 2018).

As to the learning method choice, the simple linear model with least squares fitting is the most implemented (Dinardo et al. 2013, 2018; Campagna et al. 2015; Pirow et al. 2018), but nonlinear models, such as polynomial regression (Medeiros et al. 2015, 2016; Evans et al. 2004; Safari and Tavassoli 2011) and a third-order square root curve (Y. Kim et al. 2008), have also been proposed. Similarly, regression models by parts, which combine linear and polynomial regression, are also used (Medeiros et al. 2015, 2016). Finally, some studies have explored the use of ANN for flow rate estimation (Venkata and Navada 2018; Göksu 2018), since ANN performs well in highly nonlinear processes, and it is not necessary to have prior knowledge of the data.

Results reported in the literature of soft metrology systems applied to flow rate are diverse, and the comparison is complex due to differences in operational conditions related to magnitude, equipment characteristics, data acquisition, sampling, and installation parameters, among others. Some papers have reported the influence of certain operating parameters on each model, such as the pipe material and diameter (Campagna et al. 2015), the sensor location (Safari and Tavassoli 2011), the acquisition time (Medeiros et al. 2015, 2016), and the mechanism that drives the fluid (Dinardo et al. 2013). Also, the model accuracy varies for each specific work. Particularly, some authors report the results in terms of the R^2 parameter (Evans et al. 2004), the root mean square error (RMSE), or the mean absolute error (Kim et al. 2008; Göksu 2018; Jacobs et al. 2015). Other authors do not even report results in terms of accuracy, since their research focuses on trying to find a deterministic relationship between vibration characteristics and flow rate, and testing the influence of parameters, such as the pipeline characteristics (Campagna et al. 2015; Dinardo et al. 2013).

It is important to observe that soft metrology systems are usually developed for very specific contexts and applications, and it is necessary for the designer to carefully analyze the scope of the proposed system and the range of applications where it can potentially be used. Changes in aspects such as the measurement range, installation specifications, material, and disposition of the structures, among others, require that the system be trained again, with new databases that incorporate new

conditions or scenarios. According to this, several challenges rise around specific experimental designs for database construction, which must be oriented to a wide range of applications and operational or functional states.

Measurement Uncertainty in Soft Metrology Systems

In accordance with the International Vocabulary of Metrology (VIM), the measurement uncertainty is defined as a nonnegative parameter characterizing the dispersion of the quantity values being attributed to a measurand, based on the information used (Joint Committee for Guides in Metrology (JCGM) 2012). In this document, the word "quantity" is used as it is the one used in the translations of the VIM and the GUM into English. Note however that "magnitude" could also be used.

Measurement processes in engineering require the estimation of uncertainty associated with the value, which expresses the incomplete knowledge of the quantity and ensures the validity of results. The uncertainty estimation process is a key tool in measurement and is also a fundamental tool for achieving measurement compatibility. The importance of uncertainty can be translated to a broader sense, as it contributes to the achievement of the objectives of the organization of metrology worldwide. In particular, the International Committee of Weights and Measures (CIPM) expresses: "Mission: The main task of the CIPM is to promote worldwide uniformity in units of measurement. . .".

The main issue with the soft metrology systems is the lack of quality metrics that can be correlated with the measurement, specifically the absence of standardized procedures to determine the uncertainty of the estimated value. Likewise, it is difficult to find information in the literature that addresses the uncertainty estimation of the measured value in soft metrology. Only a few papers can be found that propose mathematical models to analyze uncertainty, and they are mostly focused on model-driven implementations, for instance, in Song et al. (2013), a virtual flow meter was developed including a procedure for uncertainty analysis. Additionally, in Cheung and Braun (2016), a general method for calculating the uncertainty of virtual sensors for packaged air conditioners is presented. These papers identify different uncertainty sources that can be categorized as:

- Database uncertainty included in the generation of the inference model.
- Physical sensor uncertainty related to the instruments used to measure the input variables in the inference model.
- Uncertainty due to environmental noise (i.e., external, not fully controllable, unpredictable disturbances).
- Uncertainty associated with the inference process.

Database uncertainty is associated with the instruments used to capture the database, with which the inference model is trained. Likewise, the physical sensor uncertainty corresponds to the input variable uncertainty in the model, but in this case, it is related to the online operational process after the model is trained.

The uncertainty due to environmental noise can also be considered as related to the measurement instruments, as the noise usually affects the circuits associated with the sensor conditioning and digitalization stages. The uncertainty associated with the inference process is directly proportional to the model training quality since this uncertainty is an expression of learning and representation capabilities that the inference routine has when capturing the system phenomenological dynamics.

Particularly, the sensor uncertainty corresponds to the same uncertainty estimated in conventional measurement systems which can be addressed with non-stochastic tools, such as the Guide to the Expression of Uncertainty in Measurement (GUM) (Joint Committee for Guides in Metrology (JCGM) 2008), and stochastic tools, such as Monte Carlo method (Joint Committee for Guides in Metrology (JCGM) 2008). It is important to note that the estimation of the sensor and database uncertainty, the GUM, is a worldwide success case as it has become the obligatory reference for uncertainty estimation. However, this guide has limitations, and some inconsistencies regarding the VIM or even the GUM supplements. From a technical point of view, the GUM presents a summary of steps for the uncertainty estimation:

1. Mathematically express the relationship between the measurand and the input quantities, given by

$$y = f(x_1, x_2, \ldots, x_N) \tag{2}$$

   where y is the measurand (output value), N is the number of input quantities, and x_i are input quantities.

2. Estimate the input quantities.
3. Evaluate the standard uncertainty of each estimated input.
4. Evaluate covariances associated with correlated inputs.
5. Calculate the estimated measurand value.
6. Determine the combined standard uncertainty of the measurement result.
7. If necessary, give an expanded uncertainty in order to have a greater probability of coverage.
8. Report and appropriately express the measurement result with the corresponding uncertainty.

In the case of a soft metrology system, it is not always possible to precisely apply the guide as the complexity of the system often makes it impossible to implement the first and the fifth steps, i.e., the relationship between the measurand and the input quantities is modeled using a machine learning algorithm that may be complex and does not always allow a classical mathematical function to be built or the evaluation of covariances. In any case, the GUM can be used to estimate the database and physical sensor uncertainty.

Another alternative is the Monte Carlo method, which simulates a large number of measurements using a random number generator; for this reason, this method can

be known as a "brute force" routine. To do this, algorithms for generating values associated with a particular probability distribution are implemented. In this regard, the Monte Carlo method requires a mathematical model for describing the measurand and the probability distributions associated with input quantities. Monte Carlo simulations have been used in the development of soft metrology systems as a tool to generate the measurement model, although not with the aim of estimating its uncertainty.

Commonly, GUM and Monte Carlo methods are compared, and pros and cons are analyzed. These methods are not totally independents as they use the same information of assumptions made for input probability distributions. The main advantage of the Monte Carlo method is that it does not require any assumptions about the output probability distribution. However, it has a high computational complexity, which can sometimes be unnecessary in scenarios where the GUM method describes the measurand well with its uncertainty. In general, these methods perform better when used in a complementary way.

On the other hand, the less studied source of uncertainty in measurement systems based on soft metrology approaches is related to learning models for inference, regression, or forecasting, which can be integrated within the framework of the whole expanded uncertainty. The rest of this document will focus on the source of uncertainty derived from computer applications, since the current literature on this subject shows analysis from the point of view of machine learning training efficiency, but not from the perspective of conventional metrology or from the implications that this has on an indirect measurement system. This means that in computational model uncertainty, there are important challenges that will need to be solved in order to reach a generalized use of soft metrology systems.

Computational Model Uncertainty

It is important to note that, depending on the field of study, different definitions of uncertainty may be found (Siddique et al. 2022), and, although the basic concept is the same in all cases, the terminology and specific methods related to uncertainty in metrology differ from those in machine learning or other computational applications.

The goal in a soft metrology system, as it is in any machine learning application, is to create an approximation model of the phenomenological relationship between the input variables and the magnitude of the value to be inferred. Indeed, a soft metrology system is affected by uncertainties inherent to any model that is an imperfect approximation of a phenomenological dynamic behavior, i.e., uncertainties associated with a process of inductive inference and from incorrect suppositions or approximations in the model structure, among others (Hüllermeier and Waegeman 2021). Traditionally, machine learning models have focused on training approaches that aim to optimize the model parameters to achieve the minimum prediction error, but do not consider uncertainty. However, there is a growing interest in uncertainty quantification, as well as in standardizing other quality metrics that

allow for model validation and evaluation of quality, reliability, and applicability (Vishwakarma et al. 2021).

Some authors propose that there are three dimensions of uncertainty in systems that model a behavior: the location, level, and nature of uncertainty (Walker et al. 2003).

- **Location of uncertainty:** This is where the uncertainty is manifested within the model structure. The specific list of uncertainty locations in a system may vary according to the system structure, but some general locations are representation boundaries and completeness, model structure, computational realizations, inputs, methods used to calibrate the model parameters, and, finally, the output accumulated uncertainty.
- **Level of uncertainty:** This refers to where the uncertainty can be placed between complete deterministic knowledge and total lack of knowledge of the study case system or process.
- **Nature of uncertainty:** This is an analysis of whether the uncertainty is due to a lack of knowledge or to the inherent randomness of the phenomenological dynamics.

This last dimension has been the most studied in machine learning literature and, although the source of uncertainty in machine learning is traditionally modeled in a statistical way, an increase in the use of machine learning in high-risk, optimal, or robust applications requires more demanding characteristics in quality and security, and for this reason, it is very important to identify uncertainty components that can be minimized and those which cannot be (der Kiureghian and Ditlevsen 2009). These uncertainty sources have been labeled epistemic and aleatory uncertainty, respectively, and this classification of uncertainty sources has become popular in machine learning. However, some authors point out that, although this categorization may appear evident, the determination of which uncertainty sources can be minimized is sometimes ambiguous as of the context may change the decision or representation conditions. Therefore, it is important to analyze the uncertainty sources in light of the context and the chosen model structure (Hüllermeier and Waegeman 2021; der Kiureghian and Ditlevsen 2009).

Epistemic Uncertainty

The concept of epistemic uncertainty is related to the lack of knowledge about the process dynamics, which can lead to a model that does not precisely represent the underlying function. Thus, epistemic uncertainty is related to improperly tuned model parameters, wrong assumptions about the model functional structure (Combalia et al. 2020; Nguyen et al. 2022), number of examples in the database, and data density in the range of study (der Kiureghian and Ditlevsen 2009; Osman and Shirmohammadi 2021; Posch and Pilz 2021). This uncertainty can be mitigated by taking actions that improve the model and data functionalities.

Epistemic uncertainty is usually formalized as a probability distribution over the model parameters or weights (Kendall and Gal 2017;

Lakshminarayanan et al. 2017). The main tool used in machine learning is Bayesian statistics, which provides a conceptual framework for expressing uncertainty toward algorithmic routines (Combalia et al. 2020). In Siddique et al. (2022), a categorization of approaches for uncertainty quantification in machine learning is mainly proposed as follows:

- *Frequentist inference*: This is the use of traditional machine learning techniques with a training procedure that is intended to give a point estimate for the model parameters w. In this case, the trained model will have a certain standard error, and therefore this approach does not actually provide information about uncertainty estimation.
- *Bayesian inference*: This is the use of Gaussian process regression (GPR) or Bayesian neural networks (BNN). This approach does not consider a point estimate for w, but rather considers a posterior probability distribution over the parameters $p(w)$, given the observed data in the training dataset.

To illustrate the use of Bayesian inference as a tool for modeling uncertainty in machine learning, we discuss BNN in contrast to conventional artificial neural networks (ANN).

Artificial neural networks (ANN) represent an arbitrarily complex function $y = f(x)$ using an interconnexion of relatively simple units called neurons. Each neuron is composed of a linear combination of weighted inputs and a nonlinear activation function, such that the output of each neuron is $y = \varphi\left(\sum_{i=1}^{N} x_i * w_i\right)$, where y is the neuron output, φ is the activation function, x_i is the *ith* input, w_i is a weight associated with the *ith* input, and N is the number of inputs to the neuron. Figure 5 illustrates the typical structure of a neuron, with N inputs.

An ANN is an arrangement of several neurons, structured in layers. Figure 6 shows an example of a three-layer ANN, although the number of hidden layers and neurons in each layer varies according to the designer's criteria. Each connection between neurons has a parameter w that represents the weight of that specific connection. The training algorithm for an ANN aims to find the optimal point

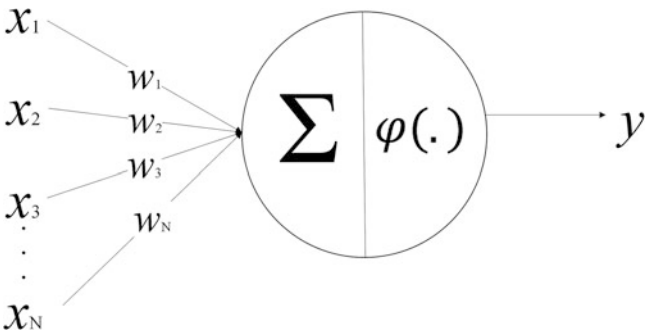

Fig. 5 Neuron structure. (Source: Authors)

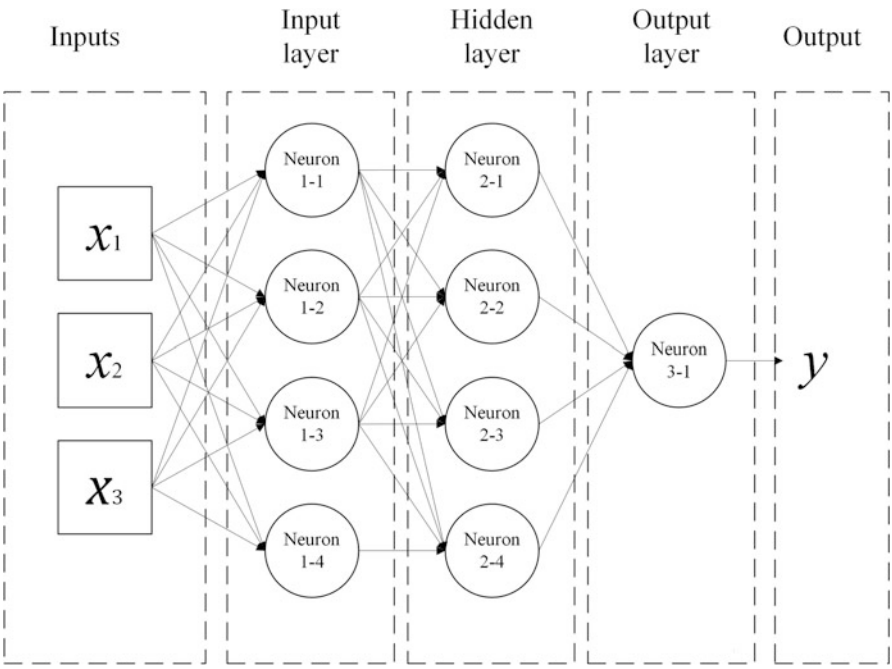

Fig. 6 ANN structure. (Source: Authors)

estimate for parameters w using strategies such as gradient descent, which are based on differentiation.

Bayesian neural networks are a type of neural network that use Bayesian inference to express the uncertainties related to the model. The main idea is to model the uncertainty in the weights w, so that the training data is used to determine a posterior distribution over the weights (instead of a single value) $p(W|X, Y)$, where $W = \{w_1, w_2, \ldots, w_N\}$ is the set of weights in the network and (X, Y) are the training examples, being $X = \{x_1, x_2, \ldots, x_N\}$ and $Y = \{y_1, y_2, \ldots, y_N\}$. From this posterior distribution, a predictive distribution of a test sample x is obtained, which is noted as $p(y|w, x)$, and is used to quantify the predictive uncertainty.

However, exact Bayesian inference is not computationally executable for neural networks because this approach establishes a high-dimensional and nonconvex problem where the needed integrals are too difficult to compute and directly sampling the posterior distribution is not viable. Several alternatives have been proposed to deal with these problems, such as:

- Markov chain Monte Carlo (MCMC) (Bardenet et al. 2017; Neal 1996), where the idea is to build a sequence where each sample depends only on the previous one, such that the samples are distributed following a desired distribution.
- Variational inference (Blundell et al. 2015; Louizos and Max 2016; Olivier et al. 2021), where this method scales better than MCMC, and a variational distribution

is proposed until it is as close as possible to the exact posterior, usually using as the measure of closeness as the Kullback-Leibler divergence (KL divergence).
- Probabilistic back-propagation (PBP) (Hernandez-Lobato and Adams 2015), where an algorithm sequentially approximates the distributions of the weights using one-dimensional Gaussians.

Additionally, epistemic uncertainty has been expressed using dropout training in deep neural networks (Gal and Ghahramani 2016), where an ANN is trained using aleatory dropout to estimate the uncertainty of the model. Dropout techniques can be configured on a regularization scheme to reduce overfitting. Particularly, Bayesian inference uses multi-class predictive entropy to analyze the epistemic uncertainty of the system (Kurmi et al. 2021).

Uncertainty estimation techniques for neural networks based on Monte Carlo sampling have been used in classification problems (Lakshminarayanan et al. 2017; Gal and Ghahramani 2016). Results show that uncertainty metrics can be used successfully to detect samples that are out of distribution or are difficult to integrate (Combalia et al. 2020). Also, Bayesian analysis has reported good results modeling uncertainty in conventional neural networks (Kendall and Gal 2017).

Aleatory Uncertainty

Aleatory uncertainty is due to nondeterministic elements that are inherently aleatory in the process dynamics and is mainly related to the noise in the observations, as well as to the influence of hidden variables or measurement errors (Kendall and Gal 2017; Tagasovska and Lopez-Paz 2019). Unlike epistemic uncertainty, aleatory uncertainty is not reduced by a deeper knowledge of the modeled process and is usually modeled by probability distribution in the output of the inference model (Kendall and Gal 2017). This type of uncertainty can be categorized as homoscedastic or heteroscedastic, depending on whether the noise is assumed to be identical or different in each of the process inputs (Wentzell et al. 2021; Ayhan 2018).

To model aleatory uncertainty, some studies, such as Ayhan (2018), propose data augmentation techniques, using simple random transformations on the data to capture heteroscedastic uncertainty in deep neural networks. A similar example is found in G. Wang et al. (2019a) where data augmentation techniques are used in medical imaging applications. In this approach, aleatory uncertainty is modeled by masking different geometries on images and analyzing prediction diversity according to the distribution variance and entropy. Another approach for estimating aleatory uncertainty consists of building a model that fits the information loss, guaranteeing that the model does not fit the noise in the data (Liu and Han 2021).

As mentioned earlier, the distinction between aleatory and epistemic uncertainty can be fuzzy or rough, and each one can be determined by a model choice (der Kiureghian and Ditlevsen 2009). In fact, some methods previously mentioned have also been used to estimate both aleatory and epistemic uncertainty. In this regard, in Junhwan et al. (2022), dropout Bayesian approaches with Monte Carlo simulation are proposed to predict and estimate uncertainty, where the aleatory uncertainty is

associated with noisy data location and outlier detection, while epistemic uncertainty is used to quantify the model performance.

Lastly, some studies make the distinction between epistemic and aleatory uncertainty, but the focus is not on the uncertainty estimation, but rather on identifying errors due to aleatory uncertainty so that they are not considered in the design process (Ali et al. 2021), or in data relabeling (Redekop and Chernyavskiy 2021).

Discussion and Final Considerations

Most applications of soft metrology are required in smart manufacturing systems, which digitally represent every aspect in a new technological platform, from the design stage to manufacture, using multi-objective control and monitoring tools, and multi-structural, multi-sensorial, and remote topologies of connectivity, in order to mobilize the dominant paradigm of internal combustion engines toward a culture of computer challenges and connectivity (Mesa-Cano and Delgado-Trejos 2021).

A new production ecosystem based on Industry 4.0 platforms requires a new perception and processing vision with new challenges and opportunities, where the concept of measurement has changed from a numeric value to representation data. In this sense, a measurement process must obtain enough information from a dataset to assess, understand, and make decisions on a phenomenological behavior. However, up to now, the uncertainty estimation in soft metrology applications is an open issue when computer routines integrate an important component in the whole measurement process. According to this, some new concepts of uncertainty estimation for computer routines have been presented in this chapter, with the aim of illustrating new analysis strategies for soft metrology approaches.

On the other hand, soft metrology structures can adapt representation spaces using measurement sets and selecting those with a high information level of the phenomenological dynamics, associated with a complex and/or expensive study variable. In this sense, decision-making systems based on measurements require prior knowledge about the nature of the data to optimize routines of prediction, regression, or inference of dynamic states, taking into account constraints in terms of the error and uncertainty mitigation within specific tolerance frameworks. Likewise, the construction of an effective representation space is problematic in terms of training sample size, as measurements or process observations can be easily obtained, but the categorization or labeling by technical experts is an expensive and complex procedure. It is also important to note that phenomenological comprehension, associated with the measurement sets, is not always achievable, which is a key factor for assuring reliability in results from the computational routines.

Mechanisms derived from soft metrology show promising research opportunities in terms of generating representation spaces with new indirect measurement methods inspired by human perception, multivariate statistical analysis, machine and deep learning, and decision support systems, among others, seeking out intrinsic structures of complex measurements for finally achieving inference results with a proper and rigorous uncertainty analysis.

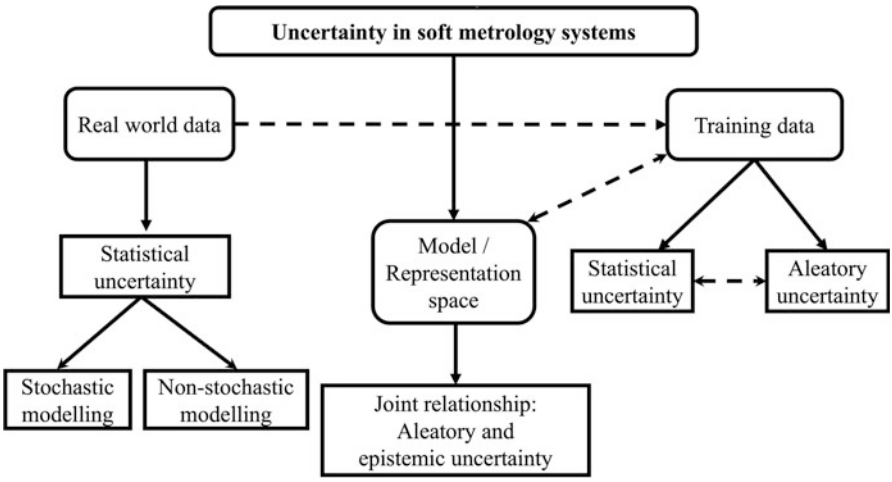

Fig. 7 Uncertainty in soft metrology systems. (Source: Authors)

Figure 7 depicts a structure that illustrates uncertainty components in a soft metrology system based on information from the literature. This structure considers two elements related to data: database uncertainty, associated with model training, and physical sensor uncertainty, associated with real-world data that constitutes the system input after training. The data-related uncertainty has an aleatory component, related to noise, and is modeled using either stochastic or non-stochastic methods. As the database is an essential input to the training stage, its uncertainty propagates throughout the model, which also has an epistemic uncertainty component, associated with the lack knowledge about the process features, i.e., the representation model/space does not have enough information about the intrinsic dynamics. As mentioned, the epistemic uncertainty can be reduced by increasing the amount of data, but this reduction is limited by the designer's phenomenological comprehension. Also, the epistemic uncertainty can be mitigated by estimating and selecting relevant features from a robust representation space, using relevance analysis techniques (Delgado-Trejos et al. 2009) .

In Vallejo et al. (2018), a conceptual scheme is presented, where training quality is directly related to representation quality, which is constrained within a certain range bound by the following factors: dataset size and phenomenological comprehension of the functional states of the variable of interest. From this conceptual analysis, for soft metrology systems, epistemic and aleatory uncertainty must be considered. In this regard, the conceptual scheme must be restructured, as depicted in Fig. 8 where the y-axis corresponds to three behaviors, which are the phenomenological comprehension (PhC), the epistemic uncertainty (EpU), and the aleatory uncertainty (AlU), as related to the dataset size and the learning capability in the x-axis. It is important to note that in this illustration the learning capability is directly proportional to the dataset size; therefore, the conceptual relationships between the y-axis variables and each x-axis variable are indistinctively assumed for all x.

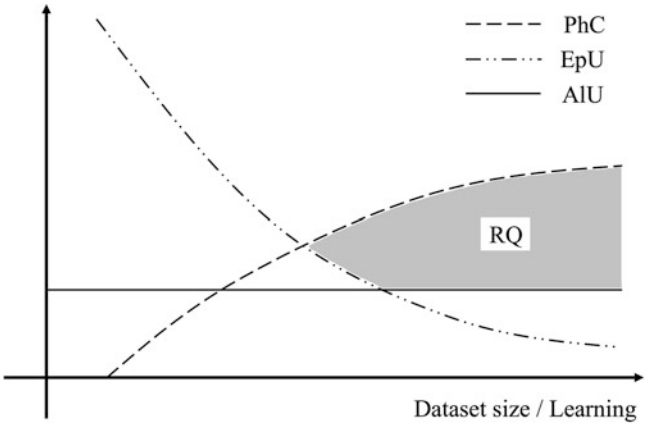

Fig. 8 Ideal region for representation quality (RQ) according to epistemic and aleatory uncertainty. (Source: Authors)

As observed in Fig. 8, the ideal region for representation quality (RQ) in soft metrology systems has an upper limit given by the phenomenological comprehension, which relates to how the computational models can be adjusted using the knowledge of technical experts, where factors that disturb the normal dynamics should preferably be included. Likewise, this region has a lower limit given by the aleatory uncertainty, as this uncertainty is linked to the internal randomness of the specific phenomenon, and with machine intelligence, it is not possible to figure out and establish decision boundaries below this lower limit. Also, as an additional constraint for some midpoints between the lower and upper limit, the epistemic uncertainty constitutes a boundary for the ideal representation quality, since this uncertainty is related to the lack of relevant representation features (knowledge derived from enough measurements regarding the specific phenomenon) that dictate how the system should behave, capturing its intrinsic dynamics.

Conclusions

In this book chapter, the concept of soft metrology and challenges related to two types of involved uncertainties are discussed. In general, the contribution of the epistemic and aleatory uncertainty in the global uncertainty of a measurement process for soft metrology must be focused on the uncertainty propagation derived from the computational effort in representation spaces, where the measure value is inferred from multivariate structures. Particularly, the intrinsic representation noise within data is associated with the aleatory uncertainty, since this natural noise comes from phenomenological disturbances produced by the interaction dynamics of the real world, and for this reason, it is considered independent of the model tuning of machine learning and the dataset size. In contrast, the epistemic uncertainty can be corrected by minimizing the model parameter tuning and assuring enough dataset

size, where the phenomenon understanding has an important role, considering that the upper limit of the representation quality in soft metrology is achieved based on how well the phenomenon is understood.

Finally, several soft metrology challenges are connected to the proper phenomenological comprehension for data acquisition where each representation state has enough number of samples, and this dataset allows the design of an appropriate indirect measurement method in terms of robustness and accuracy. Likewise, the uncertainty estimation, specifically, epistemic uncertainty, also requires phenomenological comprehension to lead the computational effort toward an effective representation space, where several data processing techniques, such as time-frequency analysis, nonlinear dynamics, and others, must be tested and analyzed in terms of representation quality and learning capability for inference, regression, and/or forecasting. Although there are many other challenges, it is important to note that the inclusion of strengths derived from computer intelligence routines in metrological processes must be further explored in the coming years.

Abstract

Optical technologies continue to expand to ease engineering metrology and improve precision of measurements. Invariantly, the optical techniques are used for the continuous, high-speed inspections of items of all shapes, sizes, and materials in Industry 5.0. Combining optics with sensors and competitive digital procedure benefits the rapid, portable, and large measurement.

Though it is impossible to accommodate the vast knowledgebase of the optical metrology, an attempt is made to cover the glimpse of recent recommendations, well established, and accepted optical methods and dimensional metrology measurement that are covered in this chapter. The applications of different properties

https://doi.org/10.1007/978-981-99-2074-7_69

of light and their respect techniques are discussed. The implementation of optical concept for the dimensional metrology instrumentation is categorically described.

Finally, some of the new works and prospective research are given. Therefrom, new frontiers may be thought off.

Introduction

Optical technologies continue to expand and improve precision and ease in engineering metrology. Invariantly, optical techniques are used for the continuous, high-speed inspections of items of all shapes, sizes, and materials in industry 5.0. Combining optics with sensors and competitive digital procedure benefits the rapid, portability, and sensitivity to the large measurement volume.

Laser interferometry, confocal microscopy, and white light technique with the aid of computation-based digitizing technologies are extensively in practice for dimensional measurements (Harding 2008). On the contrary, X-ray tomography, and terahertz metrology are already in use for inspecting the internal geometry of the biological and engineering artifacts.

Metrology

Metrology can be precisely defined as the science of measurement concerning the application (OIML VIM 2000). Consumer requirements that inspire new products and their trade demand well-established regulations, authentic measurements, and reliable measuring instruments through legal metrology (ISO/IEC-17025 2017). Behind the scene, scientific metrology ensures timeline stability of reference standard value of quantities for the conformity of meeting the geometric specifications and the traceability of measurement to SI units (Quinn and Kovalevsky 2005; Pierre Fanton 2019; Foster 2010; Pendrill 2014). Nevertheless, the development of manufacturing, ensuring the suitability of measuring instruments and their calibration, is dealt with by applied metrology (Gonçalves and Peuckert 2011; ILAC 2007; CIPM MRA-D-05 2016). The optical method used in dimension metrology has its special place in all these categories. Because of obvious reasons and a large volume of literature, however, only unique concepts are emphasized here.

Measurement Standards

A physical quantity is measured by comparing it with a standard quantity of same kind (Ehrlich et al. 2007). The quantification will be expressed as a numerical value accompanied with by the unit. Since the meter convention, the most accepted unit of the standard of length (i.e., SI unit) is meter (https://www.bipm.org/en/publications/SI-brochure/ 2021). The standard quantity should qualify the following basic requirements (Aswal 2020; Phillips et al. 2001; Rumble et al. 2001):

(i) Easy to operate and feasible to disseminate.
(ii) Reasonable to scale to the measurand.
(iii) Quantitatively invariant – quantum-based standard.
(iv) Theoretically well defined – definition of SI units.
(v) Practically realizable – mise-en-practique.

Meter is defined by fixing a numerical value of the speed of light in a vacuum as 299,792,458 ms^{-1}. Here, the second is defined in terms of the Cesium frequency Δv_{Cs}. Numerically, the meter in terms of the defining constants c and Δv_{Cs} will be given by Eq. 1.

$$1\ m = \left(\frac{c}{299\ 792\ 458}\right)\mathrm{s} = 30,663\ 319\ \frac{c}{\Delta v_{Cs}} \tag{1}$$

The next requirement practical realization recognized by the BIPM is as follows:

(a) Direct measurement, i.e., time measurement of the transmission of light.
(b) Indirect measurement of the optical wavelength using optical interferometry.
(c) Using material measures.

The list of recommended optical frequencies for realizing the meter which are related to iodine isotope transitions is given at BIPM website (Darnedde et al. 1999; Lazar et al. 2009). On the contrary, gauge blocks, glass scales, and step gauges are the material artifacts (Doiron 2008). The laser interferometer realized the displacement as well as length of material measures. Haitjema narrated the comprehensive calibration of the displacement measuring heterodyne laser interferometer (Haitjema 2019).

Traceability to SI Standards

Traceability is a fundamental quality of measurements, which requires an unbroken chain of comparisons (through calibrations) with a defined measurement uncertainty (JCGM-100 2008). The measured is referenced to a standard that realizes the quantity as per the definition of its SI unit (Ehrlich and Rasberry 1997). Figure 1 depicts the hierarchy of traceability in practice.

Dimensional Metrology

Dimensional metrology is an applied science which deals with geometric measurements, methods (NPL, UK 2005). The invention of steam engines required a large piston that fits in the cylinder. Consequent industrial revolution demanded mass manufacturing the interchangeable parts at different places (Kacker et al. 2003; White 2011). The concepts of geometrical product specification (GPS) model, tolerancing, and the Taylor Principle of gauge design supplemented these

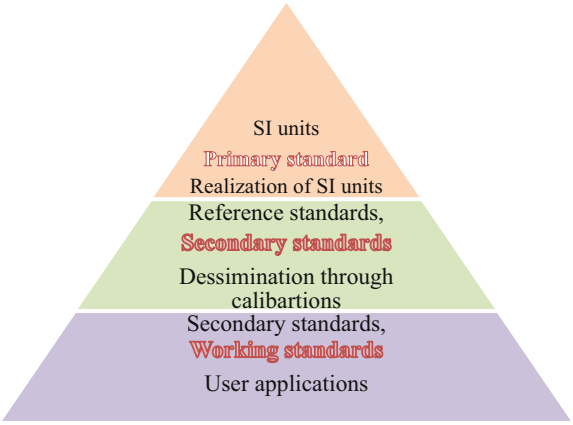

Fig. 1 Traceability of standards to SI units

requirements (ASME-Y 14.5 2018). Major milestones of the standard of dimensional measurements include the invention interferometer by Albert Abraham Michelson and the invention of the gauge block system by Carl Edvard Johannson, lapping practice by Joseph Whitworth. Dr. Richard K Leach 2003 advocated that "Metrology is not just a process of measurement that is applied to an end product," but rather the critical process requirement at every stage of product design to manufacturing (Richard Leach's Web Portal n.d.).

Conceptually, the dimensional parameters are measured in terms of length. Inserting a long cylindrical pin inside a deep cylindrical bore throughout its length is the basis of the first principle of dimensional metrology. This first principle by Taylor is based on the envelope principle (Raghavendra and Krishnamurthy 2013). The GO gauges are helpful to check and verify the violations and the conformance of the maximum material condition (MMC). The physical material distribution decides the boundaries of the separation (IS 8000 -1 2005).

Primarily, the material properties of a workpiece are important to serve its purpose (physical and chemical properties, internal discontinuities, and imperfections). Second, geometric shape and its surface condition directly influence the functional requirements. The geometrical tolerances of the workpiece are defined as deviations from geometrical ideal elements (i.e., line, surface, and curvature). Geometrical features (e.g., planes, cylinders, spheres, cones, etc.) have tolerance on (1) size deviations; (2) orientational deviations – bevels, squareness; (3) form deviations – roundness; and (4) surface conditions – waviness, roughness (ISO-14978 2018). One can identify the ratio between spacing and depth 1000:1 and 100:1 as waviness. On the contrary, roughness may be periodic or nonperiodic irregularities of a workpiece surface with the ratio between spacing and depth of the order of 150:1 and 5:1.

The ISO 17450 categorically describes the operators of the dimensional measurement process. The aim of the feature operators relevant here are as follows (ISO-17450 2011):

(a) Extraction operation acquires the coordinates from the surface of interest.
(b) Collecting the several functionally and desirable geometrical features associated with feature.
(c) Constructing virtual feature(s) from actual components within constraints (e.g., datum).

Anciently, the light is used for the measurements of distance and location. The study of the nature and properties of light is categorized as physical optics. On the contrary, the image-forming principles of lenses, mirrors, and other optical elements are covered under geometric optics. Hence, the essential concepts are reiterated.

Light and Its Interaction

The mathematical description of light propagation is given by parameters viz. the wavelength, phase, phase fronts, rays, etc. The speed of light is a quantum constant too. Figure 2 shows a snapshot of a harmonic wave that propagates in the z-direction.

$$\psi(z,t) = \mathrm{A}\ \cos\ \left[2\pi\left(\frac{z}{\lambda} - ft\right) + \gamma\right] \tag{2}$$

The field Eq. 2 of an electromagnetic wave represents the optical wave of amplitude A and offset phase γ. The wave propagates with a velocity $v = \lambda f$. Its wavelength is λ and its frequency is f. The concern of visible light where $\lambda = 400$ nm -700 nm (1 nm $= 10^{-9}$ m), and the f ranges from 400 THz to 750 THz (Gasvik 2002), is as follows:

The phase difference of the electromagnetic disturbance over a displacement in the z-axis direction is $\emptyset_1 - \emptyset_2 = 2\pi(z_1 - z_2)/\lambda$. For polychromatic radiation (say, it contains two angular velocities ω_1, ω_2), the rate of change of phase with time at a given point $|(\partial\ \emptyset\ /\partial t)z| = 2\pi f$ corresponds to the phase velocity $(\omega_1 + \omega_2)/\ (2\pi/\lambda_1 +$

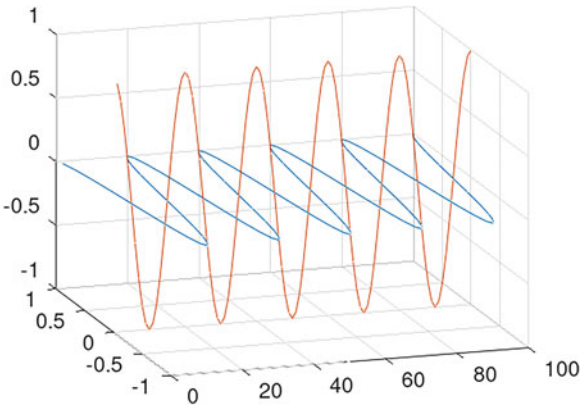

Fig. 2 Depiction of harmonic nature of light (units are arbitrary)

$2\pi/\lambda_2$). Further, the rate of change of phase with position at an instant is propagation constant. The group velocity corresponds to the slow-moving peak of envelope of polychromatic energy.

When the oscillating transverse electromagnetic radiation is propagating in z-axis direction having its electric component in x-axis direction, it is called polarized in x-axis. Consider two waves with their electric vector in x- axis and y-axis and having a phase difference ϕ. Equation 3 is their jones vector representation.

$$E = \begin{vmatrix} E_x \\ E_y \end{vmatrix} = \begin{vmatrix} E_{0x} \cos(kz - \omega t) \\ E_{0y} \cos(kz - \omega t + \phi) \end{vmatrix} \tag{3}$$

Here, k is propagation constant and E_{0x} (E_{0y}) is positional vector of electric field E_x (E_y), respectively. Alternatively, empirically measured stake's vector is used to represent the polarization in Mueller's calculus.

Primarily, the properties of light are described by the theory of classical electromagnetism. However, the quantum theory explores the interactions of light with atoms and molecules. The twentieth-century physicists adopted quantum electrodynamics (QED) as comprehensive theory of light despite the dual nature of light. QED combines the concepts of the classical electromagnetism, quantum mechanics, and the special theory of relativity.

Refraction

In 1621, Willebrand Snell discovered the mathematical relation (Snell's law) between the angles of incidence and transmission for a light ray at an interface between two media. The direction of propagation of light changes according to $n_1 \sin \theta_1 = n_2 \sin \theta_2$ at the interface of the media of refractive indices n_1, n_2. This is explained by Maupertuis with his principle of least action, that is, the path of light is of least length. Later, Fermat proposed that a ray takes the path of the least time. The optical path length of the transmission in a medium is equal to the geometrical path length multiplied by the refractive index of the medium. Accordingly, the phase difference $= k \times$ (optical path length).

The absolute index of refraction n of a medium is a ratio of the speed c of an electromagnetic wave in a vacuum to the speed v in that medium. When $\theta_2 = \pi/2$, the corresponding angle of incidence is called the critical angle given by $\theta_1 = \arcsin(n_2/n_1)$. This is called total internal reflection. This is useful to uniformly expand the plane wave from a laser beam.

Reflection

Ibn Al-Haytham, in his book "*Kitab al-manazir,*" correctly *proposed* that human vision is a passive reception of light rays reflected from objects. Following his studies, the metal-coated glass mirrors were discovered in modern-day Lebanon. However, due to the complexity of manufacture, vast majority of mirrors were simply polished disks of metal.

The mechanism of reflection in the case of dielectrics such as glass involves the influence of the electric field of the light on the electrons in the material. Consequently, the moving electrons generate fields and become new radiators. Thus, the light refraction from the glass is the reflected light which is the combination of the backward radiation of all of the electrons. On the contrary, the metal surface contains free electrons to oscillate with the incident light. The phase difference between their radiation field and the incident field is π (180°) at the interface. Here, the forward radiation cancels the incident light, and backward radiation would be the reflected light.

Diffraction

Diffraction effects studies by Jesuit mathematician Francesco Grimaldi were published in 1665. His experiments advocated the emerging of a cone of light from an aperture instead of a rectilinear ray. Diffraction refers to the bending of light around obstruct to encroach the shadow regions (Shimizu et al. 2019). In classical physic, the mechanism of diffraction of the optical wave is explained by the Huygens–Fresnel principle and the principle of superposition of waves. The propagation of light involves every particle of the transmitted medium on a wave front as a point source for a secondary spherical wave (Bhaduri et al. 2014). Encounter through an aperture gives interference bands depending on the wavelength of the light. Fraunhofer's model of the optical waves deals with far-field diffraction (i.e., at a long distance from the diffracting object), and it is focused at the focal plane using an imaging lens. On the contrary, Fresnel worked out the near-field diffraction using the approximation of the Kirchhoff–Fresnel diffraction equation. Diffraction limits the lateral resolution of detecting two adjacent light sources or illuminated objects. The angular resolution Θ due to diffraction-limited for a circular aperture diameter d at the first null of the Airy disk is $\Theta = 1.22\ \lambda/d$. Here, λ is the wavelength of illuminating light. Most often the microscope used in metrology has the diffraction limit, which is proposed by Abbe for a microscope as $d = 1.22\ \lambda/2n \sin \Theta$. Here, "n" is reflective index of medium through which light passes on to the object.

Interference

Optical waves are three directional, unlike, the two-dimensional as in the figure. Traditionally, the interference of light is explained using the classical wave model. The superposition principle states that at least two identical waves propagate to incident on a point; the results amplitude at that point are equal to the vector sum of the amplitudes of the individual waves (de Groot et al. 2021).

$2I \cos(\phi/2) \cos(kz - \omega t + \phi/2)$ is the mathematical representation of intensity due to the interference of two sinusoidal waves with phase difference ϕ. This indicates a constructive (bright fringe) interference for the phase difference of even multiples of π. The destructive interference occurs when the $\phi = \{\pi, 3\pi, 5\pi.\}$ between the monochromatic light waves (Dewhurst and Shan 1999). The generic equation of optical interference is $I_1(r) + I_2(r) + 2\sqrt{I_1(r)I_2(r)}\ \cos[\phi_1(r) - \phi_2(r)]$; here the displacement of wave is represented as exponential form $U(r) = A(r)e^{i(\Phi(r) - \omega t)}$ at point r. The

waves derived by the amplitude division and/or the wave front division supplement the essential requirement of interference that is same polarization (Ortlepp et al. 2020). Moreover, a wave of different polarization state occurs when the waves of different polarization are added. Michelson interferometer used for displacement measurement and the Mach–Zehnder interferometer are examples of amplitude-division systems (Michelson 1893). Young's double slit interferometer and Lloyd's mirror involve wave front-division.

Optical Techniques

Optical phenomena viz. reflection, refraction, diffraction, and polarization are used to device different instrument for different applications. The wave properties of light relate space and time too. Traditionally, the ray optics rely on the concept of rectilinear propagation of light. The ABCD matrix method deals with the ray optics (Saidane 2000). Nevertheless, the wave propagation describes diffraction, interference, with ease. Figure 3 depicts the broad categorization of dimensional metrology instruments (Castro 2008).

Ray Optics

Ray optics follow the three laws of geometrical optics:

1. Rectilinear propagation in a uniform, homogeneous medium.
2. Reflection – on reflection from a mirror, the angle of reflection is equal to the angle of incidence.
3. Refraction – total internal reflection that follows Snell's law.

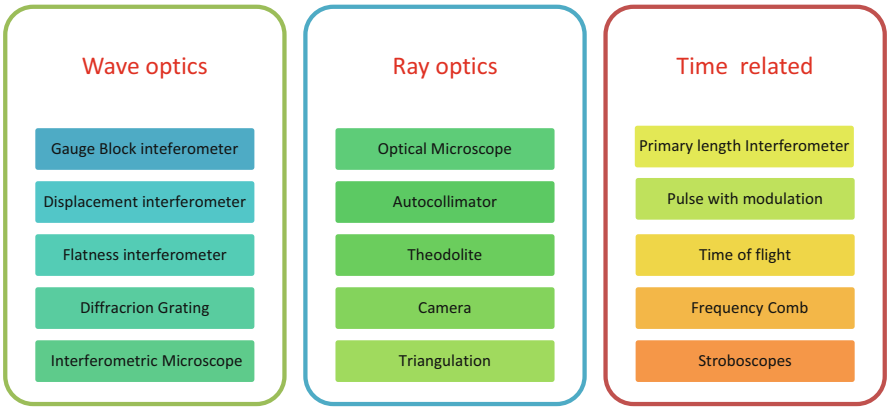

Fig. 3 Principles used for instrumentations

Telescope

The prime intention of telescope is a collect maximum optical flux. Larger the aperture size/objective of lenses, much denser will be the collected information. Thus, the collected light is focused to form image. The light-gathering power is equal to the product of the area of the collecting-lens and the solid angle subtended at the lens by the observed region of the source.

Image Forming

The imaging formation involves mapping of surface of a given object on to another surface known as image plane. Each illuminated point of the object corresponds to the projected image. The ratio of the size of the image to the size of the object is called the magnification of the image-forming optical system. The collected surface region of the image and the focal length of the lens determine the size of the field of view of the lens.

Aperture diffraction causes imperfect image despite of a perfect shape of mirror, or a lens. Practicable curvature of the optics induces image aberrations in addition to aperture diffraction (Fuerst et al. 2020). Monochromatic and polychromatic are main classes of aberrations. The first-order monochromatic aberrations are decomposed into five constituent aberrations by Philipp Ludwig von Seidel (Vrbik 2021). The five Seidel aberrations are (1) Spherical Aberration, (2) Coma, (3) Astigmatism, (4) Curvature of Field, and (5) Distortion.

Optical Coherence Tomography (OCT), a technique, views the subsurface images below the skin and through tissues. Ophthalmologists obtain details of the retina using OCT. Cardiologists take help of OCT to diagnose coronary artery disease. Researchers are involved in developing materials for preparing phantoms for the experiment of OCT.

Microscope

The optical microscope contains optics to produce an enlarged image of a sample placed in the focal plane. Often, microscopes have refractive or reflective optics to focus light on the eye or on to another light detector. The typical magnification of a visible light microscope is 1250X with a theoretical lateral resolution of around 0.25 μm.

Many modern, high-resolution microscopy techniques meticulously coupled the object illumination sections with detection optics to achieve optical sectioning (Wimmer 2017). This interface involves coinciding the illuminated point/plane and the collection point/plane (Schneider et al. 1999).

Wave Optics

The visible spectrum ranges from (4.3 to 7.5) $\times$ 10^{14} Hz. Most electronic detectors are unable to follow the electric variations of light. The interference phenomena average the intensity over time and space. Different types of instruments are developed based on the interference or diffraction and the spectrum of wave. In 1678, Huygens proposed that every point that a luminous disturbance meets turns

into a source of the spherical wave itself. The sum of the secondary waves, which are the result of the disturbance, determines what form the new wave will take.

Spectroscopy

Spectroscopy is the study of the interaction light with the matter. The electromagnetic energy is a function of the frequency, or the optical wavelength relates to the molecular spacing (Gaigalas et al. 2009). Various discovered spectroscopic effects are useful to investigate the response of different material and engineer novel materials. Absorption emission elastic scattering are some spectroscopy processes. Inelastic scattering phenomena involve a shift in the wavelength of the scattered radiation due to exchange of energy of radiation and the matter. These include Raman and Compton scattering.

Holography

Holography is a technique to exploit the superimposing of a second wave front (normally called the reference beam) on the wave front of interest. A wave front is recorded and later reconstructed to generate three-dimensional images. Holograms are also generated using computer to model the two wave fronts (Rehman et al. 2012).

Optical Dimensional Measurements

The dimensional measurements can be broadly divided into five categories. Different optical instruments are used to measure the dimensional parameters. Figure 4 shows the dimensional metrology categories.

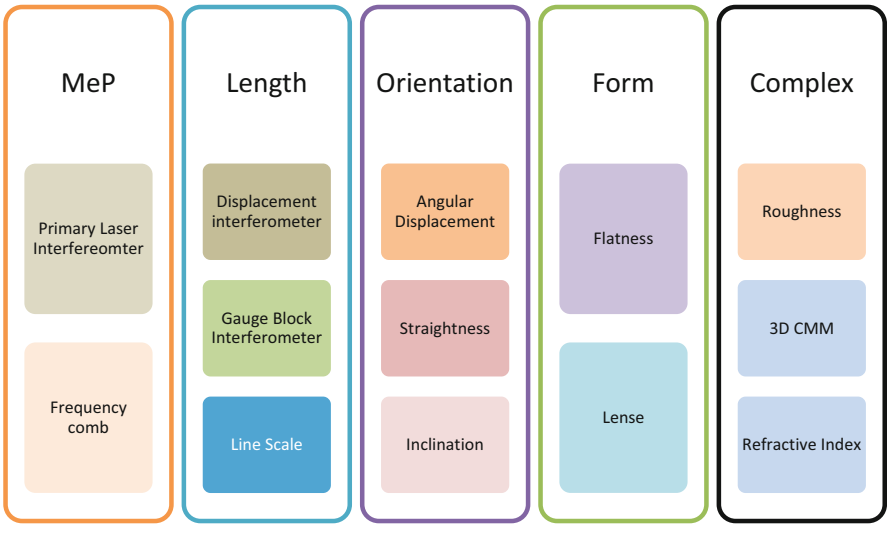

Fig. 4 Optical measuring methods of dimensional parameter

Optical Comb

Since, the frequency of optical radiations realizes a natural/quantum unit of length, the visible range of the spectrum is used for the measurement standard for the microdisplacements. Interferometry specifically solves the problem of inability of sensor to respond to the extremely high frequency of oscillation of the electromagnetic field (0.6 PHz). The optical path lengths of the reference and the "object" paths are compared to ascertain a difference of an integer multiple of the wavelength interference (Hall and Ye 2003). The length/displacement is determined by counting the interference fringes and applying the refractive index corrections of the medium of interest. On the contrary, the wavelength of the light that corresponds the interferometric fringes must be known precisely. Therefore, the calibration of the wavelength of recommended optical radiations is inevitable. Atomic transitions make ideal frequency references and hence are reproducible. Recently, optical frequency comb is adopted as a reference for calibrating optical frequencies (Araujo-Hauck et al. 2007). The optical field of the laser pulse train is described by a carrier frequency, $\nu_c = \omega_c/(2\pi)$, that is modulated by a periodic pulse envelope. Often, frequency comb is generated with a mode-locked laser (Fortier and Baumann 2019a). It produces a series of optical pulses separated in time by the round-trip time of the laser cavity. Typically, the time period of the optical pulses is (1–10) ns. The spectrum of such a pulse train approximates a series of Dirac delta functions separated by the repetition rate (the inverse of the round-trip time) of the laser. This series of sharp spectral lines is called a frequency comb or a frequency Dirac comb (Fortier and Baumann 2019b).

Popularly, iodine-stabilized He-Ne laser sources are used for dimensional metrology. The atomic energy level transition gives the laser radiation of multiple wavelengths; which corresponds to a wider bandwidth rather a sharp line of optical spectrum. The spectral line width is of Lorentzian form (Eickhoff and Hall 1995). Moreover, atomic vibration induces Doppler shift $\Delta v = v\sqrt{(8\pi kT \ln 2/mc^2)}$ between half power points. Here, m is mass of the optical frequency (v) emitting atom and k is Boltzmann constant. The output laser spectrum is convolution of the frequency-spectral response of resonator cavity and Doppler-broadened gain curve of the active medium (Rubin et al. 2022). Lamb dip, polarization, and saturation absorption stabilization are useful feedback control mechanisms to refine the separation of mirrors of the optical cavity. Allen variance serves as a measure of the stability of a laser source.

Linear Measurement

The measurement of a rectilinear displacement of movable structures, machine platforms, and objects, a distance between two designated marks on a surface, any end faces of solid block, and peaks or valleys are considered as linear measurements in dimensional metrology. Moreover, external and inner diameter of cylindrical objects, rings shapes, also belong to linear measurement (Li et al. 2014). Glass

graticules, steel scale, tape, and meter bar are popularly known as line reference standard artifacts (Swyt 2001). Similarly, gauge blocks, snap gauges, and diameter artifacts are called end standards (Stone et al. 2011).

Displacement Laser Interferometry

Displacement measuring interferometry (DMI) outperforms in position monitoring and measurement due to the high resolution, wide measurement range, and fast response. Moreover, the laser beam in the DMI can be used as a virtual axis of measurement to eliminate Abbe offset errors (Flügge 2014; Abduljabbar 2014; Haitjema 2008). Commercially, DMIs employed a homodyne or the heterodyne techniques to measure rectilinear displacement, plane angular – rotation, straightness, etc. (Kim et al. 2011). The reproducibility of measurement is supplemented by the wavelength-stable laser source, refractive index sensor electronics (Badami et al. 2016).

End Gauge Block Interferometer

The measurement of gauge block is based on the optical interference principle (Twyman-Green type) to estimate the fringe fraction corresponding to the length of the gauge block under calibration (Hu 2013). The length of the gauge in the ambient conditions of measurement is $L_A = (N + f)\lambda/2$. "N" is an unknown integer number of half wavelengths, and "λ" is the wavelength of the light (Jin et al. 2006). If the gauge length is known by mechanical measurement to be better than "$\lambda/2$," then the correct value for "N" can be calculated and the gauge length "L_a" calculated (Ali and Naeim 2014). The length measured under the ambient conditions must be corrected to the standard temperature of 20 °C: $L_{20} = L_A(1 + \alpha\Delta fT)$. Here, "α" is the thermal expansion coefficient of the gauge block and "Δt" is the difference between the temperature at which the gauge block has been measured and 20 °C. The lasers are frequency stabilized; the ambient conditions of the air are monitored in order to correct the wavelength for the refractive index of the air applying Elden's eq. (Schödel 2015).

Line Scale Measurement

The linear encoder is composed of a grating and a reading head system. The grating has the incremental grooves with an equal spacing structure. In the reading head, a laser beam from the laser diode (LD) is divided into two beams by a beam splitter (BS1). One beam passes through BS1 and propagates toward the displacement assembly, while the other is projected onto the scale grating after passing through the reference mask. The laser beam passing through a beam splitter 1 is then divided into another two beams by another beam splitter 2. The beams are projected onto the scale grating and a reference grating, respectively. The spacing of the reference grating grooves would be same as the incremental grooves of the scale grating. Two beams diffracted from the scale grating pass through BS2 and coincide with those from the reference gratings (Li et al. 2016). The reference and measured signals are analyzed to determine the line graduation spacings.

Angular Measurement

The geometric angle is essential dimensional parameter. Angle gauge blocks, regular polygon, and the angular indexed rotary stage realize the plane angle. The SI unit of plane angle (radian) is defined as the ratio of a unit circumference to a unit radius (Arif Sanjid 2013). Autocollimator, laser interferometer, spirit level, and theodolites are the typical instruments used to measure the angle. The inclination of the surface concerning the ground, the squareness between two planes, and the parallelism of end faces of prismatic objects are additional angular qualities of concern (Weichert et al. 2009). Often, the inclination is realized using a sine bar (sine arms) in terms of the length of the gauge blocks (a micrometer), and distance between the rollers (supports) of the sine bars (tilting table), respectively.

Autocollimator

An autocollimator is an optical instrument used for the measurement of deflection of the reflective plane (Vrhovec et al. 2007). The pitch (i.e., interior) angle of prismatic gauge blocks is calibrated using autocollimator on an angle-indexed rotary stage. An autocollimator projects a collimated optical beam of an image (say graticule) onto a target mirror. The return beam will be collected onto a graduated scale or an electronic detector (Igor et al. 2021). The least count of visual (electronic) autocollimator is of the order $0.2''$ ($0.01''$), respectively. Precision autocollimators can detect return beam with a measuring range up to $\pm 2000''$.

The calibration using two autocollimators is shown in Fig. 5. A precision index table (Moore Index Table), of 200 mm diameter and a least count of 15 min, is placed on a rigid, stable, leveled surface plate. A small table adjustable in three planes with leveling screws is placed on the top of the index table.

Two autocollimators with a range of ± 5 min and a least count of 0.2 s. of arc are placed on a rigid stand radially to the index table. The axis of the autocollimator objective lens is leveled and adjusted so that the working face of the angle gauge is in the field of view of the autocollimator and the face is square to the axis of the autocollimator. This can be checked by observing the position of reflected image by taking reflection on both the faces of the angle gauge in turn.

Laser Tracker

Laser tracker combines the principle of the theodolite and the state-of-the-art technology: a stabilized laser beam. The laser beam determines the displacement of the cube corner prism using time of flight method interferometry. The azimuth and elevation angles of the target direction are sensed using angular encoders. The embedded software use triangulation concepts to perform the volumatic analysis of large-scale metrology (Francis et al. 2010).

Form Measurement

The flatness refers to controlling the uniform local heights of a surface or a median plane. Technically, the flatness tolerance is defined as the separation of two parallel

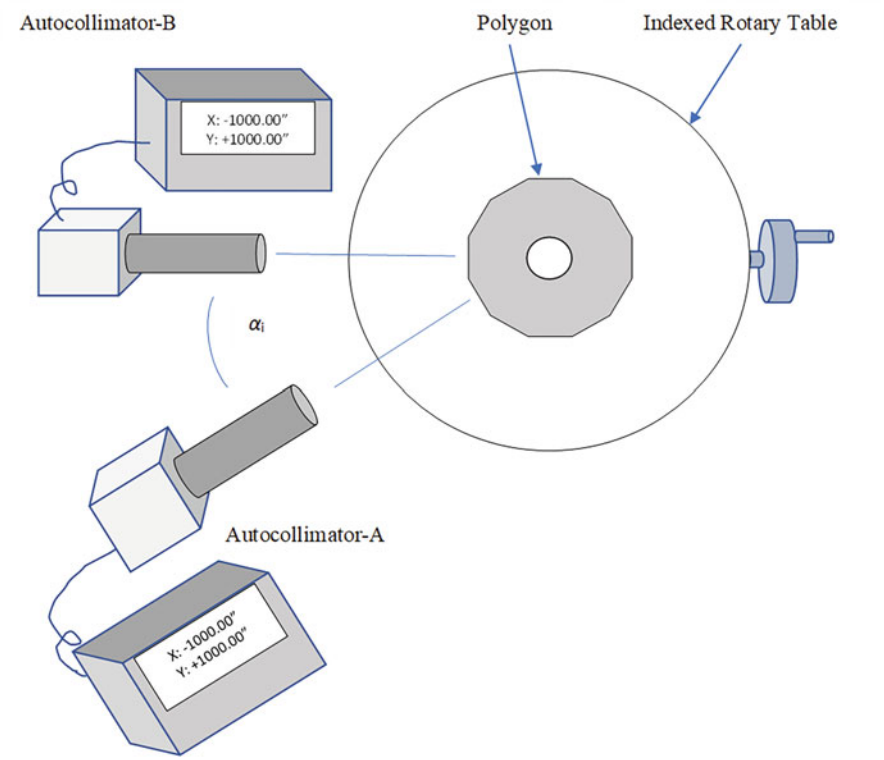

Fig. 5 Calibration of angular artifacts (regular polygon) using autocollimator

planes on either side of the assumed flat surface. The coordinates of the profile of the surface must lie between these two planes to pass the quality check of flatness tolerance. Primary flat surface is realized by a silver ambiguation liquid level. Despite of the influence of the curvature of earth, the liquid meniscus is perpendicular to the direction of gravity which is considered as flat as few nanoradians. At the National Metrology Institute of Germany, the concept of light propagation in straight-line is explored to establish secondary standard of flatness and straightness (Feng et al. 2004). These measurements are traceable to SI unit of length and angle. Diamond-lapping processes are ideal for producing reflective surfaces, which can be measured for flatness using this method directly after the lapping operation.

Usually, the flatness of a component like optical flats and grounded surface are measured using a monochromatic light source and a highly lapped reference optical flat. A sodium light emitting wavelength approximately 589 nm shines the interface of the reference flat and the surface under test. The resultant interferometric bands are made up of a bright and dark fringe and correspond to 294 nm. On the contrary, Fizeau interferometer uses a collimated laser beam of 633 nm and phase-shifting mechanism to measure optical flats with an accuracy of 10 nm (Nyakang et al. 2013).

Complex Measurement

The parameter viz. surface roughness, refractive index of lens, geometry of hardness indenter, and deformation of odd shaped objects due to the stress and thermal gradient are some of the complex measurements in dimensional metrology (de Groot 2015). They involve simultaneous measurement of multiple dimensions of length, angle, or unconventional optical methods of measurements. Spackle interferometry and fringe projection techniques are some of such unconventional practices.

Spackle Interferometry

Conventional interferometry deals with the optically smooth-polished surfaces and well defined the optical path. On the contrary, speckle interferometry deals with the ordinary diffusing objects, which roughness is comparable to the wavelength (Smith and Smith 2002). The objects' undertest is illuminated with coherent light, giving rise to speckle fields, i.e., strongly fluctuating distributions of light intensities and phases (Colonna De Lega 1997; Creath 1988; Moore et al. 1999).

Speckle interferometry (SI) aims to create and record a two-beam interference pattern involving at least one speckle wave. Speckle waves are spontaneously reflected or transmitted by diffusing surfaces exhibiting rapid spatial intensity and phase fluctuations. The phase shift between the spatial spackle waves is a function of the geometrical path difference $\delta(r)$ they traveled $\varphi(r) = 2\pi/\lambda\, n\, \delta(r)$. Here, λ is the vacuum wavelength of the light source and "n" the refractive index of the propagation medium.

SI operates in differential mode by taking an initial state most often related to a fixed configuration as a reference state and the other spackle state of the small perturbation. These specklegrams are recorded by a digital camera and correlated statistically to estimate the measurand (Tendela et al. 2015). SI is widely used for the complex dimensional measurement like surface roughness, deformation of structure/objects due to stress.

Fringe Projection

A shadow moiré pattern is a virtual interference pattern that follows geometric interference principle. Moiré fringe image is generated by covering the measurement area with a physical grating. Then the surface is illuminated and viewed at opposite directions. The fringes are projects on to the surface by which light passes through the grating at a tilted angle (Chasles et al. 2007). This shadow is observed at a tilted angle from the opposite direction to the light source. A moiré pattern can be seen as a pattern of fringes. The topology of the surface with the peak/valley rings represents the same height relative to the physical grating.

Summary and Future Prospective

In the dimensional metrology, optical methods are robust, reliable, and non-replaceable. Since the comprehensive exploration is vast enough to cover many volumes, the sustained and prevalent techniques are briefed in this chapter.

Moreover, only the gist and some critical issues are emphasized. Optical comb, laser trackers, and spackle photometry are emerging topics of research interest. The Michelson interferometer with Fourier transform can be dramatically enhanced with optical frequency combs (Badami et al. 2019; Picqué and Hänsch 2019). The optical medical imaging demands metrological scale for volume scattering of diffuse materials of the optical properties of biological tissue. Such materials are used as phantoms to evaluate and validate instruments that are useful for clinical trial which will be traceable to the scales for reflectance and transmittance (Lemaillet et al. 2016).

The picometer range displacement measurement length ruler demanded by the lithography of semiconductor chip fabrication is under experimentation by combining the X-ray diffraction and displacement interferometry (Köchert et al. 2011). Flatness interferometry for X-ray mirrors, establishing traceability to X-ray diffraction grating, are some more prospective areas of research (Alcock et al. 2016). Spherical and cylindrical interferometer designs are for measuring the volume of silicon spheres of the Avogadro project. NMI, Germany, has determined a precise diameter determination with an uncertainty of one nanometer or less. Optical methods of simulating curvatures and devising interferometric digital twin are frontiers in digitalization of metrology. Similarly, the NMI, Germany, developed a technique of assessing the tactile probe of a microcoordinate measuring machine using a microscope, and combination with contact trigger sensing of coordinates is still to be commercialized (Cui et al. 2012; Fan et al. 2012).

Conclusion

The concept of traceability of measurement to the SI unit of length, the internationally adopted recommendations and their practices for dimensional metrology are explored. The properties of the light and their dimensional application are explained. Thereafter, different optical techniques and instrumentation are discussed. The optical methods of dimensional metrology parameter are elaborated. Additionally, advance in dimensional metrology using optical techniques are emphasized.

extract useful information from the dense digital representation. Since such systems can be used to compute the deviation between as-built and as-designed objects, they tend to complement more traditional coordinate measurement machines. Due to their compactness, short acquisition time, and affordability, 3D imaging systems constitute an interesting tool for quality control operations, reverse engineering and metrology-assisted assembly, and/or manufacturing. These systems can thus act as important enabler for cyber-physical systems, which are critical to Industry 4.0.

Active 3D imaging · Metrology · Optical metrology · Measurement uncertainty · Industry 4.0

Introduction

Many manufacturers are embracing the digital Fourth Industrial Revolution (comprising AI, robotics, IoT, 3D printing, etc.). The shift toward Industry 4.0 has led to ever closer interactions between the physical and the virtual (Alcacer and Cruz-Machado 2019; Uhlemann et al. 2017; Zezulka et al. 2016). Deploying cyber-physical systems requires a means to acquire dense and accurate digital representations of the geometry of manufactured objects, manufacturing equipment, and sites (Uhlemann et al. 2017). Three-dimensional imaging systems are tools that can enable such cyber-physical systems. The systems are affordable, small, and allow noncontact measurement with short acquisition times and high densities ($>10^5$ points/sec) (Catalucci et al. 2022; Drouin and Beraldin 2020).

Three-dimensional systems combine one or many cameras, and most often, a controllable light source (coherent or noncoherent), which allows to acquire dense and accurate digital representations of object geometries. Modern 3D imaging systems also require complex software stacks to extract useful information from the dense digital representation. They have short acquisition times, which make it possible to use them for quality control, digitization, metrology-assisted assembly, etc. Since 3D imaging systems can be used to compute the deviation between as-built and as-designed objects, they complement more traditional coordinate measuring machines (CMM). Typically, CMMs enable the acquisition of a few very accurate 3D points, while 3D imaging systems acquire millions of 3D points that are usually less accurate. The sheer volume of such lower accuracy data requires a robust software stack. In this chapter, we focus on 3D imaging systems that target the digitization of manufactured objects, with a special emphasis placed on this software stack.

Any discussion of 3D imaging systems characterization must be preceded by a rigorous definition of uncertainty, accuracy, precision, linearity, repeatability, and reproducibility (Gage R&R) in in situ conditions. Two authoritative texts on uncertainty management and terminology are the *Guide to the Expression of Uncertainty*

in Measurement (GUM) and the *International Vocabulary of Metrology* (VIM) (ISO 1995; Joint Committee for Guides in Metrology 2008). The ASTM's E2544 provides a definition and description of the terminology for 3D imaging systems (ASTM 2010). Due to space constraints, we refer the reader to the previous chapter of this book and to the above-mentioned authoritative texts for rigorous definition of those terms. The use of lasers is associated with eye safety hazards and, for more details, we refer the reader to the *American National Standard for Safe Use of Lasers* (ANSI Z136 2007) or to their particular organization's laser safety officer. Note that high-power low-coherence (and noncoherent) light sources can also pose eye safety issues (BS EN 2008).

The core section in this chapter covers the measuring principle of 3D imaging systems, as well as the sources of error associated with their use. We then discuss hardware and software aspects of 3D imaging systems. Toward the end of this chapter, we present some Industry 4.0 applications, and finally, we provide some concluding remarks.

Measurement Principle

Most of the 3D imaging technologies presented in this chapter are classified as optical noncontact 3D imaging systems because they emit light into the environment and use the reflected light to estimate the distance to a surface in the environment. The three most used measurement principles in commercially available systems are time-of-flight (ToF), interferometry, and triangulation. Other classifications of the principles have been proposed as well (Besl 1988; Blais 2004; Jahne et al. 1999; Nitzan 1988).

Time-of-flight is based on accurate clocks, interferometry requires accurate wavelengths, and triangulation systems are based on the intersection of light rays in 3D space. A triangle is defined when the values of two interior angles and the length of the included side are known. With these values, the lengths of the other two sides can be computed. The included side is known as the baseline of a triangulation system, while the two others are known as light rays. In the presence of a complex geometry, one of the light rays corresponding to a 3D point may be blocked by other parts of the surface being digitized. Obviously, when such occlusions occur, triangulations become impossible. Note that the two interior angles can be measured indirectly. The coordinates of a pixel in a camera can be transformed into interior angles when the camera's parameters are known (Hartley and Zisserman 2004). An active triangulation system is composed of one or many cameras and one projection system, while a passive one consists of a least two cameras. The remainder of this chapter will focus on 3D imaging systems based on triangulation, and which are well adapted to advanced manufacturing applications.

Typically, in interferometric systems, a laser beam is split into two paths. One of the paths is of known length, while that of the other is unknown (Jahne et al. 1999). The difference in path lengths creates a phase difference between the coherent light beams and this phase difference is used to compute the distance. Of interest are

systems based on optical coherent tomography (OCT), which can be designed with a very compact scanner head that allows accessing hard-to-reach areas of manufactured components (Zanardi et al. 2010). In ToF systems, the distance is computed from the round-trip time of light, which can be converted into distance (Drouin and Hamieh 2020). Obviously, interferometric and TOF systems are classified as active.

Some of the 3D imaging technologies presented in this chapter are classified as optical contact systems because they measure distance by emitting light into the environment and using the reflected optical energy on collaborative targets fixed on the environment's surfaces. Collaborative targets can be either corner reflectors, spheres, or 2D circular stickers. Corner reflectors for their part are typically used with interferometry or time-of-flight system, while spheres and stickers are used with triangulation systems. Optical contact systems can be used to extend the working volume of noncontact 3D imaging systems, and many vendors offer solutions based on this combined use. Here, we briefly discuss these contact technologies in the context of extending the working volume of noncontact 3D systems.

Sources of Uncertainty

Uncertainty quantification in the 3D imaging measurement of coordinates remains a complex endeavor. When trying to characterize the uncertainty associated with the measurement obtained by a 3D imaging system, many users concentrate their effort on the measurement device (i.e., the hardware). Manufacturers of 3D scanner usually provide one or many numerical values, which are used to characterize the uncertainty of the measurement taken by their systems (VDI 2005, 2008). It is crucial to realize that these values are obtained in very specific conditions, using specific methodologies and selected test objects. Such values, typically associated with a 3D scanner by the manufacturer, may not be representative of the uncertainty of the measurement taken by an end user. The uncertainty associated with a measurement (outcome) depends on the 3D scanning technology used, including all physical phenomena that define the point clouds acquisition process (i.e., hardware), the methodology (measurement strategy, sampling, etc.), the software (filtering, algorithms, hyper parameters, etc.), the ambient conditions in which the measurement is performed, the materiel properties of the sample being digitized, surface texture variations, the part size, geometric complexity, and finally, the people performing the measurement. These uncertainty sources are illustrated in Fig. 1, and are briefly described in the remainder of this section.

The impact of the people performing digitization is often underestimated. As an example, users' visual acuity and expertise can significantly impact the digitization process. Note that the methodologies and best practices followed by operators can have a significant impact on a measurement result. Use of a sound methodology and best practices can allow to reduce the errors induced by the operator and improve the system's repeatability and reproducibility. Because many 3D imaging systems are simple to operate, some users may fail to define and use a methodology adapted to

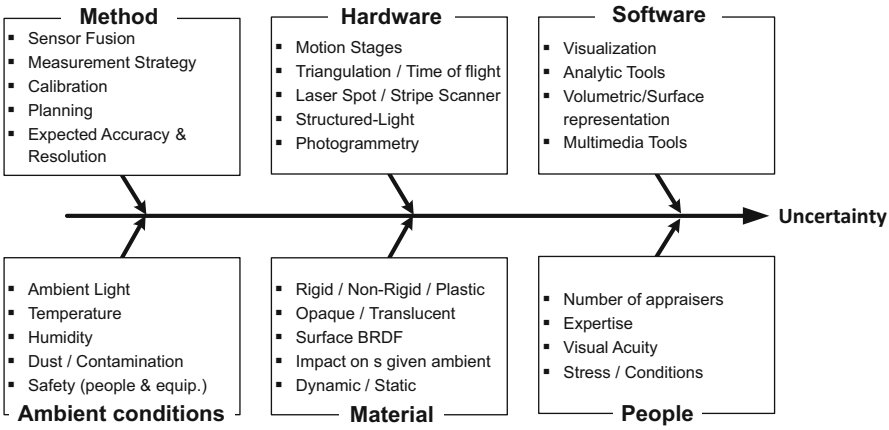

Fig. 1 Diagram showing typical sources of uncertainty for the most common 3D imaging technology use case. (Adapted from Drouin and Hamieh (2020). Figure courtesy of NRC)

the targeted application. For instance, the uncertainty associated with the measurement of many active 3D imaging systems varies within their specific measurement volumes in a nonintuitive manner (Drouin et al. 2017). This often results in methodological errors in which a system well adapted for a given task is positioned in a suboptimal manner.

Ambient conditions can significantly influence the outcome of a 3D acquisition. A case in point is where artifacts could be induced by a powerful ambient lighting source with a spectral distribution overlapping with that of the active 3D imaging system. Depending on the 3D acquisition system used, vibration can also introduce artifacts, while temperature variations can provoke changes to the relative position of the components within a 3D imaging system. For a triangulation system, this corresponds to a baseline change, and can result in a systematic scaling error of the digitized representation (Drouin and Beraldin 2020). In an interferometric system, it is critical to have no variation for the path of known length (Jahne et al. 1999). Any variation of the refraction index (and thus, on the speed of light) in the air between the imaging system and the artifact being digitized will introduce artifacts in the digital representation (Drouin and Hamieh 2020). The severity and type of artifact depend on both the measurement principle used and the implementation detail of a specific 3D imaging system. As an example, a temperature gradient in the air between the object being digitized and the 3D imaging system could introduce artifacts. When the gradient is perpendicular to the line of sight of the acquisition system, aberration will be introduced in the optical system, which can limit the performance of the imaging system. When the gradient is aligned with the line of sight, a change of effective focal length of the optical systems could be introduced. For triangulation system, this could induce scaling issues of the digital representation. In general, high-end 3D imaging systems will apply some form of compensation that takes any variation in the ambient environment into account. A simple and

popular approach for temperature is to simply include a warming period to bring the system to a given temperature prior to acquiring data. Another popular approach is to include sensors and to apply a correction function.

The properties of the object being digitized can greatly affect the overall uncertainty of a measurement. Other than the obvious fact that some objects are rigid, while others are not, the small-scale mechanical texture of an object (i.e., its surface roughness) can significantly impact the uncertainty of a measurement performed using a 3D imaging system. The characterization of the mechanical texture was discussed in Leach (2011) and Yoshizawa (2009). Because of this small-scale texture, the different coherent waves emitted by a 3D imaging system are reflected on the object and reach its detector with slightly different paths, resulting in different phases. This induces constructive and destructive interference, also known as speckle noise (Baribeau and Rioux 1991; Dorsch et al. 1994; Drouin and Beraldin 2020; Leach 2011). The presence of a semitransparent coatings and variations of the surface reflectance can also significantly affect the overall performance of a 3D imaging system. The geometric configuration of the surface of an object can generate specularity and inter-reflection, which can produce many artifacts. Descriptions of many of the artifacts introduced by the surface properties are included in Drouin and Beraldin (2020). Moreover, there may be some interactions between the object being digitized and the ambient condition at the time of digitization. The most obvious of such interactions involve the thermal expansion of the object being digitized.

The software used may also affect the uncertainty. While a coordinate machine measurement (CMM) will typically measure a few points on the surface of an object, a 3D imaging system generates millions of points, which must then be analyzed, and in some cases, visualized. The software/hardware divide is somewhat blurred as there may be processing going on directly on the acquisition hardware, while others are executed on a host computer. Processing can include filtering (smoothing), outlier removal, surface completion, fusion of multiple acquisitions, alignment (registration) of a digital representation with a reference one, etc. Each one of these processing steps may affect the uncertainty.

The uncertainty associated with a measurement taken by a 3D imaging system depends on the measurement principle used. Triangulation systems (in with the effect of out-of-focus blurring are neglected) have an uncertainty that increases with the distance, whereas with time-of-flight systems, the uncertainty should be independent of distance (Drouin and Beraldin 2020; Drouin and Hamieh 2020; Drouin and Seoud 2020). Note that for a subset of the active triangulation systems, an uncertainty model that takes into account out-of-focus blurring is presented in Drouin et al. (2017). The range uncertainty for practical scanner configurations has a slanted “U” or “W” shape (see Table 2 for an example). Typically, we expect that triangulation systems will operate at a shorter standing distance than time-of-flight ones. Also, the performance of a triangulation system is related to its physical size (i.e., the length of the baseline) and the uncertainty is expected to increase as their physical size is reduced. As a rule of thumb, noncontact 3D imaging systems that are designed to digitize objects with a working volume ranging from a few cubic centimeters to approximately a few cubic meters are expected to be based on

triangulation (Drouin and Beraldin 2020). Time-of-flight technologies are expected to be encountered for working volume starting at approximately a few cubic meters (Drouin and Hamieh 2020; Drouin and Seoud 2020). Optical contact system can be based on triangulation (when large baselines are used), or can be time-of-flight or interferometry systems.

Measurement Device

In this section, we review the taxonomy presented in Drouin and Beraldin (2020), which classifies active triangulation systems based on the method used for structured light. We conclude with a discussion on the contact and noncontact 3D imaging system combinations used. We refer the reader to Drouin and Beraldin (2020) and Leach (2011) for a more in-depth description of short-range 3D imaging technologies. We consider four distinct categories: spot scanners, stripe scanners, systems that use structured light patterns, and handheld scanners (see Fig. 2). While the first two categories typically use coherent light sources, the last two can use both coherent and noncoherent light sources. It is easier to mitigate the impact of ambient lighting when a system uses coherent or low-coherent light. However, coherent and low-coherent light source are more severely affected by speckles, which for their part, are a function of the mechanical texture of the component being digitized. Note that, the impact of speckle noise for a given surfaces can be reduced by shortening the wavelength and increasing the bandwidth of the light source (Baribeau and Rioux 1991; Dorsch et al. 1994; Leach 2011).

Spot Scanner

The first and simplest system is the spot scanner, in which a scanned laser beam illuminates a very small circular spot on the component being digitized. The simplest implementation of a spot scanner would use a linear detector, which consists of a camera with a single row of pixels. For each image acquired by the linear detector, a

Fig. 2 Left: Experimental spot-based scanner described in Blais (2004) and Drouin and Beraldin (2020). Center: Commercial stripe-based scanner mounted on a translation stage. Right: Commercial structured-light scanner. (Figure adapted from Drouin and Beraldin (2020). Figure courtesy of the NRC)

3D point is computed by triangulation using the position of the laser spot on the detector. Motion stages, galvanometer-mounted mirrors or a combination of both, are used to acquire a 3D scan of the object. This makes the acquisition slow and sensitive to vibration. Note that some high-end spot scanners allow to dynamically adjust the spatial sampling of the scanner, the optical power, and the focalization distance of the laser (Blais 2004; Drouin and Beraldin 2020).

Stripe Scanner

Typically, in a stripe scanner, a laser beam is passed through a cylindrical lens, or diffractive optical element in order to illuminate the object being digitized with a thin laser stripe. The simplest implementation of a stripe scanner would include a camera with each of its rows acting as a spot scanner. These systems are sometimes called profile scanners, and the term profilometry is frequently used in the literature in association with them. A complete digital representation of an object can be achieved by installing the scanner on top of a conveyor belt, or on a motion stage (Blais 2004; Drouin and Beraldin 2020).

Structured Light

The third type of active triangulation projects a structured-light pattern onto the scene (Jahne et al. 1999). These devices are sometimes referred to as area scanners (VDI 2002). Note that the use of the word *scanner* here is somewhat abusive since these systems do not scan a light beam over the object being digitized. Rather, they project structured patterns that simultaneously cover a large part of a component being digitized. This is illustrated in Fig. 2. The light patterns are structured either spatially, temporally, or both and allow building pairs of corresponding points between the projected and the captured pattern (Salvi et al. 2004). Those projector-camera pairs can be used to triangulate 3D points. Some systems use a single structured pattern, which minimizes the distortion due to vibration, while others use a small number of patterns that require a static environment. There are many types of patterns that can be used, and for more information, we refer the reader to Salvi et al. (2004).

Handheld

The last type of scanner is a handheld scanner, which can be used in dynamic environments where the operator moves the scanner in front of the object being digitized. Some such systems allow both the 3D scanner and the object to be moved simultaneously. Handheld scanners are composed of a positioning and a measurement system, and the latest devices are typically either stripe-based scanners or structured light systems. The positioning system is further described in §4.6. Note that handheld

scanner performs a significant amount of processing within the scanner as they are constantly merging newly acquired 3D points with existing ones. More details about their inner working can be found in Hebert (2001) and Tubic et al. (2003, 2004). The characterization of a handheld sensor is presented in Givi et al. (2019).

Multi-View Configuration

The commercial implementation of spot, stripe and structured-light scanners can use one or many cameras. Typically, a handheld scanner will contain more than one camera. In a popular two-camera design, the light source is located at the center of the system, with a camera located on each side. Such a configuration allows two triangulation strategies and some scanners can use both strategies simultaneously. The first strategy performs the triangulation independently for each camera. The system then selects the 3D points that seem to be the most reliable and discard the others. The second strategy is named active stereo. In this, the triangulation is performed between points in the two cameras. The projector is only used to find pairs of points in the cameras that correspond to the same 3D point. Some active-stereo systems use a single structured pattern and benefit from recent progress that has been made to the design of passive triangulation algorithms. In this context, the projector is used to add extra texture on the scene in order to improve the performance of passive triangulation algorithms (Drouin and Seoud 2020). Using two cameras allows to design systems that can reduce the impact of occlusion, specular reflection, speckle, and color variation of surfaces. These artifacts are described in detail in Drouin and Beraldin (2020).

Combining Pose and Surface Measurement

Contact and noncontact systems can be used together in order to extend the working volume of noncontact 3D imaging systems. This is a popular configuration used by many handheld scanners. Laser tracker and triangulation-based passive systems are two popular commercially available options. When using a passive triangulation system, 2D retroreflective target are positioned on the 3D scanners. When a laser tracker is used, spherically mounted retroreflectors are included in the mechanical design of the scanner. For each surface measurement, the position of the 3D scanner with respect to the positioning system is known, and all measurements can be transformed into a single coordinate system. Some handheld scanners can have an integrated positioning system. In that case, the 2D targets are installed on the object being digitized (Hebert 2001). The 3D imaging systems can also be installed on a robotic arm, and encoders of the arm can provide the positioning information required to bring all surface measurements into the same coordinate system. The reader is invited to explore the hand-to-eye calibration functionality included in the OpenCV library and review the work of Tsai and Lenz (1989). Descriptions of medium-range contact and noncontact 3D imaging systems can be found in Drouin and Hamieh (2020), Muralikrishnan et al. (2016), and

Remondino and Stoppa (2013). The fusion of multiple 3D scans can also be accomplished without a positioning system by using software that exploits the complex geometry of successive overlapping 3D scans (Salvi et al. 2007; Zhao et al. 2021). This fusion is known as a rigid registration. This registration can be used to align two point clouds (SCAN to SCAN) or a point cloud with a CAD (SCAN to CAD). Rigid registration methods are described in the next section.

Software

Essentially, a measurement error propagates through data processing pipelines including filtering, registration, datum fitting, and feature extraction (Forbes 2018; Senin et al. 2021). Computer-Aided Inspection (CAI) software provides various options to fit the measured points (source data) to a target *XYZ* coordinate system. Most CAI software applications propose different options for data filtering (strategy for removing outliers, simplification, down-sampling, Fig. 3 – step 0) and different fitting algorithms and options that optimally adjust the measured points to a nominal definition (CAD) in various methods (Gaussian best fit, Chebyshev best fit, etc.). As a result, the performance of a measurement system is an estimate of a combination of various measurement errors (random and systematic) that include hardware (equipment error), software (algorithmic error) and operators. Note that both the software and operator can still strongly correlate.

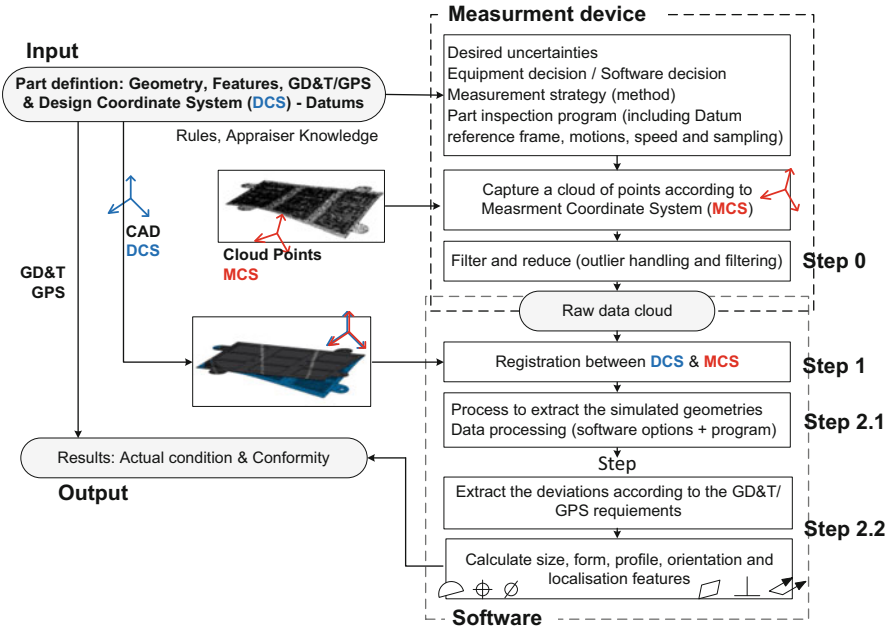

Fig. 3 Typical inspection process using the point cloud obtained with a 3D imaging system

The term *Algorithmic Error* is defined here as the inaccuracy resulting from a choice of the wrong algorithm, method, parameter, or hypothesis for achieving the intended result (i.e., size of a feature, orientation error, profile error, localization error, etc.). In the specific case of dimensional metrology, computational 3D metrology includes the implementation of algorithms to achieve computations on discrete data collected by measuring equipment. Standards such as the ASME Geometric Dimensioning & Tolerancing (GD&T) Y14.5 (ASME 2020) or the ISO Standards Geometrical Product Specifications (ISO 1101, ISO 5459, etc.) (ISO-GPS 2016) define concepts, symbols, and rules to communicate information on technical documents (included in 2D drawings or 3D annotation CAD files). The aim is to ensure a common understanding by all stakeholders or agents (i.e., design, manufacturing, quality control). Knowledge of the GD&T/ISO-GPS standards is essential to ensure that drawing information (requirements) is being interpreted properly. The manufactured part is inspected using a 3D imaging system and compared with the definition and requirements in order to verify dimensional and geometric feature specifications (i.e., actual size, form error, localization error, orientation error, etc.). Deviations are then computed and displayed as results. The comparison of these results with tolerances determines the conformity status of the manufactured part. Figure 3 presents the inspection process model step by step.

Presenting the contributions of each step in the inspection process in this manner is arbitrary. Other authors have presented the process somewhat differently. For example, with respect to coordinate metrology, Weckenmann et al. (2001) suggest that the main contributors to uncertainty can be subdivided into five groups: measuring devices, environmental conditions, work pieces, software (algorithms used, filtering, conditions for removal of outliers, stability of the algorithm, layout handling, etc.), operators (skills, certification, GD&T/ISO-GPS decoding and interpretation, etc.), and the measurement strategy (amount of data, sampling, number of measurements, etc.). An impressive volume of work has been produced by the community in terms of investigating the measuring device, environment, and workpiece components. Although no common understanding of software validation procedures currently exists, the reader is referred to Greif et al. (2006), as well as to the TraCIM EMPIR project (EURAMET 2020; Forbes et al. 2015; Müller 2014), for research that has been performed on software validation in the field of metrology.

Rigid Registration (Step 1)

In 3D optical scanning, the scanned point (SCAN) cloud is usually not in the same coordinate frame as the CAD model. Scan data lie within the measurement coordinate system (MCS) and the CAD model is located in the design coordinate system (DCS) (Fig. 3 – step 1). Therefore, the measured point cloud must be transformed (translation and rotation) into the DCS using a 3D transformation. This transformation can be rigid (Besl and McKay 1992), affine, flexible (Aidibe et al. 2020), or non-rigid (Myronenko and Song 2010). This operation is commonly called registration (Li and Gu 2005). The iterative closest point (ICP) (Besl and McKay 1992) and its

variants, are the most popular computational methods of the rigid registration. The ICP algorithm starts with coarse registration to find a good initial estimation of the rigid matrix transformation. This step can be carried out through principal component analysis (PCA) (Liu and Ramani 2009), features matching (Li et al. 2007), statistics methods (Attia et al. 2018), heuristic algorithms or Genetic Algorithms (Ji et al. 2017). A review of coarse registration methods can be found in Diez et al. (2015).

The fine registration process tries iteratively to minimize a sum of the squared Euclidian distances (or Hausdorff distance in some variants of the ICP (Ghorbani and Khameneifar 2021)) between the SCAN points and their closest estimated points on the CAD using a rigid transformation (translation vector T & rotation matrix R). The minimization can be obtained using a Singular Value Decomposition for point-to-point (Arun et al. 1987), point-to-plane (Chen and Medioni 1992), or point-to-surface errors (Mitra et al. 2004). The numerical solution of this optimization problem (minimization) can be obtained by various numerical methods (such as the quasi-Newton optimization algorithms, genetic algorithms, etc.) where the global optimum is not guaranteed and the solution will always depend on some hyper parameters that must be carefully chosen. The approach performs well when the point cloud matches the CAD. In the case of manufactured parts, the inherent variation in manufacturing processes induces deviations between the two sets (point cloud and CAD). Various studies have proposed to identify and eliminate outliers (attributed to the process-induced error) from data by the M-estimation (Ding et al. 2019) or signal-to-noise ratio metric (Zhu et al. 2007). To sum up, the ICP and its variants perform well with two identical geometric sets (SCAN & CAD) and the robustness is good even with a noise level of the measurement (Liu et al. 2018). However, when significant differences exist between SCAN & CAD (damage zones, manufacturing defects and nonconformity, scale and deformation) the registration process is affected by the unreliable correspondences (defined in damaged regions), and an optimum transformation cannot be achieved. The algorithm introduces averaging-out errors in the quality of the alignment. In addition, the registration algorithms are sensitive to the local density of the measured points. High-density areas will have significantly more weight, which may affect the alignment result.

Readers interested in hands-on registration and manipulation of 3D points obtained by 3D imaging systems can explore the Point Cloud Library (Rusu and Cousins 2011), the MeshLab open-source application (Cignoni et al. 2008), and the KinectFusion library (Newcombe et al. 2011). In addition, a comprehensive review of 3D image registration techniques, which includes an experimental comparison of a broad set of registration techniques to determine the rotation error, translation error, and root-mean-square error, is proposed in Salvi et al. (2007).

Features Extraction (Step 2)

The ISO-GPS (2016) and ASME Y14.5.1 (2020) standards define dimensional and geometrical specifications (tolerances) as a means of expressing the limits (threshold or statistical behavior) of surfaces and features variations with respect to nominal

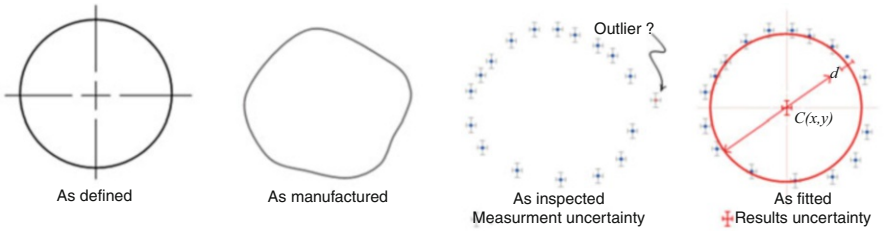

Fig. 4 Illustration of the feature extraction process

model definition (CAD). A quality control process uses a measuring device (including measurement equipment, the hardware, and CAI software) to verify the conformity of the parts to these tolerances. Figure 4 illustrates the feature extraction process. In addition, the ASME 14.5.1 (2020) standard presents a rigorous mathematical definition of GD&T consistent with the principles and practices of ASME Y14.5, which allow to determine actual values of each requirement (e.g., thickness, form error, localization, etc.). Mathematical equations in ASME Y15.4.1 define relationships between real numbers, 3D vectors, DCS associated with datum reference frames, and sets of these quantities. Indeed, once the registration step is completed, to convert the measurement points as captured, it is mandatory to select: (*i*) the appropriate algorithm (e.g., Gaussian least square, maximum inscribed size, etc.) and some related hyper-parameters; (*ii*) working hypotheses (e.g., treatment of outliers, noise filtering, missing data, etc.). It should be noted that this standard frames the mathematical definition but does not propose any specific algorithm to be used to find a solution, and even less so the set of hyper-parameters to be used (see Fig. 3 – step 2).

In GD&T/ISO-GPS, the extraction can be broken down into two steps. The first is the extraction of the feature size (such as a plan, circle, or free form profile, see Fig. 4). The second is the identification of its shape error and its conformity with some constraints (translations and rotations) related to datums defined by reference frames (see Fig. 4).

Feature Fitting (Step 2.1)

Generally, the fitting problem consists in selecting an appropriate algorithm to adjust data points collected from the inspection of a manufactured part to a geometric feature (e.g., plane, cylinder, circle, free form, etc.). The perfect form of estimation obtained by a fitting is called a reference feature or substitute feature (Forbes 2006a, b). ISO 14405-1:2016 posits size as a fundamental geometric descriptor. It also defines a new set of modifier tools for the size. Jbira et al. demonstrated that defect and noise measurement significantly affects results with ISO-14405-1 modifiers (Jbira et al. 2018).

Fundamentally, the fitting problem is an optimization problem defined in Eq. 1.

$$l_p = argmin\left(\sum_{i=1}^{n} |d_i|^p\right)^{\frac{1}{p}} \tag{1}$$

Where n is the number of measurement points and d_i is the shortest distance between measurement data and the reference form. If $p = 2$, the fitting problem is a Gaussian Least Square (LS) fitting. In that case, the solution is found by the pseudo-inverse operator. The solution is explicit and unique for a set of data. And if $p \to \infty$, l_∞ solution is the Chebyshev or *minimax* fitting. In this case, an iterative optimization algorithm is used to find an approximation of the solution. The global optimum is not guaranteed and the solution depends on several hyper parameters (convergence criteria, starting point, algorithms used, etc.).

Various methods have focused on the problem of fitting surfaces applied to many fields, but the estimation of form errors continues to be a challenge (Rhinithaa et al. 2018; Srinivasan et al. 2012; Xiuming et al. 2013). For example, in the specific case of circular, cylindrical, and spherical forms, one such method can be a Voronoi diagram used to determine the minimum circumscribed circle (MCC) or maximum inscribed circle (MIC). To obtain an MCC, the points of the diagram that lie farthest from its center are used. The center of the MIC lies on the Voronoi vertex or on the Voronoi edge. The distance between the circle center and the convex vertex represents the radius. The Delaunay Triangulation is usually used to calculate the convex and Voronoi diagram (Tran et al. 2015). In Nurunnabi et al. (2019), the authors compared different algorithms to facilitate the choice of the adequate execution method for MCC, MIC, and MZC in order to compute roundness errors. In addition, they used a new geometric concept based on the reflection of a mapping technique to assess roundness errors. They proposed a selected benchmark of algorithms in the literature in order to provide the optimal execution method. It was concluded that no single algorithm provides the best solution. Geometric primitive reconstruction is a significant problem in the field of computer-aided design (CAD). Goch and Lubke (2008) proposed a new algorithm to approximate geometry elements using Gauss and Chebyshev criteria. Nurunnabi et al. described the problem of circle fitting for complete and incomplete datasets with outliers (Nurunnabi et al. 2017, 2018). They proposed a robust approach for circle fitting, which had to merge the PCA and robust regression. Their experimental results confirmed the performances of the proposed approach with different percentages of tolerance of clustered outliers. Also, Guo and Yang (2019) proposed a new procedure for circle fitting. They used Taubin's approach to compute the center and radius, and then they identified and removed the outliers by calculating the Euclidian distance. Their experiments demonstrated that the iterative procedure could resist against the occurrence of outliers. More specifically, in the case of geometric elements of plane form, Deschaud and Goulette (2010) proposed an accurate algorithm to extract planes in noisy point clouds using filtered normal and voxel growing. In a first step, they estimate the better normal at the data points. The second step consists in computing a score of local planes, and then they apply the growing voxels. Finally, they evaluated the proposed algorithm on different numbers of points and compared it with existing algorithms. The method had a linear algorithmic complexity and was able to detect large and small planes in very large data sets. Nguyen et al. presented a comparative study of least square plane fitting algorithms with different segmentation methods (e.g., RANSAC, RGPL, Cabo, RDPCA) (Nguyen et al. 2017). They validated the study using two

real point clouds collected by a scan system. The results demonstrated that the RGPL method gives the best result for planar surface extraction. Marriott et al. (2018) presented an unsupervised extraction planar method. They proposed to adjust data with a piecewise-linear Gaussian mixture regression model whose components were skewed over planes. In Besl and McKay (1992) and Moroni et al. (2014), the problem of fitting full- and half-geometrical primitives (e.g., circular, spherical, and cylindrical primitives) was addressed. The authors used the Levenberg Marquardt (LM) method to approximate these geometries. They also proved that using the chaos optimization method improves the initial algorithm estimation. In fact, the chaos LM algorithm provides efficient results even when the input data points are incomplete and noisy. Chiboub et al. (2021) proposed a robust approach based on a non-vertex solution for generating reference soft gauges for complex shapes (free form) to estimate the form (profile) error based on the *minmax* fitting (Chebyshev fitting). The authors proposed two implemented fitting algorithms called the exponential penalty function (EPF) and the hybrid trust region (HTR). The two algorithms were tested on a number of generated reference pairs. Their performance was evaluated according to two metrics: degree of difficulty and performance measure.

GD&T/ISO-GPS Specification Extraction (Step 2.2)

An experimental investigation of three commercial inspection software packages to evaluate algorithmic errors was proposed by Jbira et al. (2019). The artifact used in the study is shown Fig. 5. The inspection software packages are typically used to analyze point clouds generated by 3D imaging systems. The benchmark and experimental case studies demonstrate the influence of the algorithm choice. Figure 6 contains an illustration of the testing artifact with ASME GD&T specifications. In this reproducibility study, only one measurement points cloud, one operator, the same CAD, and many fitting algorithms with different shapes (circle, plan, and oblong hole) and features (size, circularity, and flatness) were evaluated. The experience demonstrated the presence of a significant variation between the three CAI softwares. Using the example of a Gaussian least square (LS) algorithm (deterministic analytical solution is well known), results demonstrate a small variation between the CAI software packages. However, for the Chebyshev criteria (*minimax* algorithm), minimum circumscribed circle (MCC), or maximum inscribed circle (MIC), the results showed a significant variation between the CAI software packages. These differences can be due to filtering and smoothing operations, a reduction in the point density, the treatment of outliers, the registration algorithm, and optimization parameters (when the tolerances allow degrees of freedom in translation and rotation). All these sources have an effect on variations that which we call *Algorithmic Errors*.

According to Table 1, the LS algorithm provides the same diameter values for software #1 and software #2 (19.874 mm). In addition, software #*1* and #2 with an MCC algorithm provide the same diameter values (20.091 mm), but software #3 shows a somewhat different value (20.093 mm). The MIC algorithm shows the same values for software #1 and software #2 (19.760 mm), but software #3 provides a

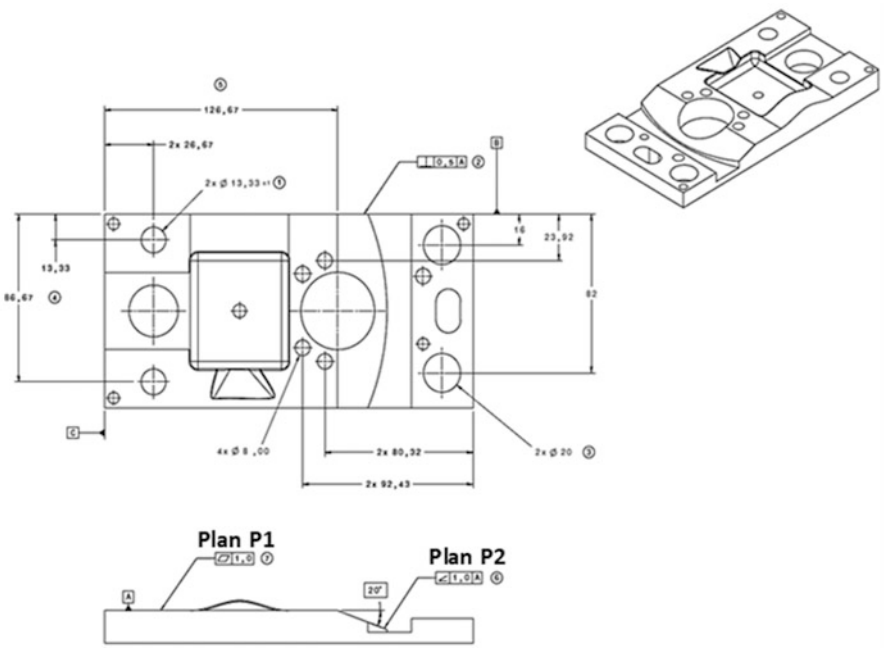

Fig. 5 Artifact used to evaluate algorithmic errors as proposed by Jbira et al., courtesy of (Jbira et al. 2019)

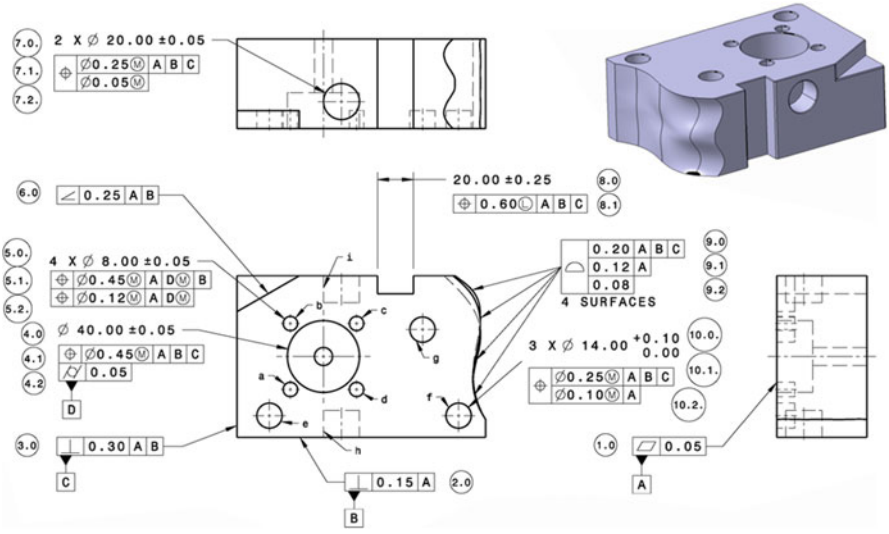

Fig. 6 SME GD&T-based benchmark with many DoF configurations. Note the complexity of the symbology used including modifiers and datum reference systems, courtesy of (Aidibe et al. 2020)

Table 1 Results for the inspection of size and surface features. The flatness and angularity shown are, respectively, for planes P1 and P2 of Fig. 5 [Dimensions in mm]

		Feature of size (circle)			Planar surface features	
Software	Algorithm	Diameter	Δ_{dia}	Cicularity	Flatness P1	Flatness P2
#1	LS	19.874	−0.126	0.186	0.107	0.070
	MIC(MIP)	19.760	−0.240	0.186	0.107	0.070
	MCC(MAP)	20.091	0.091	0.186	0.107	0.070
#2	LS	19.874	−0,126	0.205	0.119	0.031
	MIC(MIP)	19.760	−0.240	0.208	N/A	N/A
	MCC(MAP)	20.091	0.091	0.195	N/A	N/A
	Minmax	19.907	−0.093	0.185	N/A	N/A
#3	LS	19.873	−0.126	0.034	0.051	0.035
	MIC(MIP)	19.721	−0.279	0.034	0.051	0.035
	MCC(MAP)	20.093	0.093	0.034	0.051	0.073

slightly different value (19.721 mm). Finally, with the *minimax* algorithm, available only in software #2, the diameter is equal to 19.907 mm. According to Table 1, software #1 and software #3 provide the same circularity values for all methods: 0.186 mm and 0.034 mm (LS, MIC, MCC and *minmax*), while software #2 provides different results for each method.

In addition, in the same study, the authors computed the flatness of two planes (P1 (Datum A) and P2 with an angularity specification related to datum A) (Table 1). Results with the LS (l_2) option are shown in bold. According to Table 1, CAI software #1 and #3 offer three adjustment algorithms for P1 (Datum A), the LS, Minimum Plane (MIP), and Maximum Plane (MAP). CAI software #2 only offers one algorithm (LS) to fit a plane. Only the best fit is available. For P1, software #1 gives the same flatness value (0.107 mm) for the three algorithms (LS, MIP, and MAP). In the case of software #2, only the best fit is available (0.119 mm). From the Table 1, the results for P2 are similar to those for P1. Software #1 gives the same flatness value (0.070 mm) for the three algorithms. In the case of software #2, only the best fit is available (0.031 mm), but software #3 gives different values (0.035 and 0.073 mm).

The use of datums with GD&T/ISO-GPS features controls degrees of freedom (DoF). In 3D space and for a rigid part, three translations ($T = [T_x, T_y, T_z]$ or $[X, Y, Z]$) and three rotations ($R = [R_x, R_y, R_z]$ or $[U, V, W]$ define of DoF. Depending on the functional requirements (e.g., assembly, performance, aesthetics, etc.) rules of the GD&T/ISO-GPS can be applied by designers to block needed degrees of freedom. In some cases, designer can require all the DoF (Fig. 7, right side), or even leave all the DoF (e.g., flatness, profiles not related to a datum, etc.) as shown in Fig. 7 (left side).

Aidibe et al. propose a GD&T-based benchmark for an empirical evaluation of the performance of different laboratories and operators in a CAI context considering different criteria related to dimensional and geometrical features (Aidibe et al. 2020). In the study, an artifact was designed to include some basic geometries (such as the

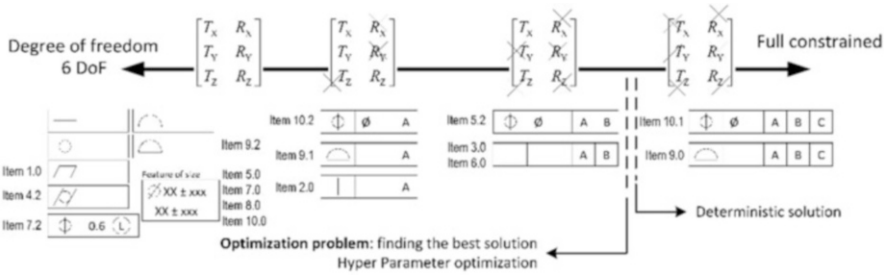

Fig. 7 Schematic presentation of the use of DoF with ASME GD&T (Item #x refers to GD&T requirements as defined in Fig. 6 (Aidibe et al. 2020)

cylinder and plane) and complex free-form surfaces with many configurations for DoF (Fig. 7). Five artifacts were manufactured including defects. All operators used a CMM (with, accuracy $\ll$ defect). The results from this inter-laboratory comparison study showed significant performance variability in three cases: (*i*) where the surfaces are complex such as a free form; (*ii*) in the case of a composite profile and localization GD&T/ISO-GPS; (*iii*) when the algorithm employed is not deterministic (e.g., when the tolerance is not fully related to the reference frame). This emphasized the importance of training and certification in order to ensure a uniform understanding among different operators, combined with a fully automated inspection code generator (including the use of the appropriate algorithm) for GD&T/ISO-GPS purposes.

A DoF with a GD&T/ISO-GPS implies that the tolerance zone can move (in translation T_i or in rotation R_i, or any combination) according to a specific degree of freedom. We refer readers to ASME (2020) and ISO (2011) for annotation rules and examples. Our interest in this chapter is to pay special attention to the algorithmic error that can be induced. Indeed, in the case of the complete blocking of the DoFs, there will be no optimization error, and the calculation of the conformity of a feature is deterministic. For example, the true position of a cylindrical element in 2D is calculated by the well-known formula: $2\sqrt{\delta_x^2 + \delta_y^2}$, and the profile error of a surface is calculated by:

$$2 \max \mid \overrightarrow{\delta_n} \mid .$$

When DoFs are involved, the estimation of deviations requires an optimization operation. Indeed, the tolerance zone can move in translation or in rotation (or both), and in some cases, its size is not constant. This is the case, for example, of circularity, cylindricity, and a dynamic profile (Y14.5-2018). Generally, the optimum is defined by the zone (1-D, 2-D or 3-D), which minimizes the maximum error (Chebyshev criterion). In these cases, there is no explicit or unique solution. The result is obtained by running an iterative optimization algorithm (e.g., Newton's method, gradient methods, evolutionary algorithms, genetic algorithms, etc.). Moreover, like any optimization algorithm, the identification of the global minimum is not guaranteed.

Applications

In this section, we briefly present two 3D imaging applications that demonstrate its use in the context of Industry 4.0. First, we present a 3D printing application where measurements taken by structured light scanners are used in a closed manufacturing loop that relies extensively on rigid registration. Then, we illustrate the use of a 3D imaging technology combined with augmented reality (AR) for jigless assembly.

Metallic Additive Manufacturing

Recent years have seen significant progress in the development of metallic additive manufacturing (MAD) (Frazier 2014). However, MAD is not perfect, with one of its drawbacks being the required labor intensive post-processing. It calls for the inclusion of support structures in printed components in order to prevent the deformation of overhanging geometries (Alfaify et al. 2020). The support structures need to be removed manually. Moreover, some components may require polishing and some un-sintered powder can be found on some surfaces. These manual tasks must be performed by skilled workers, which may introduce repeatability and reproducibility issues. A metalworking robotic cell produced by Rivelin Robotics allows to automate these labor-intensive tasks (see Fig. 8). The solution uses intensive 3D imaging

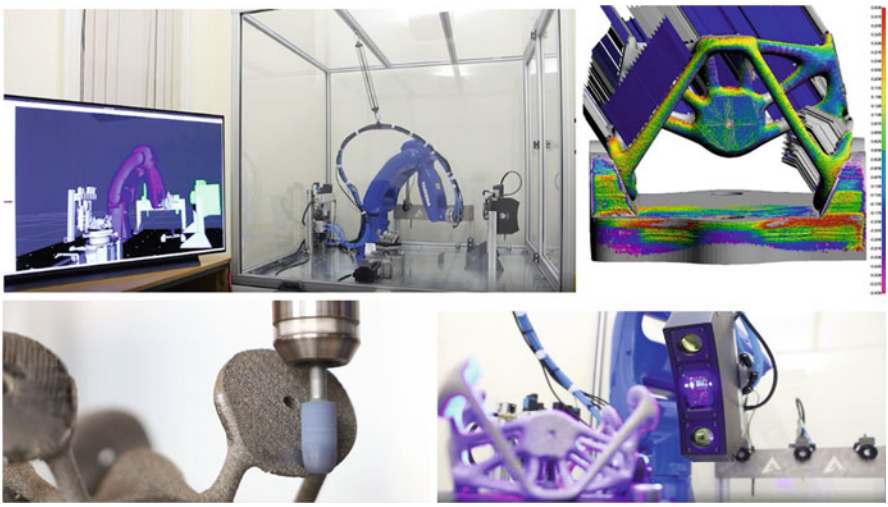

Fig. 8 Top left: Image of the metalworking robotic cell. The digital twin is visible on the left screen. Top right: A 3D scan of the printed component aligned with the CAD. The deviation between as-built and as-designed is color coded. Note that support structure is still attached to the printed component. Bottom left: The robot polishing a surface of the component is guided by the alignment between the acquired digital representation and the CAD. Bottom right: The robot is holding the 3D imaging system, which is acquiring a point cloud. The printed component is mounted on a rotation stage. Figure courtesy of Rivelin Robotics and NRC

and digital twining. The portion of the work presented here is a collaboration between Rivelin Robotics, Renishaw, the University of Sheffield, and the National Research Council of Canada. Note the results of the feasibility study we present here are not necessarily representative of the performance of the robotic cell currently being marketed by Rivelin Robotics. The remainder of this discussion focuses on the effort made, at the early phase of the project, to estimate the magnitude of the error related to the 3D imaging acquisition and processing. When defining a minimum viable product, the required functionalities and associated budgets are defined. Of interest here are the budgets related to the acquisition and processing time, the cost of imaging hardware and the uncertainty budget. For many new automating applications (including this one) that use in-process optical metrology, the available uncertainty budget, at a given manufacturing step, may be difficult to quantitatively define, or is simply unknown.

The manufacturer of the structured-light scanner selected uses a ball-bar test to associate an accuracy statement to their product (VDI 2005, 2008). We also performed our own validation using a well-characterized planar surface with surface properties similar to those of printed components. The artifact was installed on a fully characterized translation stage and was moved to different positions in front of the 3D scanner. At each position, an acquisition was performed. The acquisitions were repeated with different orientations of the planar surface. The root mean square (RMS) of the surfaces of all acquired range images can be computed. Moreover, since the translation is known, the error between the parallel surfaces (i.e., thickness error) can be computed. The results are shown in Table 2.

In a second round of experiments, a representative printed component was scanned at different distances from the scanner (see Fig. 8) for a representation of the printed component). Again, we used the characterized translation stage. It is possible to register two consecutive scans and compare the computed displacement

Table 2 A characterized planar surface was moved to different positions in front of the 3D scanner. The root mean square (RMS) error and distances to plan 1 are given for 11 different positions on the surface. In this experiment, the planar surface is perpendicular to the scanner

		Distance to plane 1	
Plane index	RMS (μm)	Nominal (mm)	Measured (mm)
1	26	0	0
2	20	10	9.997
3	17	20	19.993
4	15	30	29.993
5	13	40	39.996
6	13	50	49.996
7	16	60	59.990
8	20	70	69.987
9	26	80	79.976
10	32	90	89.976
11	39	100	99.975

Table 3 A representative printed component was moved to different positions in front of the 3D scanner. The SCAN-to-SCAN registration errors using two software packages were computed. We also evaluated the SCAN-to-CAD-to-SCAN error for one of the software packages

		Measured (mm)		
		SCAN to SCAN		SCAN to CAD to SCAN
Pose displacement	Nominal (mm)	Software #1	Software #2	Software #2
1–2	10	10.000	10.001	9.948
2–3	10	10.000	10.001	9.926
3–4	10	10.002	10.004	11.162
4–5	10	10.000	10.002	10.675
5–6	10	10.002	10.005	9.998
6–7	10	9.998	10.001	10.008
7–8	10	9.997	10.003	10.041
8–9	10	9.999	10.004	10.103

with the nominal one. While not shown here, this experiment was repeated using a rotation stage. The results are given in Table 3 for two different software packages that produced similar results. In both cases, the root mean square error between the registered models is approximately 33 μm for the entire registration models. We also computed the SCAN-to-CAD registration for each scan and then computed the SCAN-to-SCAN registration error using the SCAN-to-CAD-to-SCAN transformation chain. This was computed only using software #2, which has an option for SCAN-to-CAD alignment. This test was designed to quantify an upper bound for the scan-to-CAD registration error, which is a key algorithm used in this application.

Assembly Assisted by 3D Imaging Systems – Jigless Assembly

Traditionally, in many industrial fields, assembly is done with dedicated fixtures (jigs, templates). This is a method that is widely used to position different parts, subsystems, and systems in different industrial sectors, such as aerospace, rail transport, urban transport, and many others. The advantage of this traditional approach is its robustness and resource qualification requirements. However, it is based on obsolete vision: produce a single product at high volume. Its manufacturing cost and inadaptability to change are obstacles to productivity.

New functionalities of contact and contactless 3D measurement technologies (such as Indoor GPS, photogrammetry, laser trackers, and 3D imaging) allow to use 3D measurements, not in a classic role such as quality control, but as external encoders for positioning, tracking, and adjusting components during assembly operations (see Fig. 9). In other words, the assembly assisted by 3D metrology approach aims to extend the metrology capabilities over the entire space of a plant and reduces the use of templates, provides greater flexibility, and improves productivity.

Various scientific and technological challenges, inherent to this approach, need solution to its full industrial deployment. (*i*) The strategy to adopt for the fusion of

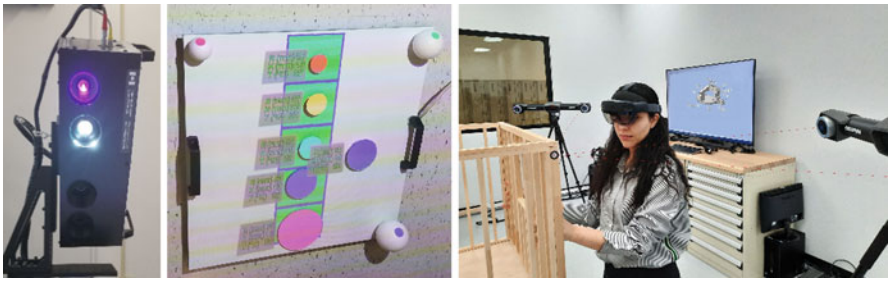

Fig. 9 Left: A structured-light system that incorporates a projector for augmented reality (see Boisvert et al. 2020). Middle: An example, used for public outreach, of a jigless assembly task guided by the structured-light system shown on the left. Right: Demonstration of a metrology-assisted assembly within a research laboratory context. Note the AR headset and the two noncontact 3D imaging systems used to guide the assembly

data from different 3D measurement technologies. (*ii*) Estimating the uncertainties of an assembly made by measurement. (*iii*) Ensuring metrological traceability. (*iv*) The strategies to adopt for setting monitoring targets. (*v*) The behavior of compliant (non-rigid) parts during assembly. Readers interested in the jigless assembly using augmented reality (AR) can explore (Chiboub et al. 2021; Gomes de Mello et al. 2020).

Concluding Remarks

In recent years, new families of affordable 3D imaging systems that target the entertainment industry were introduced (Drouin and Seoud 2020; Giancola et al. 2018; Zanuttigh et al. 2016). Ruggedized versions of some of these scanners are now available. This paves the way to low-cost Industry-4.0 applications that were not economically viable using conventional 3D imaging systems. Since these low-cost systems are targeted at acquiring 3D videos of humans, they are especially attractive for new robotic applications in which humans and machines interact closely (cobot).

As mentioned, earlier, the uncertainty associated with the measurements of optical metrology systems vary within their respective measurement volumes in a nonintuitive manner. This can lead to the use of problematic methodologies in robotic applications, which consist of many possible positioning of the 3D imaging system. Some of the software used by robotic experts can integrate the measuring volume of 3D imaging systems. However, to the best of our knowledge, they do not take into account the performance variation induced by the positioning of the 3D imaging system. Modeling this error when performing path planning would be a powerful enabler for Industry 4.0 applications and quality traceability.

Finally, the implementation of new advanced manufacturing solutions, which use in-process optical metrology, requires the collaboration of experts in the fields of metrology, mechanical engineering, and machine vision. Such a collaboration requires well-recognized terminology, standards, and characterization procedures for 3D imaging systems including hardware and software. Some researchers have

tried to unify the language of each field by developing a characterization procedure that is directly based on the GD&T (MacKinnon et al. 2013). The generalization of the use of such characterization methods would provide a well-defined common language centered on the final objective of the manufacturing process, which is to produce a good part in compliance with requirements. Many other challenges associated with the use of 3D imaging systems can be found in Catalucci et al. (2022).

Abstract

Speckle can overcome the limitations of prior techniques in non-destructive testing of a product in industrial applications, allowing for a fast, reproducible, and automated description of deformation parameters such as strain, stress, displacement, surface roughness, expansion, and thickness. Speckle metrology has progressed from a research tool to a valuable tool for metrologists, having been proven in comparison to complex, time-consuming, and expensive approaches. The advancement of technology and image processing has attracted the attention of speckle metrology. The goal of this review is to cover the fundamentals of speckle methods, as well as some current improvements and applications.

List of Symbols

a_1	Varying amplitude for the reference mirror beams in speckle interferometer
a_2	Varying amplitude for the object beams in speckle interferometer
$a(x, y)$	Background noise
A_1	Complex amplitude of the reference wavefront in speckle interferometry
A_2	Complex amplitude of the object wavefront in speckle interferometry
A_r	Specular reflection of the object
A_T	Total amplitude
$A(x, y)$	Amplitude function at the object plane
$A(\theta_1, \theta_2)$	Scattered field amplitude in angular displacement
$A(u, v)$	Amplitude function at the image plane
$b(x, y)$	Modulation noise
$B\{A(q)\}$	Fourier Bessel transform function
$c(x, y)$	Complex term
C_n	Constant of the expansion
$C_{pp'}$	Cross-correlation function in speckle correlation
d	Distance between speckle and Young's fringes planes in angular displacement
Δd	Path difference (thin film thickness)
f_0	Carrier frequency
f_1, f_2	Spatial frequencies
$F(f_1, f_2)$	Fourier transform of the scattered wavefront
$g(x, y)$	Fringe pattern describing function in speckle interferometry
$g(w)$	Function of the spectral line profile
G_2	Geometrical factor
$G(f, y)$	Fourier transform of the fringe pattern describing function
I	Intensity
I_m	Speckle intensity for the substrate at the image plane in speckle interferometry
I'_m	Speckle intensity for the thin film at the image plane in speckle interferometry
I_{max}	Maximum intensity
I_{min}	Minimum intensity
I_T	Total intensity
$I(v_z, v_z)$	Power spectral density functions of the speckles before rotation

$I(v_z', v_z')$	Power spectral density functions of the speckles after rotation
$I(v_z, v_z')$	Correlation function between the speckles before and after rotation
$I(\omega)$	Intensity of the young's interference fringes in the image plane for angular displacement
k	Propagation wave vector
l	Average height
$2L$	Width of the illuminated area
m	Order of interference
M	Magnification factor
P	Point of observation
$p(x, y)$	Reference image in speckle correlation
$p'(x', y')$	Displaced image in speckle correlation
q	Radius coordinate in the object plane
r	Radius coordinate in the image plane
R_a	Average surface height variation
ΔR	Axial displacement
S	Area of integration
$S(x)$	Surface distribution function for a specific area in one dimension
$S(x, y)$	Surface distribution function for a specific area in two dimensions
$u(x, y)$	Displacement field in u-axis in speckle correlation
$v(x, y)$	Displacement field in v-axis in speckle correlation
V	Visibility of the speckle pattern
w_0	Frequency at the center of the spectral line
δ	Spectral half width
Δx	Displacement in the object plane in x-axis
Δy	Displacement in the object plane in y-axis
Z	Focal length of the transform lens
Δ^2	Squared Euclidean distance representing the displacement fields in speckle correlation
φ_1	Varying phase of reference mirror wavefront in speckle interferometry
φ_2	Varying phase of object wavefront in speckle interferometry
$\Delta\varphi$	Phase change between reference and object beams
$\varphi(x, y)$	Phase function
λ	Wavelength
λ_a	Average wavelength
$\Delta\lambda$	Shift in wavelength
σ_r	Standard deviation of a rough surface
θ	Angle of illumination
$\delta\theta$	Angle of object rotation
$\Im[c(x, y)]$	Imaginary component of $C(x, y)$
$\Re[c(x, y)]$	Real component of $C(x, y)$

Introduction

The need to assure the effectiveness of machines and tools used in industrial applications drive the attention to robust simple accurate techniques such as speckle. Speckle can test machines and tools capabilities to function under different conditions, including vibration and temperature. Traditional investigative methods require surface contact and may be limited to object's material and measuring time. Since it is critical to employ a simple nondestructive procedure in the investigation in order to retain the object's quality, and to make the testing service available at any time, and under any circumstance, speckle as a nondestructive technique can detect object's variation when subjected to various conditions (Pino et al. 2011; Bender et al. 2018; Patzelt et al. 2019). In this chapter we will explore different speckle techniques that have proved their reliability in dimensional metrology.

Digital Simulation of Speckle

Special attention has been paid to study the phenomenon of scattering of coherent laser beams forming "speckle" of random intensity and distribution in the light field if the beams are scattered from a rough surface. This phenomenon has become one of the most important research topics in the field of coherent optics. Since that time, the basic studies of the speckle pattern dealt with proposing many and varied applications in the field of scientific and industrial measurements. A large proportion of component failures are due to surface defects caused by either discontinuity of isolated manufacturing or gradual deterioration of surface quality. One of the important factors that ensure the safety of the surface is the surface roughness, which is referred to by the variation in the average heights of the surface points, especially since the manufacturing industry depends on the surface being within certain roughness limits. Hence, measuring surface roughness has become important for quality control work in many applications.

Assume the center line average height, which is the current standard assessment of the surface roughness (average surface height variation) defined by Farid (2008) and Stempin et al. (2021) as:

$$R_{\mathrm{a}} = \frac{1}{\mathrm{Area}} \iint |S(x,y) - l| \, \mathrm{d}x\mathrm{d}y \tag{1}$$

where $S(x, y)$ represents the height distribution function for a specific area of the surface, and the average height l is defined by:

$$l = \frac{1}{\mathrm{Area}} \iint S(x,y) \, \mathrm{d}x\mathrm{d}y \tag{2}$$

Assume $S(x, y)$ as multi sine functions of different amplitudes and phases as follows:

$$S(x,y) = k_1 \sin\left(\frac{2\pi}{\lambda_1}(x+y)\right) + k_2 \sin\left(\frac{2\pi}{\lambda_2}(x+y)\right) + k_3 \sin\left(\frac{2\pi}{\lambda_3}(x+y)\right) + \ldots \quad (3)$$

The laser light scattering from rough surface is determined by the diffraction phenomena based on the electromagnetic wave propagation theory. Then the amplitude function of the wavefront scattered from a surface of a height distribution function $S(x, y)$ is given by:

$$A(x,y) = \exp(i\varphi(x,y)) \quad (4)$$

where the phase function $\varphi(x, y)$ is defined as:

$$\varphi(x,y) = \frac{2\pi}{\lambda} \quad 2S(x,y)\cos\ \theta \quad (5)$$

λ is the laser wavelength that is incident on the rough surface at an angle θ. The Fourier transform of the wavefront is expressed in (Huynh et al. 1991) as:

$$F(f_1,f_2) = \int S(x,y)\ \mathrm{e}^{\left(-\frac{2\pi i}{\lambda}(f_1 x + f_2 y)\right)}\ \mathrm{d}x\mathrm{d}y \quad (6)$$

The spatial frequencies f_1 and f_2 are given by:

$$f_1 = \frac{\mathrm{XM}}{Z} \text{ and } f_2 = \frac{\mathrm{XM}}{Z} \quad (7)$$

Z is the focal length of the transform lens, M is the magnification factor, and X, Y are the coordinates on the image plane. The Fourier transform is reformulated using the expansions of the amplitude and the phase functions as:

$$F(f_1 + f_2) = \sum\nolimits_{n=1}^{\infty} C_n \iint_A \frac{(iS(x,y))^n}{n!}\ \mathrm{e}^{\left(-\left(\frac{2\pi i}{\lambda}\right)(f_1 x + f_2 y)\right)}\ \mathrm{d}x\mathrm{d}y \quad (8)$$

where the constant of the expansion C_n is:

$$C_n = \left(\frac{4\pi\cos\theta}{\lambda}\right)^n \quad (9)$$

In the case of smooth surface (i.e., very small $\varphi(x, y) < \pi/10$), the first term in Eq. (8) at $n = 1$ is predominant while other terms are negligible. As $\varphi(x, y)$ increases, the other terms become significant.

The half width of a spectral line profile of the light source affects the patterns visibility. The spectral line profile is described by the function $g(w)$ of Gaussian distribution:

$$g(w) = g(w_0)\mathrm{e}^{\left(-4\ln 2(w-w_0)^2\right)/\delta w^2} \quad (10)$$

$$g(w_0) = \frac{1}{\delta w}\left(\frac{4\ln 2}{\pi}\right)^{1/2} \tag{11}$$

such that w_0 is the frequency at the center of the spectral line, and δw is the spectral half width. Then the spatial intensity distribution of the speckle pattern is described by:

$$I = \int_{-\infty}^{\infty} F(f_1,f_2)\, F^*(f_1,f_2)\, g(w)\mathrm{d}w \tag{12}$$

Correspondingly, visibility of the speckle pattern is determined by:

$$V = \frac{\left\langle I^2_{\max}(x,y)\right\rangle^{1/2} - \left\langle I^2_{\min}(x,y)\right\rangle^{1/2}}{\left\langle I^2_{\max}(x,y)\right\rangle^{1/2} + \left\langle I^2_{\min}(x,y)\right\rangle^{1/2}} \tag{13}$$

such that $I_{\max}$ and $I_{\min}$ are the maximum and minimum intensities obtained by constructive and destructive interference, respectively. Figures 1, 2, and 3 show digital simulation for different assumptions of $S(x, y)$ using sinusoidal functions of

variant spatial frequencies and amplitudes, and the corresponding Fourier transformation FFT.

A simulation of the dependence of the speckle pattern visibility on the surface roughness for different spectral lines is shown in Fig. 4.

The wave reflected by a rough surface is the sum of many independent secondary waves from the scattering areas. Because the secondary waves arrive at different light paths at different points on the observation plane, the dephased secondary

waves interfere at these points. This interference varies from one point to another on the observation plane forming the speckle. This explains why the speckle appears as granular pattern. Secondary waves can interfere if their light path difference is less than the coherent length, and the coherent length that is associated with temporal coherence.

The simulation in Fig. 4 shows an inverse relationship between the speckle visibility and the spectral line half width, which is relevant to the fact that the temporal coherence length of the light source used in illumination is in inverse relation with the spectral half width.

The visibility of the speckle pattern increases with the increment of the surface roughness and the random interference until the visibility achieves its maximum limit. With further increment in the surface roughness, the scattered temporal incoherent beams increase leading to a reduction in the speckle visibility.

The pattern is an incoherent combination of the intensity, and the superposition of intensity will result in the reduction of speckle contrast since the speckle patterns are different for the lights of different bandwidths. So the spectral line of $\delta w = 5 \times 10^{14}$ Hz, which is of low temporal coherence and short coherence length reduces the speckle.

This is evident because of the fact that for larger spectral width, the speckle pattern becomes blurry and the contrast decreases. This also provides a quantitative way to optimize the image quality and also to determine the safety power level for different light sources when viewing the produced images by human eyes directly.

Speckle Photography

Speckle photography is a technique in which the object surface is illuminated with laser beams and the resulted random interference is recorded. It is a widely used nondestructive tool in metrology due to its simplicity. It is useful to analyze surface deformation that is induced by mechanical or thermal effects, and to evaluate various types of surface displacements and translations (Necklawi et al. 2007; Tausendfreund et al. 2021). In speckle photography, the surface of interest is illuminated with coherent light, and the scattered light is collected by a lens, and imaged by either photographic film or a CCD array (Fig. 5).

The scattered light will contain speckle due to the roughness of the surface, and the speckle pattern can be imaged and stored for the analysis. The speckle size can be controlled by the F-number of the imaging lens to be suitable to the size of the defect that the object encounters. Displacements, stress, or strain, etc., imparted to the surface can shift the speckle patterns proportionally to the direction of the local deformation, and the full deformation field can be determined either by the Fourier transform of the speckle double exposure or by the speckle cross-correlation.

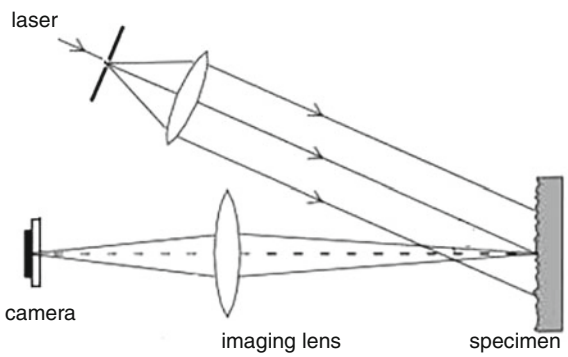

Fig. 5 Schematic diagram of the speckle photography setup

Fourier Transform of Speckle Double Exposure

Nondestructive testing can benefit greatly from optical approaches that offer sufficient information on displacement and deformation. The following items are necessary in an optical system to collect the data required for the testing procedure:

- The object's reference state.
- Optical wavefront.
- The altered object configuration.
- Imaging system.
- Detection process.
- Decoding process that analyzes the received data and converts it into a suitable format to a human or a machine.

A deformation/displacement applied to the surface creates a shift in the speckle pattern that is related to the magnitude and direction of the deformation/displacement.

In double speckle exposure, both initial and updated speckle patterns are recorded and then compared by image processing software. The difference between the speckle patterns of the two states produces speckle pairs representing a double exposure. A Fourier analysis of a double exposure speckle image determines the total surface deformation.

In the Fourier analysis method, the displacement field was determined by scanning a laser beam across the negative of the double speckle pattern in the early days of the speckle photography to form the Young's interference fringes whose orientation and spacing are relevant to the direction and the magnitude of the local deformation. Replacement of the photographic film by the CCD sensor could realize a substantial increase in the imaging speed, enable real time analysis using digital image processing, and make the speckle photography more suitable to industrial applications (Abdel Hady et al. 2012; Janák et al. 2020). Analyzing of speckle pattern using this method is effective in measuring in-plane and out-of-plane displacements.

In-Plane Displacement

In-plane displacement is a kind of displacement that occurs in the same plane of the object by mechanical or thermal effects. In order to measure the in-plane displacement of an object using the speckle photography, the speckle is recorded before and after the displacement, then the speckle images are added digitally yielding pairs of identical speckle patterns shifted by amounts Δx and Δy that are related to the displacements made in the object plane (Abdel Hady et al. 2012; Yan et al. 2019). The implementation of FFT to the speckle pairs produces Young's interference fringes, because each pair of the speckle acts as a pair of identical sources of coherent light, which interfere to form the patterns in Fig. 6. Visibility, separation, orientation, and number of the fringes are related to the amount and the direction of the displacement of interest.

Assume Fig. 7 displays the scattering system in the speckle photography. The scattering surface lies in the (x, y) plane and is illuminated by highly coherent light. Any point on the observation plane (u, v) placed at a distance R in front of this surface will receive contributions from all points on the surface. Assume that O is any point on the scattering surface plane, I is any point on the observation plane and R is the distance between O and I making an angle α with R.

The total complex amplitude at the image plane is (Necklawi et al. 2007):

$$(u,v) = \mathrm{e}^{-i\frac{2\pi}{\lambda}(R)} \int A(x,y)\, \mathrm{e}^{-i2\pi\left((x+\Delta x)\left(\frac{u}{\lambda R}\right)+(y+\Delta y)\left(\frac{v}{\lambda R}\right)\right)}\, \mathrm{d}x\mathrm{d}y \tag{14}$$

Correspondingly the intensity at the image plane is defined by:

$$I = 2\mathrm{FFT}(A(x,y))^2(1 + \cos 2\pi(f_1\Delta x + f_2\Delta y)) \tag{15}$$

where the spatial frequencies are represented by Eq. (16) showing linear relationships with object displacements.

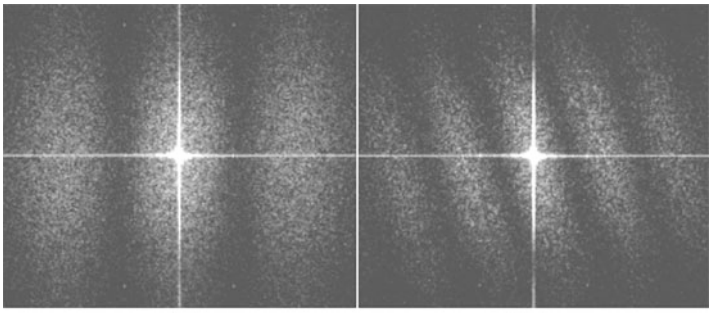

Fig. 6 Young's interference fringes obtained by applying FFT to the Speckle pairs indicate (**a**) horizontal displacement and (**b**) diagonal displacement (Abdel Hady et al. 2012)

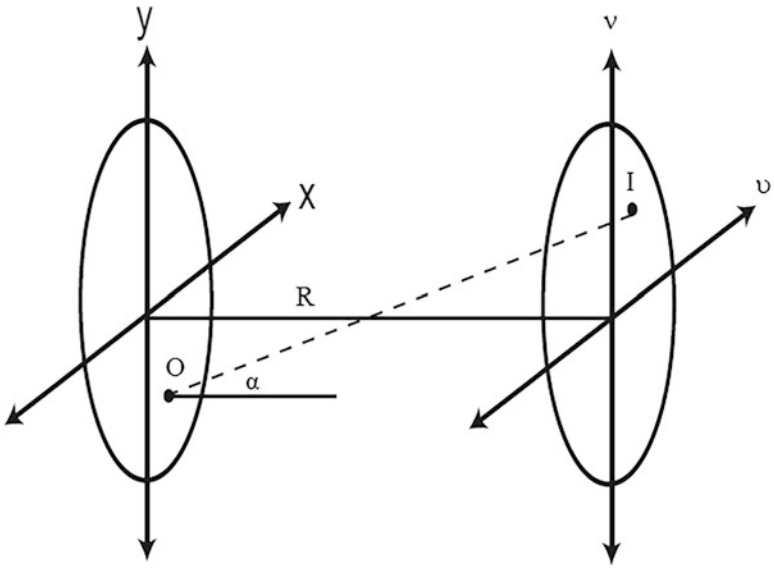

Fig. 7 The scattering system in which the scattering point *O* in the object plane is observed at the point *I* in the image plane (Abdel Hady et al. 2012)

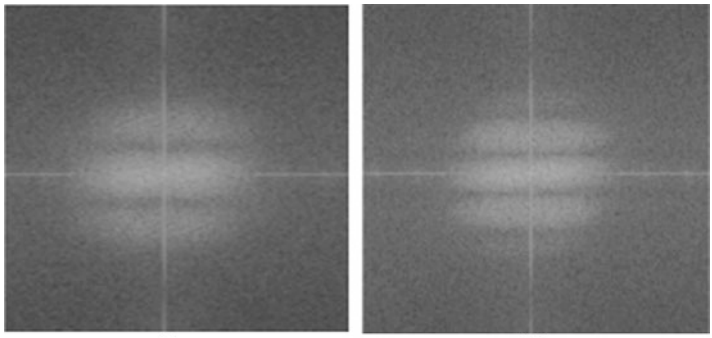

Fig. 8 Young's interference fringes provided by the Fourier transform of speckle pattern for an object under axial loads of (**a**) 0.5 kg and (**b**) 0.9 kg

$$f_1 = \frac{u}{\lambda R}, \qquad f_2 = \frac{v}{\lambda R} \tag{16}$$

Figure 8 shows Young's interference fringes produced by the implementation of Fourier transform to double exposure speckle that is resulted when placing different loads on the upper surface of an object. The interference fringes' separation, orientation, and number are relevant to the axial loads.

The results in Fig. 8 are in good agreement with the results given by automatic comparator balance of capacity 1000 g based on the three cycles method according

to OIML R 111–12,004 (OIML, 2004). The uncertainty in measurement was found to be ±2 μg.

Out-of-Plane Displacement

Out-of-plane displacement is the displacement in which the object moves out of its plane such as axial and angular displacements (Gu et al. 2018; Hu et al. 2021).

- **Axial Displacement**

In the axial displacement, the object (diffuser) is shifted axially forming an interferometer of two parallel planes in which the speckle patterns are modulated by a ring system. A double exposure of axially shifted speckle patterns forms interference circular rings when processed by Fourier transform. Each of the rings is localized in a particular plane and the number of the observable rings is limited by the speckle size (Fig. 9).

In this case the wave fields are represented in the polar coordinates and the intensity at the image plane is (Necklawi et al. 2007):

$$I = 2\left(\frac{S}{\lambda R}\right)^2 B^2\{A(q)\}\left(1 + \cos\ k\Delta R\left(\frac{r^2}{2R(R+\Delta R)} - 1\right)\right) \tag{17}$$

where S is the area of integration, $B\{A(q)\}$ is the Fourier Bessel transform function, $q = \sqrt{x^2 + y^2}$ is the radius coordinate in the object plane, and $r = \sqrt{u^2 + v^2}$ is the radius coordinate in the image plane.

At maximum intensity, the axial displacement is determined by:

$$\Delta R = \frac{2m\lambda R^2}{r^2} \tag{18}$$

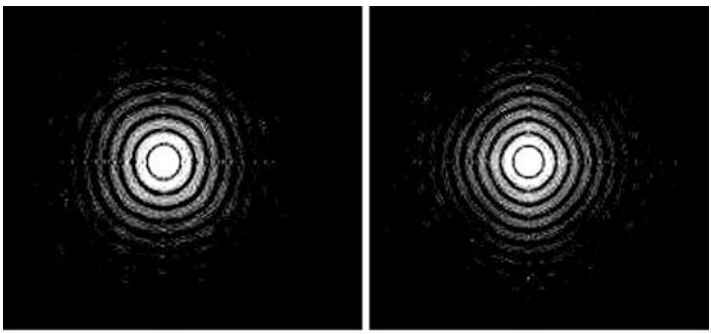

Fig. 9 Successive rings obtained by applying Fourier transform to a double exposure speckle pattern for (**a**) 20 μm, (**b**) 60 μm axial displacements (Necklawi et al. 2007)

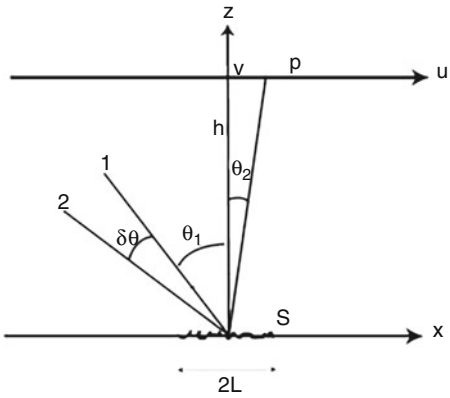

Fig. 10 Schematic diagram for the angular displacement of the object (Farid 2008)

- **Angular Displacement**

In the angular displacement, the object is rotated by an angle $\delta\theta$ (Fig. 10) such that the classical Young's fringes are formed by applying Fourier transform to the double exposure speckle patterns. As $\delta\theta$ increases, the correlation between the speckle patterns decreases.

Assuming P be the point of observation, and assuming one-dimensional rough surface represented by $S(x)$, then the scattered field $A(\theta_1, \theta_2)$ at P is given by Farid (2008) as follows:

$$A(\theta_1, \theta_2) = \frac{A_r G_2(\theta_1, \theta_2)}{2L} \int_{-L}^{L} e^{i(v_x + v_z S(x))}\, dx \tag{19}$$

where A_r is the specular reflection of the object, G_2 is a geometrical factor defined by Holzer (1978), and $2L$ is the width of the illuminated area.

The intensity of the young's interference fringes in the image plane is represented by Holzer (1978) as follows:

$$I(\omega) = \left(\frac{|A_r|^2 G_2^2(\theta_1, \theta_2)}{4L^2}\right)[I(v_z, v_z) + I(v_z', v_z') + 2I(v_z, v_z') \cos(2k \cos\theta_1 \delta\theta\omega)] \tag{20}$$

where $I(v_z, v_z)$ and $I(v_z', v_z')$ are the power spectral density functions of the speckles before and after rotation, respectively, $I(v_z, v_z')$ is the correlation function between the two speckles, $\omega/(\lambda d)$ is the frequency in the image plane, and d is the distance between the speckle plane and Young's interference fringes plane. The surface height distribution $S(x)$ is described by the standard deviation σ_r. For a very rough surface ($v_z \sigma_r > > 1$), the visibility of Young's interference fringes is described by:

$$V \approx \mathrm{e}^{-((2\pi/\lambda)\sigma \sin\theta_1 \delta\theta)^2} \tag{21}$$

which proves the inverse relationship between the visibility of Young's interference fringes and the angular displacement.

Speckle Cross-Correlation

Techniques that measure the displacement based on analyzing Young's interference fringes can only indicate the value of the displacement but not the field of the displacement. A technique such as the cross-correlation can identify the field of displacement by determining the cross-correlation function between the speckle patterns recorded before and after displacement or deformation (Hofer et al. 2018). The speckle patterns are recorded in a sequence of images as the object undergoes the deformation, and the speckle positions are traced, matched, and analyzed by iterative method (Sutton et al. 1983, 1986). This enables tracking the variation of the object's surface corresponding to the strength and the direction of the influencing factor that causes the deformation to the object (Fig. 11). The processed data can visualize the field of displacement with an accuracy that depends on the resolution of the recording sensor and the stability of the optical system. Both flexibility and simplicity of this technique increase its applications in surface engineering science.

The first image in the recorded sequence is considered as the reference case while the others show the gradual variation from the reference case. Each image is divided into sub-images in which the speckle movement is traced to extract the length and the direction of the displacement vectors by the maximum cross-correlation. The cross-correlation technique is more informative as it can provide complete data analysis for different kinds of materials and deformations. It compares the sequential speckle images to extract the relative motion of the speckles by calculating the cross-correlation function.

In Fig. 12, if $p(x, y)$ is the reference image, and $p'(x', y')$ is the displaced image, and $u(x, y)$, $v(x, y)$ are the displacement fields, then the relation between the two functions is represented by the squared Euclidean distance (Gonzalez and Woods 1992):

$$\Delta^2 = \sum\nolimits_{x,y} (P(x,y) - P'(x - u(x,y), y - v(x,y)))^2 \tag{22}$$

The expansion of this equation yields the cross-correlation function that finds the similarity between $p(x, y)$ and $p'(x', y')$ (Perie et al. 2002; Chu et al. 1985):

$$C_{\mathrm{pp}'} = P(x,y) * P'(x - u(x,y), y - v(x,y)) \tag{23}$$

$$P * P' = \mathrm{FFT}^{-1}(\mathrm{FFT}(P*)\ \mathrm{FFT}(P')) \tag{24}$$

The displacement fields $u(x, y)$ and $v(v, y)$ are determined by evaluating the normalized cross-correlation of the speckle patterns before and after the deformation.

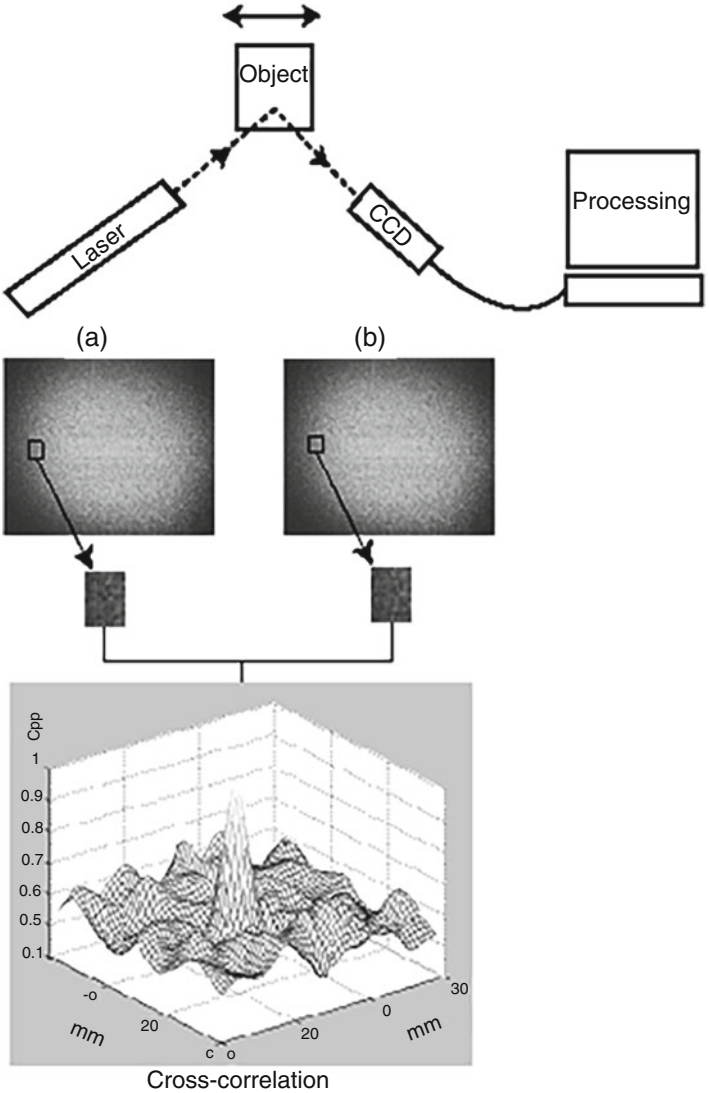

Fig. 11 Cross-correlation function that detects the field of displacement from the reference case in (**a**) to the shifted case in (**b**) (Farid et al. 2012)

Speckle photography could provide accuracy of ±4 μm for dynamic displacement of the object. The results in these measurements are affected by the cosine error influenced by the angle between the axis of object movement and the axis of measurement, while in case of static displacement of the object such as expansion and strain, the accuracy could achieve ±0.2 μm due to the absence of the cosine error.

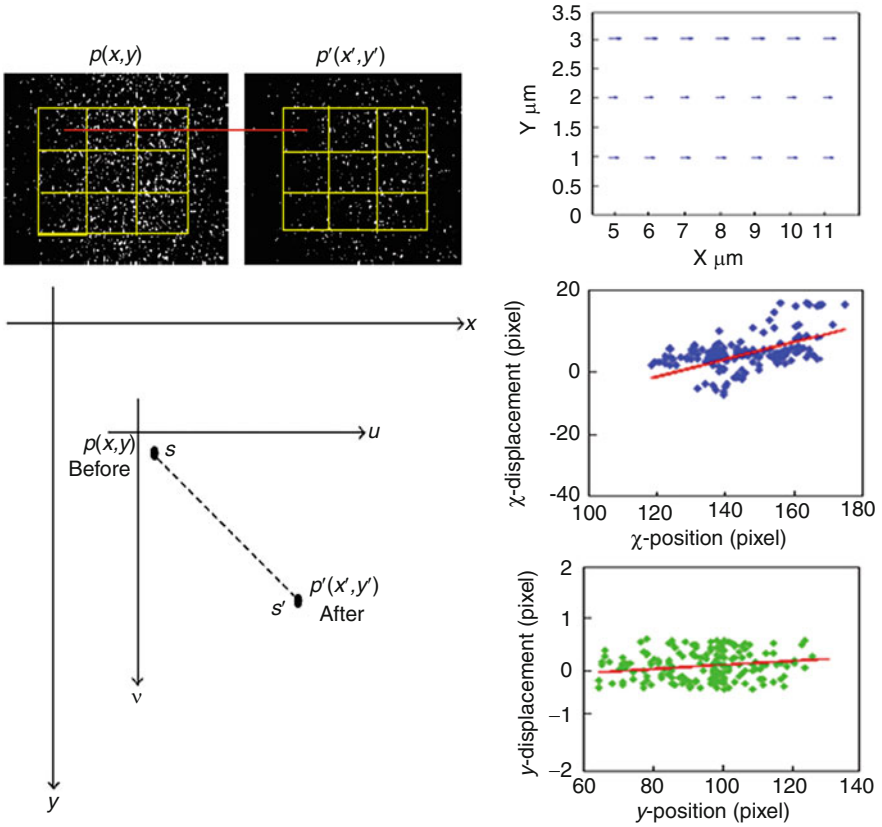

Fig. 12 The image $p'(x', y')$ is shifted from the object $p(x, y)$ by the displacement fields $u(x, y)$ and $v(x, y)$ (Farid et al. 2012)

Extending the Measurement Capabilities of Speckle Photography

The speckle patterns that characterize the scattering parameter of an object can be induced by coherent and incoherent sources. The scattered beams interfere coherently and induce speckle patterns with high contrast in case the scattering parameter is within the coherence length of the light source. As the scattering parameter increases to a value that is greater than the coherence length, the contrast decreases. A tunable source allows controlling the speckle contrast by wavelength sweeping, which is suitable to characterize very rough surfaces by synthesizing a comparable wavelength (McKinney et al. 1999).

However, incoherent sources can induce speckle patterns that are effective in measuring fine dimensions. Argon-ion lasers are of high advantage in illuminating large objects due to the high output powers, hundreds of milliwatts to several watts allowing them to be delivered by optical fibers with considerable intensities. Solid state laser diodes are small compact portable tunable sources, which provide variable

wavelength (Tatam 1998; Huang et al. 1997; Galannlis et al. 1995). This wavelength is shifted by the modulation of the cavity effective index via temperature control (low frequency modulation capability) or the injection current (high frequency modulation capability). Large wavelength shifts of 0.3–1.5 nm can be produced by the injection current inducing mode hops. Also the emission wavelength can be shifted by several nanometers at a rate of 0.3 nm/K by temperature tuning. Then tuning by temperature and by current is considered as coarse and fine tuning, respectively. Speckle photography uses diode lasers due to coherence, reliability, and low cost sources for surface measurement required in modern industry (Wei 2002). Surface roughness can be characterized by correlation methods in which the speckle images are taken either at different illumination angles (angular correlation) or at different wavelengths (spectral correlation), then the images are analyzed using point to point correlation or by Fourier transform in the far field (Jakobi 2000).

Some studies (Tchvialeva 2010; Strzelecki et al. 1998) could explore the effect of the wavelength on the speckle contrast, and the relation between the scattering surface and the speckle at arbitrary wavelength, to determine the surface roughness at arbitrary wavelengths. Moreover Shirley and Lo (1994); and Shirley and Hallerman (1996) discussed the dependence of speckle on the tunable laser emission. In Farid et al. (2015) the speckle photography used the diode laser to improve the visibility of the interference fringes to provide accurate measurement of roughness values at extended range. A suitable wavelength was selected for measuring a specific roughness based on the speckle visibility. As roughness increased, the speckle contrast decreased correspondingly due to the reduced temporal coherence associated with the coherence length. To avoid speckle reduction, the diode laser enabled scanning the wavelengths to produce a suitable synthetic wavelength of a larger coherence length. The large scattering parameter could then lie within the new coherence length, and consequently, the speckle contrast was improved.

The following formula presents the field amplitude of the wavefront scattered by a rough surface that is represented by a distribution function $S(x, y)$:

$$A(x,y) = A_o e^{i\varphi(x,y)} \tag{25}$$

such that $\varphi(x, y)$ is the phase function at wavelength λ and incidence angle θ, and described as:

$$\varphi(x,y) = \frac{2\pi}{\lambda} 2S(x,y)\ \cos\ \theta \tag{26}$$

The Fourier transform of the scattered wavefront is represented by:

$$F(f_1,f_2) = \int A(x,y)\ e^{\left(-\frac{2\pi i}{\lambda}(f_1 x + f_2 y)\right)}\ dxdy \tag{27}$$

Consequently, the intensity of the speckle pattern at single exposure becomes:

$$I = \int F(f_1,f_2)F^*(f_i,f_2)g(\upsilon)\mathrm{d}\upsilon \tag{28}$$

where $g(w)$ is the function that describes a symmetrical spectral line profile as follows:

$$g(w) = g(w_o)\mathrm{e}^{\left(\frac{-4\ln 2(w-w_o)^2}{\delta w^2}\right)} \tag{29}$$

where w_o is the central frequency, and δw is the spectral half width. The object is illuminated with different wavelengths λ_1, λ_2 for each exposure, and the amplitude at each wavelength becomes:

$$A_1(x,y) = A_{01}\,\mathrm{e}^{i\phi_1(x,y)} \text{ and } A_2(x,y) = A_{02}\,\mathrm{e}^{i\phi_2(x,y)} \tag{30}$$

$$\begin{aligned} &\text{and } \phi_1(x,y), \phi_2(x,y) \text{ are : } \phi_1(x,y) = \frac{2\pi}{\lambda_1}\,2S(x,y)\,\cos^{\circ}\theta \\ &\phi_2(x,y) = \frac{2\pi}{\lambda_2}\,2S(x,y)\,\cos^{\circ}\theta \end{aligned} \tag{31}$$

where $\lambda_2 = \lambda_1 + \Delta\lambda$.

The total amplitude after double exposure is:

$$A_T(x,y) = A_1(x,y) + A_2(x,y) \tag{32}$$

Assuming I' is the second exposure intensity, and then the total combined intensity at the double exposure $I_T = I + I'$ is:

$$I_I = |A_T|^2 = A_1^2 + A_2^2 + 2A_1A_2\,\cos\,\left(4\pi\left(\frac{1}{\lambda_1} - \frac{1}{\lambda_2}\right)S(x,y)\,\cos\,\theta\right) \tag{33}$$

$$I_I = I_1 + I_2 + 2\sqrt{I_1I_2}\,\cos\,\left(\frac{4\pi\,\Delta\lambda}{\lambda_a^2}S(x,y)\cos\,\theta\right) \tag{34}$$

where λ_a is the average wavelength.

The reconstruction of the double exposure speckle pattern in the image plane yields Young interference fringes of the following visibility (Farid et al. 2015):

$$V = \mathrm{e}^{-\left(\frac{4\pi\sigma\,\Delta\lambda}{\lambda_a^2}\,\cos\,\theta\right)^2} \tag{35}$$

$$\sqrt{-\ln(V)} = \frac{4\pi\,\sigma\,\Delta\lambda}{\lambda_a^2}\,\cos\,\theta \tag{36}$$

where σ is the standard deviation of the surface distribution function $S(x, y)$.

Farid et al. (2015) used transverse and longitudinal single mode where single frequency operation is maintained over several hundred GHz. Maximum Optical output power is 80 mW. The full lasing tuning range of the laser lies within 779–781 nm. Modulating the laser diode temperature rather than injection current could control the wavelength in order to keep the intensities of the speckle patterns unaffected by increasing the roughness degree from 4.5 to 18 μm. The object was illuminated by an arbitrary wavelength and the speckle pattern was recorded referring to the first exposure. The wavelength was then tuned by raising the temperature of laser cavity to 297.15 K, 303.15 K, 309.15 K, and 315.15 K.

and the second exposure was recorded. Selecting two different wavelengths induced a change in the speckle patterns. The construction of the combined speckle (double exposure) formed Young's interference fringes of number and visibility depend on $\Delta\lambda$ and σ of the object. Figure 13 shows the effect of tuning the wavelengths on improving the visibility of the interference fringes when measuring increased roughness. This proves the advantage of this method in extending the measurement capabilities of the speckle photography for high roughness degrees.

The curves in Fig. 14 explore the relation of the visibility of Young's interference fringes with the tuned wavelength for different roughness degrees (4.5, 9, 18 μm) based on Eq. (35).

From Fig. 14, it is clear that the visibility of Young's interference fringes decreases with roughness increment. By selecting an appropriate $\Delta\lambda$ the visibility can be improved to enable better analysis at the increased roughness.

Both experimental and theoretical results in Figs. 13 and 14, respectively, are similar, and show good agreement with the reference values of the standard roughness specimens used in the experiment. The speckle photographic technique using diode lasers as coherent sources could fit the very rough surfaces since the speckle contrast could be improved by scanning laser frequency to select the suitable wavelength. The accuracy of this technique was found to be ± 0.6 μm.

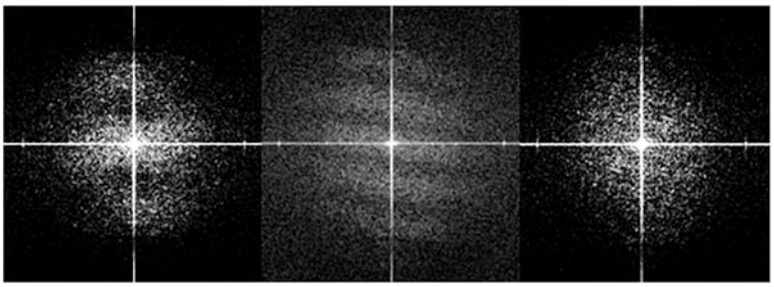

Fig. 13 Young's fringes' visibility for roughness $\sigma = 18$ μm at $\Delta\lambda = 0.4$ nm, 0.7 nm, and 1 nm

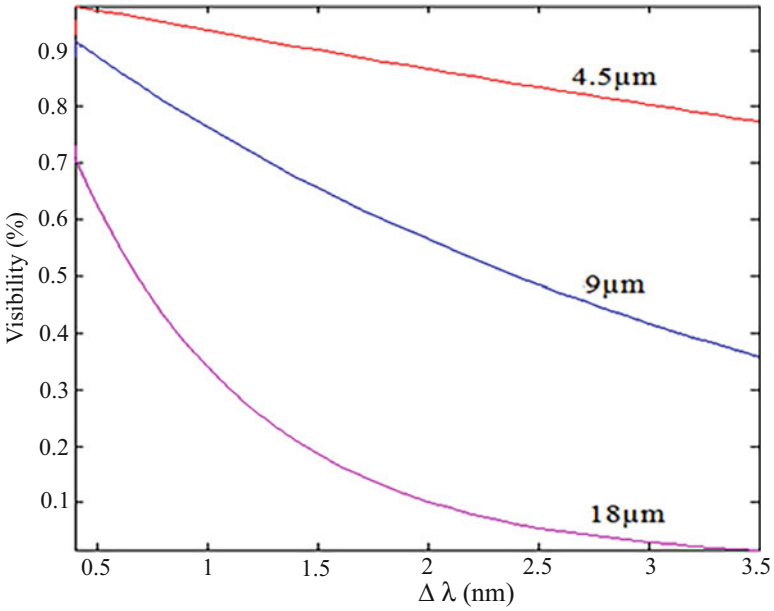

Fig. 14 Dependence of Young's interference fringes visibility on the tuned wavelength

Speckle Interferometry

A motion or deformation of an object surface causes a change in the intensity or phase of the individual speckles in a speckle interferometer. Interference fringes are a visual representation of this change that can be determined (Goodman 2007; Tokovinin et al. 2020).

The phase change caused by the thin film thickness is extracted by analyzing the intensities of the interference patterns in Fig. 15a, and the thickness can be calculated by converting the interference fringes into a wrapped phase map with a phase between 0 (black) and 2π (white).

An unwrapped phase map with a continuous grayscale can be obtained if 2π is correctly added or subtracted every time a discontinuous jump of 2π appears (Svanbro 2004). By this, both thickness and surface deformation of the film is obtained by one-dimensional FFT with phase unwrapping (Necklawi et al. 2006).

Assuming A_1 and A_2 the complex amplitudes of the wavefronts coming from the thin film and the reference mirror, respectively:

$$A_1 = a_1 e^{i\phi_1} \text{ and } A_2 = a_2 e^{i\phi_2} \tag{37}$$

where a_1, a_2 are varying amplitudes, and φ_1, φ_2 are varying phases.

The speckle intensity at the image plane on the substrate is:

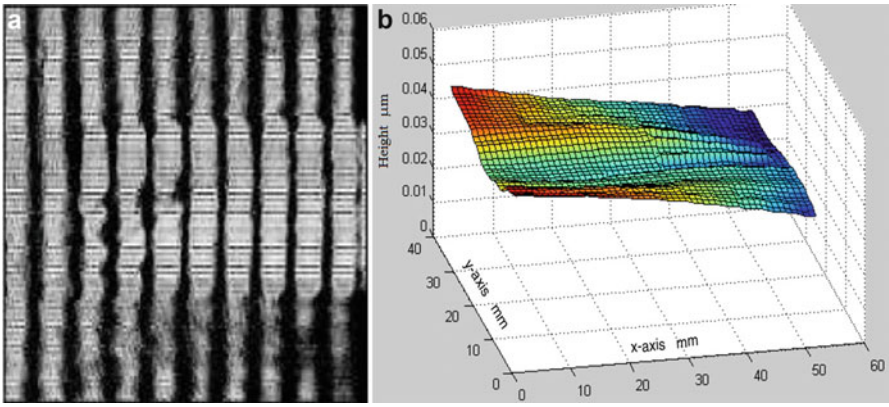

Fig. 15 (**a**) Thin film interference fringes captured from the speckle interferometry, and (**b**) Thin film profile mapping

$$I_m = I_1 + I_2 + 2\sqrt{I_1 I_2}\cos\ \varphi \tag{38}$$

such that

$$I_1 = A_1 A_1^*, \quad I_2 = A_2 A_2^*, \quad \phi = \phi_1 + \phi_2 \tag{39}$$

The speckle intensity on the thin film is:

$$I'_m = I_1 + I_2 + 2\sqrt{I_1 I_2}\cos\ (\varphi + \Delta\varphi) \tag{40}$$

Maximum correlation is reached at

$$\Delta\varphi = 2n\pi \tag{41}$$

While minimum correlation is at

$$\Delta\varphi = (2n+1)\pi \tag{42}$$

The variation in the correlation between I_m, I'_m represents the variation in the thin film thickness.

$\Delta\varphi$ depends on the path difference of the traveling waves resulted from the thickness of the thin film.

The path difference is given by:

$$\Delta d = \Delta\varphi \frac{\lambda}{4\pi} \tag{43}$$

where Δd is the thickness of the thin film, and λ is the wavelength of the light source.

Fourier Transform and Phase Unwrapping

When an object encounters a deformation, the uniform spacing between the fringes is lost as the fringes deform, resulting in localized areas of compressed and expanded fringe spacing. Scanning across this area would detect changes in fringe frequency that corresponded to fringe spacing changes. The essential phase information is separated by extracting this fringe frequency from the dominant carrier frequency to analyze surface deformation (Brayanston-Cross et al. 1994; Yun et al. 2017). This is achieved by applying the Fourier transform method to handle the fringe pattern described by the following equation:

$$g(x,y) = a(x,y) + b(x,y)\cos\ [2\pi f_0 x + \varphi(x,y)] \tag{44}$$

where $a(x, y)$ is the background noise, $b(x, y)$ is the modulation noise, f_0 is the carrier frequency in the x-direction, and $\varphi(x, y)$ is the phase information of interest.

Equation (4) is displayed in its complex form as follows:

$$\begin{aligned} g(x,y) = a(x,y) + \frac{1}{2}b(x,y)[&\cos(2\pi f_0 x + \varphi(x,y)) + j\sin(2\pi f_0 x + \varphi(x,y)) \\ &+ \cos(2\pi f_0 x + \varphi(x,y)) - j\sin(2\pi f_0 x + \varphi(x,y))] \end{aligned} \tag{45}$$

where $\cos(2\pi f_0 x + \varphi(x, y)) - j \sin(2\pi f_0 x + \varphi(x, y))$ is the complex conjugate.

Equation (45) can be rewritten in more convenient form thus:

$$g(x,y) = a(x,y) + \frac{1}{2}b(x,y)\left(e^{j\varphi(x,y)}e^{j2\pi f_0 x} + e^{-j\varphi(x,y)}e^{-j2\pi f_0 x}\right) \tag{46}$$

let $c(x, y) = (1/2)b(x, y)e^{j\varphi(x, y)}$ and $c^*(x, y)$ be the conjugate. Thus,

$$g(x,y) = a(x,y) + c(x,y)\ e^{j2\pi f_0 x} + c^*(x,y)\ e^{-j2\pi f_0 x} \tag{47}$$

The Fourier transform of the intensity distribution is given by

$$G(f,y) = A(f,y) + C(f - f_0, y) + c^*(f + f_0, y) \tag{48}$$

By choosing a carrier frequency that is suitable for the resolution of the image, and the cutoff frequencies, the phase information can be separated from the unwanted frequency modulation and the high frequency speckle. Then the phase map is calculated using the inverse transform of $C(x, y)$, and the phase distribution is given by

$$\varphi(x,y) = \arctan\left[\frac{\Im[c(x,y)]}{\Re[c(x,y)]}\right] \tag{49}$$

where $\Im[c(x,y)]$ and $\Re[c(x,y)]$ are the imaginary and real components of $C(x, y)$.

The solution of this equation is the wrapped phase in the form of sawtooth function with discontinuities, i.e., with edges as fraction $[\Im[c(x,y)]/\Re[c(x,y)]$ changes by 2π. Methods that eliminate the edges are known as phase-unwrapping methods, which can be realized by finding the edges and adding $\pm 2\pi$ to the wrapped phase when passing an edge (Robinson 1993; Stetson et al. 1997).

In order to obtain phase information from the interference fringes of the thin film, the Fourier transform technique requires only one fringe pattern, and the desired phase information can be extracted from the high frequency speckle and DC noise by carefully selecting cutoff frequencies. Despite the existence of discontinuities and pixel noise, a fringe pattern can be handled by combining the Fourier transform approach with phase unwrapping to display the phase information (Fig. 15b). This method requires one image, and as a result, the device is simple and noise-resistant. The speckle interferometer could measure the thickness of the thin film with accuracy of ± 0.02 μm.

Future Prospective in the Field of Speckle Metrology

The speckle techniques discussed in this chapter are very promising for future applications. For example Speckle can be used in measuring light wavelengths. This can develop compact wavemeters and spectrometers, although the resolution will be limited by the strong correlations between the speckle patterns produced by closely spaced wavelengths as in a diode laser. Analyzing the speckle images in a proper way can overcome this limitation.

Speckle can also be used as a tool to extract a unique code from the component's surface, and the pattern can then be used as a secure digital fingerprint. In this case, the intensity correlation can be used as a numerical identifier.

Furthermore, speckle photography is appropriate for in-process measurements. The limitation of this fast and robust measurement technique based on image correlation techniques is the inability to detect out-of-plane deformations in the measurement system's direction, which may increase the measurement error of in-plane deformations. Practical methods can be developed for inferring local out-of-plane motions of the object surface from speckle pattern decorrelation and reconstructing 3D deformation fields while maintaining in-process capability.

Moreover, compound speckle interferometer can be developed for measuring three-degree-of-freedom (3-DOF) displacement using a combination of heterodyne interferometry, speckle interferometry, and beam splitting techniques, while maintaining high resolution and simple configuration. This combination will enable high measurement capabilities to be applicable to real-world applications.

Traceability to SI Unit

To establish traceable measurement for speckle technique in a real-world environment, the optical system must be calibrated and a traceable reference source used.

Using a traceable "reference," such as a laser source with a wavelength suitable for the range of optical measurement, can disseminate length traceability to the measurand.

The measurands in the speckle techniques discussed here are represented ni metric dimensions. Because speckle analysis is dependent on image processing, the pixel must be converted to length unit, and this conversion is done according to pixel size in each magnification, which drives the attention to the importance of calibrating the optical system.

A preliminary test can be done to calibrate the speckle technique readability by moving the object laterally or axially in reference steps using calibrated motorized stage. The displacement represented by laser speckle is compared to the reference one to perform a traceable full-field measurement calibration. This can be used to assess a specific setup in a real-world environment related to a specific application. It can also help to understand the measurement system's performance by comparing measurements to a reliable, calibrated source, such as the motorized stage. The optical system calibration investigates the effect of measurement process variables on measurement accuracy. Understanding these influences increases confidence in the reliability of both singular and comparative measurements, while also assisting in the refinement of experimental design.

In some cases, calibration is accomplished by comparing optically measured quantities to theoretical predictions. In other cases, a variety of measurements are proposed for evaluating out-of-plane displacements.

Some approaches propose applying artificial deformation to a reference image in order to provide an accurate representation of a real speckle pattern. Or artificial speckle with well-known characteristics can be added to the image in a controlled manner to assess optical system calibration.

When evaluating the uncertainty, systematic and alignment errors are identified through the calibration of the optical system. In speckle technique that uses digital image correlation, it is necessary to consider the influence of variance errors on measurement uncertainty. This requires computing spatial and temporal standard deviations of the quantity of interest from static object images to quantify the variance errors.

Also, both standard deviation and spatial resolution are necessary in evaluating the uncertainty in dimensional measurement using speckle. The standard deviation shows the smallest value of the measured dimension that can be detected, while spatial resolution is the smallest distance between two independent measurement points. In addition, other factors including the environment, lighting, and speckle size contribute to the uncertainty in measuring displacements using speckle techniques.

Conclusion

Some interesting areas have been discussed including different applications of speckle metrology in nondestructive testing. Technological development in the speckle field provides fast and simple analysis of different types of deformation overcoming many limitations.

Abstract

Optical phantoms with tissue-mimicking properties have long been recognized as an important intermediary stage for developing metrological techniques, and their use in preclinical studies is extensively growing. This chapter discusses the various phantoms currently being used in multiple biomedical applications using spectroscopy, optical tomography, and imaging. The chapter emphasizes on their material composition and optical characteristics. As a result, it is an

endeavor to give the researchers well-informed range of potential applications of optical phantoms in optical metrology. This chapter also describes the current state of the art for measurement techniques used to define the key properties of phantoms used in medical diagnostic measurements. Also, measurement tools and methodologies are described in detail. It was analyzed that the maximum deviation of length measurements in the phantoms without calibration is -3.5 ± 0.18 *mm at* $k = 1$, *98% level* of confidence.

Introduction

Optical metrology is the science of measurement of material properties with high precision and accuracy. The most common uses of optical metrology are in the manufacturing industry, where features can be measured with sub-nanometer accuracy. This has led to the creation of a wide variety of optical measurement devices – from telescopes and binoculars, to microscopes and cameras. However, optical metrology is also beginning to find applications in the life sciences, including in the field of oncology. Most commonly, optical metrology is used to determine the dimensions of tumor cells and other cellular phenotypes. Furthermore, it is being used to determine the size and shape of cells and tissues for cellular studies and determine the amount of fluid in the brain for neuroscience studies. Today, we are able to make images and data of human body tissues that would have been inconceivable just a few decades ago. Although the measurement of light to detect the presence of defects and abnormalities in human body is not a new idea, today, several techniques have been developed to measure light as it passes through the tissues in order to detect possible abnormalities, for example, using the backscattered light. The development of measurement and diagnostic imaging systems has necessitated the usage of multiple materials to mimic human tissues' properties in the testing of the instruments for its applicability, harmfulness, repeatability, or several other parameters (Cohen 1979; Seltzer et al. 1988; Olsen and Sager 1995; Pogue and Patterson 2006). These phantoms serve a variety of functions:

1. System design and development from the ground up
2. Improving current systems' signal-to-noise ratio
3. Controlling the devices' quality
4. To assess the systems' performance.

The optimization of the image quality and patient radiation exposure is one of the main requirements for clinical radiological imaging. Real patients can be used for the radiation measurements; however specific phantoms are needed for image quality

assessments. A number of phantoms are designed to accomplish both tasks simultaneously for this optimization. The sharpness and noise are the important parameters used to define the quality of the radiographic images. Their quantitative assessments are performed by physical measurements. For example, the sharpness and the noise of imaging systems can be described in the frequency domain by the modulation transfer function (MTF), and by the normalized noise power spectrum (NNPS), respectively. Detective quantum efficiency (DQE) is determined from these metrics and gives the efficiency of a detector when using input signal-to-noise ratio provided by a limited number of photons to form an image at a certain dose level. When the system fully establishes, and to be used in clinical trials with a proper ethical approval from the competent authority, there are standards or recommendations for imaging quality control phantoms for system performance and usage validation. The instrument's parameters can only be validated for clinical trials if the object is made in such a way that it retains the same properties as original tissue has, which are termed as phantoms (Vardaki and Kourkoumelis 2020). Moreover, medical physics organizations such as the Canadian Organization of Medical Physicists (COMP) and American Association of Physicists in Medicine (AAPM) gave recommendations on the necessity of phantoms for new technologies, systems, and to keep track of the existing systems (Pogue and Patterson 2006). Researchers have developed and demonstrated the phantom by various ways. This chapter provides a detailed study of the numerous tissues mimicking optical phantoms, their characteristics, and uses in metrological applications.

Optical phantoms usually approximate the optical features of human body tissues, which are often utilized to replicate interaction of light with biological tissues. The main purposes of using phantoms are: simulating light propagations with geometry of real tissues, calibrating optical devices, and performing a traceable measurement using instrument. Phantoms are used in a variety of imaging qualitative/quantitative measurement applications, such as radiology, dermatology, endoscopy, ophthalmology, and diagnostics to mimic the properties of human tissues for measurements. For example, a typical phantom is made of a material that simulates the soft tissue but also has optical properties in similitude with human tissue optical properties. Although, for precision measurements, phantom properties are carefully calibrated in order to closely match the optical properties of human tissues, and constructed using such tissue mimicking materials, generally, those materials are typically made of a plastic or other material that is typically white and has a shiny, gelatin-like appearance (Vardaki and Kourkoumelis 2020). Furthermore, they are also used to create images of human organs that would be difficult or impossible to image using other techniques, such as CT scans. However, properties for optical phantoms can be altered by adding specific materials to the medium that is used to form the phantom. This enables the optical properties of the medium also to be mimicked.

The necessity of the phantoms is shown in Fig. 1 (Vardaki and Kourkoumelis 2020).

In this study, we have evaluated advances in the design, development, and fabrication of phantoms for optical metrological applications that imitate the optical, geometrical, and mechanical characteristics, along with the intricate structures of

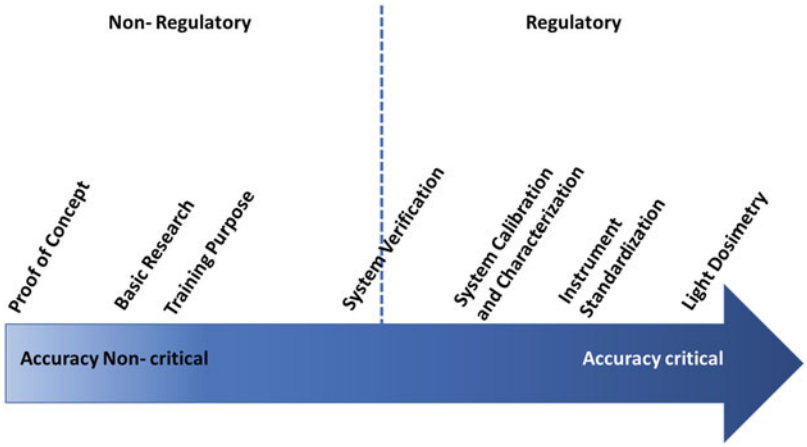

Fig. 1 Necessity of the optical phantoms in system development (Vardaki and Kourkoumelis 2020)

tissues, with a focus on materials with maximum endurance. Furthermore, this chapter attempts to analyze the advantages and disadvantages of each phantom kind, as well as topics such as system purpose, shape, and tissue type. In an effort to offer the most thorough information feasible at this level of development, the trade-offs between structural, biological, and chemical functionality are also mentioned.

Tissue Optical Properties

In the early 1980s, a boom in research interest for clinical studies in breast cancer imaging for transillumination in near-infrared, also known as diaphanography, prompted the creation of phantoms for near-infrared spectroscopy and imaging of tissues (Watmough 1982, 1983; Drexler et al. 1985). Later, multiple applications such as therapies using photodynamic and laser treatment drew interest in designing the phantoms because when it came to therapeutic effectiveness, understanding the optical fluence in tissues was crucial (Grossweiner 1986; Jacques and Prahl 1987; Flock et al. 1987). The development of measurement devices used for enhancing spatial and temporal resolution in the early 1990s prompted many researchers to examine imaging and spectroscopy of tissues, resulting in the creation of a variety of tissue phantoms (Grossweiner et al. 1987). Recently, the use of optics in medicine has grown substantially, with aesthetic laser surgery becoming the major commercial technique and diagnostics using fluorescence and reflectance as important commercialized challengers (Cerussi et al. 2012). In order to design and develop phantoms, it is the pre-requisite to measure the tissue optical properties to determine both the coefficients (i.e., scattering and absorbance). The details of the optical properties are discussed as follows.

Both diagnostic and therapeutic applications in optical metrology are influenced by the optical characteristics of human tissue. In diagnostic applications, the capacity of light to infiltrate a tissue and probe and then exit the tissue is critical to detect, whereas, in therapeutic applications, the capacity of light to permeate a tissue and deposition of energy via the tissue's absorption qualities is crucial (Jacques 2013). As a result, defining a tissue's optical characteristics is the first step in appropriately developing equipment, interpreting diagnostic results, and establishing therapy regimens. The cue to match and mimic properties of phantoms utilizing physical and biological aspects of tissues that govern its interaction with light (Arnfield et al. 1988). The optical properties always are specific to micro- and macroanalysis applications. It's critical to match the scattering coefficient (μ_s), absorption coefficient (μ_a), and anisotropic coefficient g (scattering angle cosine) in tissues for small-scale applications. Whereas, a scattering length is termed as the reciprocal of scattering coefficient across greater distances (i.e., greater than three times scattering lengths) $1/\mu_s$, it is also defined as the reduced scattering coefficient , i.e., $\mu_s{}' = \mu_s (1 - g)$. For transmission through thick tissues, it is possible to replicate the tissue's effective attenuation coefficient only, which is stated in the wavelength zone where the theory of diffusion is correct as $\mu_e = \left(3\mu_o\mu_s'\right)^{-1/2}$ (Salomatina et al. 2006; Bevilacqua et al. 1999). Furthermore, for spectroscopy applications, it is necessary to separate out absorption and scattering coefficients to facilitate spectral fitting, therefore the tissue must have both the values. The aforementioned properties are the prerequisites while choosing the useful phantom materials and design along with other aspects to consider such as thickness, heterogeneities, containers, and all geometrical designs (O'Sullivan et al. 2012). However, in real-time applications, just a few of these attributes are crucial, while the others can be disregarded or given a lesser priority. It was stated that the following features should be there while designing the phantoms (Cheong et al. 1990; Cheong 1995):

1. Depending on various tissues, the absorption and scattering characteristics might vary.
2. Multiple features have a wavelength dependency comparable to tissue.
3. Particular interest should be there for different molecules (e.g., NADH, FAH, collagen, tetrapyrroles, fluorophores, and actinometers).
4. Properties should be time independent and have higher stability under varying environmental circumstances (e.g., humidity, temperature).
5. Mechanical and surface characteristics are comparable to those of tissue.
6. Capability to incorporate optically diverse regions (e.g., inclusions of tumors and layered skin).
7. Brownian motion or flow can be included into the phantom.
8. Capability to integrate thermal characteristics resembling tissues.

For an accurate replication propagation of infrared or visible light in a particular tissue, its optical characteristics must be reproduced at the measurement wavelength. Furthermore, by reproducing optical qualities (scattering coefficient), the replication

of co-dependent variables such as the concentration of distinct chromophores (absorption coefficient) and the shape, size, and concentration of scattering components in the tissues (Strömblad 2015; Bashkatov et al. 2007) is done. Apart from that, fat emulsions like Intralipid and Liposyn, milk, TiO_2, latex, and polystyrene microspheres are all commonly utilized scatterers in the construction of tissue phantoms. Whereas, Inks (black ink, India ink, red ink), biological absorbers (hemoglobin, carotene, melanin) and dyes (naphthol green dye, blue dye, indocyanine green, nigrosin, indocyanine green) are all examples of absorbing medium. By combining the necessary amounts of absorbing and scattering agents in the volume of phantoms, the desired optical characteristics may be produced (Ebert et al. 2001; Bremer et al. 2003; Troy et al. 2004). Table 1 lists the scattering elements of several tissue imitating materials.

Furthermore, absorbers are also important in phantoms, which can be used with the three primary scatterers (lipid, TiO_2, microspheres) discussed above. Majorly, water is the main cause, due to which absorption of phantoms occurs at most of the near-infrared and visible wavelengths. However, the coefficient for absorption is so small, below the wavelength of 700 nm, that it may be ignored, and some other absorbers may be appended to adapt the absorption coefficient and spectrums to tissues (Bednov et al. 2004). Table 2 gives a quick overview of absorbers and how they're used.

Types of Phantoms

Solid phantoms**,** liquid phantoms, polymers, silicone phantoms, gelatin/agarose phantoms, and animal phantoms are some of the most often used optical phantoms (Pogue and Patterson 2006; Tuchin 2015; Esmonde-White et al. 2011b). Those are discussed in detail as follows (Fig. 2):

Aqueous/Liquid Phantoms

These are the simplest and most adaptable in terms of manufacture since volume and uniformity can be readily regulated and handled. Because of this, the optical characteristics of liquid phantoms may be changed simply by varying the relative amounts of scattering and absorbing components in the solution while making the phantom (Pogue and Patterson 2006; Tuchin 2015). In most cases, liquid phantoms are created by combining the emulsions (intralipid, liposyn), which is commercially available with an absorber (e.g., ink) (In et al. 2014). The mixing is usually done in a container and the material of the container may differ based on usage and the likelihood of propagation of light from the container walls. Also, because phantoms are liquid, they allow for substantial flexibility during measurements, such as the integration of scattering and fluorescence characteristics. Another significant benefit of liquid phantoms over semisolid/solid phantoms is their simple and quick synthesis technique (Viator et al. 2002).

Table 1 Scattering constituents of the mimicking materials

Scatterer material	Durability	Compatibility with biological constitute	Chemical (organic/ Inorganic)	Refractive index	Size of particle	Application	References
Lipids	NP	Y	O	1.45	10–500 nm	Multiple phantom contrast investigations, intralipid, milk, and combination testing	Merritt et al. (2003), Reble et al. (2009), van Staveren et al. (1991), Esmonde-White et al. (2011a) and Masson et al. (2018)

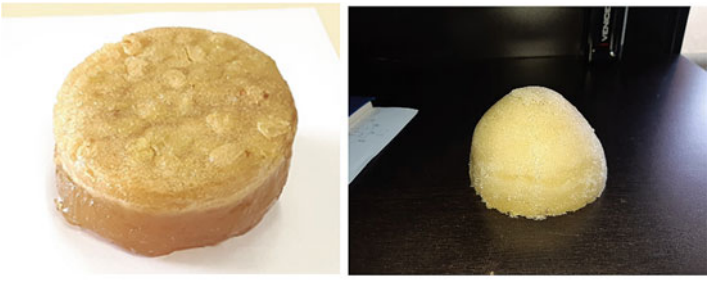

Fig. 2 Examples of tissue phantoms: (**a**) gelatin (**b**) agarose phantom (all two images are from the author's unpublished work)

Solid Phantoms

Solid phantoms are time-consuming and have low degrees of flexibility to make because their optical properties are difficult to control just by including or omitting elements from the bulk matrix (Pogue and Patterson 2006). Bulk matrices with various degrees of transparency, i.e., silicone, polymers, and wax, have been used to

create solid phantom samples. Despite the fact that polymer-based phantoms are less durable and instable in size during polymerization, they have better shelf life than animal or aqueous tissue phantoms.

Hydrogel Phantoms

Hydrogel-based phantoms, such as agarose and gelatin matrices, are a unique type of semisolid tissue phantom. Phantoms made by both of these materials have been extensively used for biocompatibility testing and imaging in metrological applications (Viator et al. 2003; Arteaga-Marrero et al. 2019). Because hydrogel phantoms are mostly composed of water, evaporation of the solvent can occur, causing the rapid change in phantom's size and optical characteristics (D'Souza et al. 2001). Also, these phantoms are susceptible to bacterial development; some of the preservatives may be employed to extend their life span.

It was stated that both types of tissue phantoms (i.e., liquid and solid) lack the genuine intricacy (Vardaki and Kourkoumelis 2020). Multiple layers of equal or different optical characteristics need to be added to increase the realistic complexity of such phantoms. Mineral inclusions to mimic tumors widely employed to increase the biological value of phantoms are used in solid phantoms. Also, to portray pathological calcifications, calcification powder (i.e., hydroxyapatite (HAP)) is frequently used into the phantom (Kerssens et al. 2010). Apart from this, if many inclusions with varying scattering and dispersion are required inside the simulated tissues some other materials are used to mimic the tissues, e.g., calcium carbonate, polymers, or trans-stilbene can be used. On one side usage of liquid tissue phantoms makes it simple to add or remove inclusions from the sample volume. Solid phantoms, on the other hand, cannot readily include inclusion characteristics after manufacturing, and also the surrounding tissue seems unrealistic, so the solution can be done using animal phantoms (Tuchin et al. 2011; Dingari et al. 2011; Roig et al. 2015).

Animal Phantoms

The most appropriate phantoms are animal phantoms because they effectively mimic the mechanical characteristics, heterogeneity, and uniformity of human tissue. Animal tissues are extensively employed in optical imaging not only for its inherent scattering and absorption capabilities, but also for its shape and chemical content (Ghita et al. 2016; Stone et al. 2010; Mosca et al. 2020; Asiala et al. 2017). It was stated in the literature that animal tissues excised and used ex vivo can serve as a realistic model due to its morphological complexity, which are also prevalent in human tissue. Despite their advantages, these are very challenging to manage for repeatable experiments due to their inability to modify optical characteristics exactly (Sharma et al. 2013). Furthermore, due to the reduction in blood volume during removal, lower absorption in tissues is predicted. Animal phantoms, on the other

hand, are valuable as a stopgap between human and in vivo investigations because they allow researchers to explore healthy and sick tissues. Such things would be impossible to do in a human patient owing to ethical concerns.

Material-Based Phantoms

Silicone Phantoms

Such phantoms were firstly employed by Oldenburg et al. (2005) in optical coherence tomography (OCT), demonstrating magnetomotive contrast using their mechanical characteristics. The most difficult aspect of making the phantom using silicone is that it is very difficult to achieve a uniform scattering and absorbing distribution. It should be free of sedimentation, aggregation, and formation of air bubbles. Also, to guarantee a homogeneous distribution of scatterers and absorbers across phantoms with silicone, several procedures such as sonication (Oldenburg et al. 2005), thinning of silicone, and evaporation (Kennedy et al. 2009; Bisaillon et al. 2008) can be utilized alone or in combination. Although, silicone phantoms have a disadvantage the most commonly used inorganic scatterers have refractive indices that are substantially bigger than biological structures, which is a disadvantage of silicone phantoms. Furthermore, the refractive indexes of alumina and titanium dioxide, for example, are 1.76 and 2.3, respectively. Whereas, other materials, such as silica microspheres, have a higher value of refractive index; therefore they have been employed less frequently in the creation of OCT phantoms (Bisaillon et al. 2011; de Bruin et al. 2010; Rehn et al. 2013).

Polarizing/Depolarizing Phantoms

Polarization has an impact on the scattering characteristics of tissue-mimicking materials. Many researchers have investigated the influence of particle size, density, and refraction index on scattered light polarization. The primary scatterers in biological tissues, as revealed by the results of these investigations, are organelles, nuclei, and tissue structures, which restrict photon penetration depth and depolarize light flowing through these media (Rehn et al. 2013). The nucleus and organelles are typically depicted as scattering particles having refractive indexes ranging from 1.34 to 1.46. Collagen and elastin are the materials with cylindrical or spherical structures in the ECM. Moreover, to make phantoms with scattering capabilities, microspheres and other microscopic particles are often suspended in liquid. Additionally, to affect the absorption qualities, India ink, hemoglobin, and colors are widely used. Furthermore, titanium dioxide (TiO_2) is another substance widely employed in optical phantoms to induce scattering. While utilizing TiO_2 particles in phantom fabrication, they are used in the mediums like polydimethylsiloxane or polyurethane to make polymers. It is possible to modify the amount of depolarization by changing the

concentration of TiO_2 particles. Zinc oxide (ZnO) particles are frequently incorporated with polymers to create such phantoms (Chue-Sang et al. 2019).

Fibrin Phantoms

Although silicone has a lot of benefits as a synthetic phantom material. But, its incompatibility with biological tissue components is a drawback. Fibrin phantoms get around this problem. Major advantages of the fibrin are its time-efficient construction, extended life span, stiffness at room temperature, and minimal scattering over routinely used physiologically compatible materials like agar and gelatin (Chue-Sang et al. 2019). Fibrin is a protein, which naturally occurs in humans to give structural support for blood clots (Lamouche et al. 2012). It is generated by proteolysis mediated by the enzyme thrombin from the protein fibrinogen. In surgical treatments and wound closures, it is used as an adhesive (Kennedy et al. 2010). To fabricate the fibrin, thrombin powder and fibrinogen are dissolved in saline separately and further combined to produce a gel. However, adding calcium chloride ($CaCl_2$), can enhance the gel's flexibility, the gel formation time can be sped up (Kaetsu et al. 2000).

It was discovered that most early experiments with phantoms were majorly focused on regular-shaped materials development with approximated scattering and absorption at specified wavelengths. However, the emphasis has switched to develop such phantoms that can duplicate the characteristics over a wider variety of wavelength ranges, mimic the tissue spectrum, absorption, and scattering values. There's also a lot of interest in creating highly compatible phantoms with biochemical and biological properties. Moreover, they can use biologically important molecules, e.g., melanin, hemoglobin, endogenous fluorophores like flavin adenine dinucleotide FAD, nicotinamide adenine dinucleotide NADH, and exogenous fluorophores like cyanine dyes, porphyrins (Bremer et al. 2003; Troy et al. 2004).

PVA-C Phantoms

Such phantoms were mostly used because of their mechanical properties: to create more realistic mechanical behavior of phantoms for OCT-based elastography (Lamouche et al. 2012; Kennedy et al. 2010). Poly (vinyl alcohol) is a thick, liquid hydrogel (cryogel (PVA-C)) made by dissolving a polymer (poly (vinyl alcohol), in dimethyl sulfoxide (DMSO) or water (Lamouche et al. 2012). When these solutions are frozen and thawed repeatedly, they cross-link to form cryogel. Here, the solvent (dimethyl sulfoxide, water), rate of thawing along with the additives all have an effect on the optical characteristics of PVA-C phantoms. When PVA is mixed with water, it generates a transparent film that becomes progressively opaque as the PVA concentration increases. Using alumina and block-printing ink, scatterers and absorbers may be introduced into the matrix to change the optical characteristics of PVA-C.

Tissue-Engineered Phantoms

Nowadays, methods that include tissue engineering have advanced while mirroring the structural features of tissues that may be generated or grown in culture. These tissues are particularly useful in cases when the intricate nuances of the tissue's thin-layered structure are not well described; hence inert tissue phantoms cannot properly replicate them (Pogue and Patterson 2006). This is particularly relevant in optics when anisotropic scattering occurs owing to features like collagen matrix or muscle fibers, or when the stacked sequence of tissues impacts light transit in and out of the tissue. While this discipline is still in its early stages, these models have a strong chance of becoming commonplace in molecular imaging research. This is becoming a realistic alternative as created tissues become more consistent across laboratories. Another justification for using these structures is to avoid using animals in research. In most laboratories, alternatives to animal models are accepted as long as the model is a genuine portrayal (Pogue and Patterson 2006).

Ex Vivo Tissues

Ex-vivo tissues aren't exactly phantoms, but its ubiquitous application in tissue imaging and spectroscopy is worth mentioning. Because of the biological intricacy of the tissue's absorption and fluorescence spectra, and the difficulty of effectively simulating layered structures, it's generally preferable to utilize excised tissue rather than phantoms. Also, in diffuse imaging applications, chicken or bovine muscle has been widely used as an ex vivo tissue to evaluate transmission parameters to see how the modeling or measuring system functions in actual tissue (Pogue and Patterson 2006; Vardaki and Kourkoumelis 2020). While phantoms constructed by tissue mimicking material are beneficial, there is always the risk that they do not accurately imitate tissue qualities. An ex vivo tissue might be defined as a valuable intermediary before beginning measurement experiments on humans. Apart from that, chicken breast tissues are frequently employed because they have extraordinarily low concentrations of blood resulting in a tissue with outstanding light penetration.

Although the scattering coefficient is unlikely to change considerably after removal of the tissues, even the absorption due to blood will decrease along with blood volume drops (Vardaki and Kourkoumelis 2020). Also, hemoglobin oxygenation will alter the properties and all the tissues will become ischemic after a few seconds of removal. Only pre- and post-cryogenic freezing can preserve the tissue's oxygen and energy level status. Moreover, excised tissue may retain thermal characteristics and provide a useful model of nonperfused organs for optical therapy experiments as well. However, ex vivo tissue loses the heat convection caused by blood flow, making it a poor model for long-term heat dispersion investigations in perfused tissues. Table 3 lists types of phantoms along with their usage in optical methodologies.

Table 3 Different types of phantoms that are used for multiple applications

Container/bulk matrix	Wavelength	Type of phantom	Absorbing element	Scattering element	Purpose of development	References
Agarose	785 nm	Liquid		Intralipid	To estimate depth of focus of the system	Chuchuen et al. (2013)

Materials for Optical Phantoms and Their Durability

The material chosen in developing the phantom has the most influence on how the phantom may be employed (Pogue and Patterson 2006). These materials are also known as bulk matrix. The basic types of matrix materials are outlined in Table 4. Different materials are ideal for different uses while developing the phantoms. In the table below, the utilization of various phantom matrix compositions is also explained.

It was stated that to increase the durability of phantoms, some additives are added in the materials. Some of the most common additives are, e.g., formaldehyde in gelatin phantoms, which raise the melting temperature by enhancing fiber cross-linking (Pogue and Patterson 2006). This phantom may be used at room temperature without a need to be refrigerated. Apart from that, agar-based phantoms can also be used for this; however, they can grow frail and collapse when stressed. In addition, biochemical substances such as wood preservative, mild acid ethylenediamine tetraacetic acid EDTA, inclusion of penicillin, and sodium azide create a stable and durable phantom without any type of bacterial development. Usage of these additives will maintain good biological compatibility and stability for a longer period of time. Moreover, the usage of vegetable oil has also been defined in order to preserve water content. Furthermore, the addition of blood to hydrogel phantoms gives a good approximation of tissue spectra in the near-infrared, where hemoglobin and water are the prominent absorbers. These phantoms are suitable for therapeutic studies because they can have

Table 4 Bulk matrix and their composition

Phantom material	Durability (permanent/ temporary)	Solid/ liquid	Refractive index	Recommended use	References

the same elastic characteristics as human tissue and similar thermal qualities as well. The designing and development of different optical phantoms, the research of interest, is very useful in order to assess and calibrate new measurement systems.

Measurement Modalities
This section describes the measurement modalities used for analysis of the different optical parameters while designing and developing the optical phantoms.

"A measurement result is complete only when accompanied by a quantitative statement of its uncertainty. The uncertainty is required in order to decide if the result is adequate for its intended purpose and to ascertain if it is consistent with other similar results." The Uncertainty of measurement provides a quantitative estimate of the quality of a test result, and therefore is a core element of a quality system for calibration and testing laboratories. To reflect this, various international metrological and standard bodies jointly developed a Guide to the Expression of Uncertainty in Measurement (GUM) to provide such laboratories with a framework of formal metrological terminology and methodology for expressing uncertainty of measurement. Subsequently, international standards ISO/IEC 17025 and ISO 15189 (17025 re-written for medical testing), have required complying laboratories to provide estimates of uncertainty for their test measurements, referring to GUM for the appropriate methodology (Bakhshaee et al. 2015). The uncertainty of measurement, traceability, and numerical significance are separate but closely related concepts that affect both the format and the information conveyed by a quantitative test result. A detailed error analysis of the measuring procedure is required for accurate measurement of optical characteristics. Developing a tight error budget for a specific procedure allows SI traceable measurements to be accomplished. Traceability to the international system of units is critical for guaranteeing that measurements made everywhere in space and time are comparable to measurements taken anywhere else in space and time. This is the most effective technique to ensure the long-term integrity of data generated by a measuring system. In addition, the use of SI units provides a consistent basis for the reporting of clinical laboratory data.

Uncertainty "A parameter associated with the result of a measurement, that characterises the dispersion of the values that could reasonably be attributed to the measurand" (VIM).

Traceability: "Property of the result of a measurement or the value of a standard, whereby it can be related to stated references, usually national or international standards, through an unbroken chain of comparisons all having stated uncertainties" (ISO 15189).

Numerical Significance The significant figures of a number are those that have some practical meaning. The significant figures of a number express its magnitude to a specified degree of accuracy.

Another method for ensuring long-term measurement repeatability and consistency is to compare measurements to a standard material manufactured using a

controlled process of fabrication and for which the user has assigned the conventionally true value to its physical properties of interest. This is often the only viable option. The creation of fluorescence intensity standards is a good illustration of this. Absolute estimation of fluorophore concentration from fluorescence intensity measurement necessitates knowledge of the molecule's quantum yield, among other factors. Measurements can be used to determine quantum yields, but they are problematic. To tackle the practical difficulty of fluorescence measurement standardization, researchers compare their readings to a solution of fluorophores of known concentration created in a controlled manner. A recipe-based technique might be used to standardize diffuse optical measurement. This technique has many flaws. The repeatability of the standard would be restricted by the variability of the optical characteristics of the stock intra-lipid solution or the variability in the size distribution of the TiO_2 powder. The long-term repeatability of the standard would also be jeopardized due to the unclear future availability of its ingredients. If the reproducibility of a phantom is based on a precise recipe rather than an accurate, stable, and recognized characterization setup, users of this specific phantom risk the manufacturer of one of the recipes' elements ceasing to make the product. The authors experienced this challenge when attempting to get a new batch of TiO_2 powder with a specific size distribution that was no longer accessible from any source. This issue is solvable if a characterization method that produces SI traceable measurements based on a rigorous metrological methodology with a narrow error margin is available. It will be feasible to identify a replacement and check that the new phantoms created with this product are equivalent to the prior one using this way. If phantoms are manufactured in the centralized manner described earlier by a small number of laboratories or firms, it may become feasible to measure the optical characteristics of each phantom generated and therefore reach the maximum degree of precision and quality control.

Uncertainty Parameters While Designing the Phantoms The majorly defined uncertainty parameters of optical phantoms are given as follows:

- Diffuse total reflectance (ToR)
- Reduced scattering coefficient, i.e., $\mu_s' = \mu_s\,(1 - g)\,\mu_s$ is a scattering coefficient and g is a scattering anisotropy factor
- The intrinsic absorption
- Scattering
- Fluorescence
- Refractive index of the matrix material
- Effective attenuation coefficient $\mu_e = \left(3\mu_o\mu_s'\right)^{-1/2}$
- Backscattering intensity
- Reduced scattering and absorption coefficients
- Aging-related alteration of optical properties, retainment, stability over a period of time, shelf life of the phantoms

- Poor repeatability between various instances of the phantom may not have a direct impact on the quality of the system itself, but may induce perceptions of inconsistency and poor repeatability with respect to the instrument itself when presented to the target user. Such scenarios are definitely not desirable from a commercialization point of view.

The sources of uncertainty in the imaging system, as above and apart from that magnification, pixel-to-millimeter unit conversion, and penumbra effect, are also considered, and the lengths of the phantom before and after imaging system calibration were compared. The maximum deviation of length measurements without calibration is -3.5 ± 0.18 mm at $k = 1$, 98% level of confidence. Furthermore, length correction values are expected to be useful for diagnosis and treatment planning, where precise length measurements are essential while designing and developing the phantoms.

Conclusion

In this chapter, a detailed overview of optical phantoms and materials is presented to highlight field of interest in an area with a wide range of applications and approaches. It is discussed that a significant variety of optical tissue phantoms are available, with different forms, geometries, and optical characteristics ranging from simple to complex. Optical tissue phantoms have become a typical feature of an experimental setup for investigations translating into a clinical setting due to their design flexibility, time efficiency, and low cost of production. However, due to lack of homogeneity and a "gold standard" for comparison, tissue phantoms have significant issues and problems. But, as imaging and spectroscopy systems utilized for human body tissues get regulatory certification for marketing and clinical use, standardized phantoms are needed to establish the accuracy and repeatability of newly created instruments and they should take on a new degree of importance in the scientific community. Unfortunately, commercial manufacturing of these phantoms is not readily available at this moment. Yet some researchers are developing anatomically accurate phantoms with realistic optical properties in order to bring the field closer to homogeneity. It is the need of hour to develop commercialized phantoms with well-controlled optical properties for pre-clinical trials. The detailed review presented in this chapter is the first stage in compiling a summary of the field progress. However, optical field is vast, so we have limited the scope of the chapter to near-infrared spectroscopy and optical imaging. It is concluded that optical phantoms developed using multimodality is an emerging area of interest. Therefore, major advancements are needed in the field of optical phantom designing for metrological applications in order to develop commercial pre-clinical imaging systems.

Abstract

Quantitative Microscopy refers to the surface metrology of microscopic structures. It deals with the interaction of light with material and quantifies the changes in terms of surface measurements. This chapter describes optical metrology techniques used in qualitative and quantitative microscopy and explains the different extended depth of focus techniques used in quantitative microscopy. The prime focus is on the usage of liquid lenses as a potential solution for extended depth of focus imaging in quantitative microscopy. This chapter summarizes a number of applications of liquid lenses in microscopy dealing with the scope in industry and biological sciences. In the last section, the concept of uncertainty of measurement along with the uncertainty budget has been explained taking into consideration the relevant factors responsible for uncertainty.

Optical metrology · Optical microscopy · Quantitative microscopy · Extended depth of focus imaging · Digital holographic microscopy · Electrically tunable lens · Uncertainty

Introduction

Metrology is the science of measurement. Metrology finds many applications in the fields such as in the manufacturing industry for interchangeability, quality control, component matching, yield enhancement, and process development. Metrology and optics have always been intertwined. Optical Metrology deals with the qualitative and quantitative measurements that are based upon the interaction of light with matter. Optical techniques have been widely used for quantitative measurements, topographic measurements, roughness measurements, etc. With the beginning of new computing technologies and fast sensing and switching devices, a plethora of optical metrology technologies have developed to make the surface measurements easy.

Angle measurement equipment and telescopes enhance vision in estimating the sizes of faraway stars, while microscopes allow the eye to examine the surface grain structure and the internal features of living cells quantitatively. Small micro- and nanostructures are manufactured and utilized in a number of scientific and technological applications. Most applications of these structures are in semiconductor industry where the need for compact structures is increasing day by day. Microscopic methods are especially useful for surface characterization of micro- and nanostructures. This surface metrology is referred to as quantitative microscopy.

Microscopy is a branch of science that deals with the study and imaging of microscopic objects whose dimensions cannot be resolved with unaided eye (Croft 2011). Since its inception in the seventeenth century, optical microscopy has been utilized as a key tool for the imaging of micro objects and for surface metrology of micro- and nanostructures. The following are the main aspects that are required for a

precise and consistent structural metrology of microstructures with an uncertainty level below micrometers or less: careful control of the measurement conditions and measurement system parameter settings, and maintaining a high level of measurement reproducibility (Osten and Reingand 2012).

The widely recognized types of microscopy based upon the applicable frequency range in the Electromagnetic spectrum are optical scanning, electron scanning probe, and X-ray microscopy (Grubb 2012; Yamamoto and Fujimoto 2014; Takahashi et al. 1997; Zuo 2015). Optical microscopy is used in the visible region of light and provides moderate to high resolution images (up to submicrons). For nanometrology, electron and scanning probe microscopy (SPM) are used as they provide ultra-high resolution. An example of SPM is tunneling or atomic force microscopy. In X-ray microscopy, the soft X-ray band of light is used and it can achieve resolution up to 30 nm. All of these microscopic techniques have their own advantages and disadvantages, and they provide varied but usually additional information about the structures being measured. As a result, thorough and trustworthy measurements of complex structures with tough constraints (like measurement uncertainty), the necessity of using different microscopic methods arises. Visible region microscopic metrology has advantages over its contemporaries in the terms of cost, nondestructive behavior, and noninvasive property.

This chapter focuses on optical metrology techniques along with a brief of interference- and non-interference-based microscopic metrology techniques. The prime focus is on quantitative microscopy metrology and imaging of through-focus or extended depth of focus samples. A wide variety of extended depth of focus techniques that have been used in literature are discussed. These techniques range from systems that are over decades old to recently developed instrumentation that have broadened the new capabilities in quantitative microscopy. However, due to the promising achievements of liquid lenses in extended depth of focus, a detailed study is being done on the advent and applications of liquid lenses in microscopy, and numerous industrial and biological applications have been presented for use in quantitative and 3D microscopy. This chapter attempts to cover the majority of tunable liquid lens applications in the visible region; nevertheless, given the large number of techniques and articles reported, some exclusions are unavoidable.

Principle of Optical Microscopy

Optical microscopy is concerned with microscopic imaging in the visible area of the electromagnetic spectrum, i.e. (wavelength: 400–700 nm). It involves interaction of light with the specimen and the collection of scattered/transmitted light to generate an optical image (Grubb 2012). The different light phenomena associated with optical microscopy include diffraction, reflection, and refraction. Primarily, the principle of optical microscopy is to magnify the image of a microscopic specimen using an objective lens. The arrangement of the optical microscope has been described in Fig. 1. The optical microscope operates by collecting light from an optical source using a condenser lens, which focuses it on the condenser aperture. At

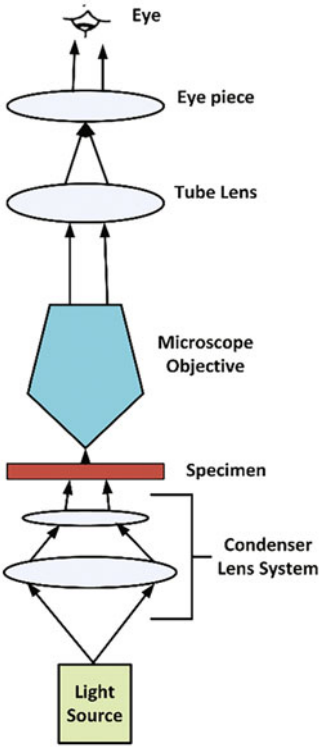

Fig. 1 Schematic of a conventional optical microscope

the focal plane of the objective, an image of the object present at the working distance is produced. The image acquired at the image plane is magnified using the eye piece lens. CCD/CMOS sensors are positioned at the image plane of the eyepiece to record a digital image of the specimen (Sluder and Wolf 2007).

Important Parameters in Optical Microscopy

1. **Magnification**: Magnification is referred to the measure of the degree of visual enlargement observed for a small entity. It is measured in multiples, for example, 10×, 12.5×, 25×, 40×, 60×, and 100×. The enlarged image is obtained at the stationary imaging plane of the objective.
2. **Resolution**: In microscopy, the term "resolution" is defined as the capability of a microscope to differentiate between two laterally placed distinct points of a specimen as separate entities. The resolution of a microscope is dependent on the objective's numerical aperture (NA) as well as the operating wavelength of light at which the specimen is examined. Resolution in diffraction-limited microscopic system is defined by Abbe's diffraction limit, $d = \lambda/(2 \times \mathrm{NA})$, where "$d$" is

the minimum resolvable distance between two distinct entities, "λ" is the operating wavelength, and "NA" is the objective's numerical aperture.

3. **Numerical aperture**: The numerical aperture is defined by the amount of light that enters the front aperture/pupil of the microscope objective. Numerical aperture gives a measure of resolving a fine specimen detail at a fixed working distance of the objective. The numerical aperture is given as $\mathrm{NA} = n \sin\theta$, where "$n$" is the refractive index of the medium and "θ" is the half angle of the light entering the microscope objective's front aperture.
4. **Field of view**: The field of view (FOV) number is the diameter of the field in millimeters, which is observed at the intermediate image plane. FOV number or Field number is used to represent the diameter of the focused object field in an optical microscope.
5. **Depth of focus (DOF)**: The thickness of the focal spot of the objective is referred to as its depth of focus. The terms depth of focus and depth of field are interchangeably used in image and object space, respectively. The focal depth of a microscope is the depth of the layer of the sample, which remains in sharp focus even if the distance between the objective lens and the specimen plane is changed (Grubb 2012).

Types of Optical Microscopy

Quantitative/Metrological Optical microscopy has been predominantly divided into further subcategories based upon its use in different application areas. The most commonly used optical microscopy techniques can be classified as:

1. Non-interferometry based
2. Interferometry based

Non-interference-based techniques include wide-field, bright-field, dark-field, light-sheet, oblique illumination, dispersion staining, fluorescence, confocal, and deconvolution microscopy. Interference-based microscopy techniques include differential interference contrast, interference reflection, phase contrast, and digital holographic microscopy. The interference-based microscopy techniques have an additional reference arm that is interfered with the object arm before imaging (Kim 2011). The interference allows the recording of phase information of the sample and the quantitative data about the sample can be retrieved. Figure 2 shows the different types of optical microscopy techniques and their categorization as interference and non-interference-based techniques.

Non-Interferometry-Based Microscopic Metrology Techniques

Bright Field Microscopy It is the most commonly used and simplest optical microscopy technique in which the sample is illuminated with an optical source

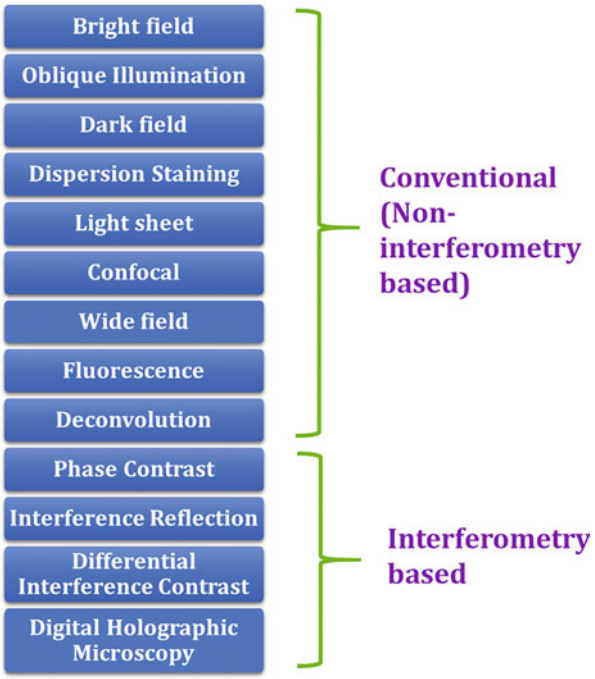

Fig. 2 Optical microscopy techniques

and a contrast is generated when the light is transmitted through the sample. The main advantage of bright field microscopy is the minimalism of the setup with only basic tools required for imaging. This technique is majorly used in the imaging of micro samples that have intrinsic color like chloroplast in plants, stained live cellular and tissue structures, peptide detection, and allows definitive identification, etc. (Michael Conn 2004). The major limitation of this technique is that contrast is very low for weakly absorbing samples, and it is not suitable for transparent specimen. One of the best methods of overcoming these limitations is the use of colored filters on light source and staining of samples in transparent cases. Moreover, bright field microscopes have magnifications limited up to 1300×.

Oblique Illumination Microscopy The light is projected obliquely onto the specimen in this approach to get a high contrast image. It is of great use for imaging unstained samples like living cells, crystals, diatoms, and other translucent or semi-transparent specimens. Because the orientation of the samples changes relative to the angle of incident light, oblique angle illumination might produce misleading pictures of the samples and lower resolution. Therefore, this microscopy is not suited for quantitative measurements or topographic measurements of the sample. However, if higher-order terms of the diffraction pattern of the sample are taken, the imaging resolution can be enhanced (Sanchez et al. 2018).

Dark Field Microscopy In this technique, the background light is eliminated from the optical image. It is most commonly used to image cell suspensions, pond water microbes like algae, planktons etc. It improves image contrast without the use of stain, and thus do not kill cells. The most common benefit is that no special sample preparation is required. The limitation of this technique is that large amount of light is required for imaging and also the sample should be thin enough to overcome the artifacts produced due to diffraction (Rijal n.d.).

Dispersion Staining It uses variations in an unknown material's refractive index dispersion curve compared to a reference material's dispersion curve to classify or describe that unknown material. It is an optical staining approach that produces colors without the use of a stain or dye. This approach is most commonly used to confirm the presence of asbestos in building materials. This technique is limited for use because both materials have similar refractive indices over some wavelength range in visible region but the dispersion curves for refractive indices must not be same for these materials. It can be utilized to differentiate them by constraining them to adopt separate colors (Mccrone 1974).

Light Sheet or Selective Plane Illumination Microscopy In light sheet microscopy, the illumination beam is incident at right angle to the imaging system to form a sheet of light through a 2D plane of the sample. It is applicable for 3D imaging in tissues, because of the capability of selective illumination of tissue layer. Furthermore, light sheet microscopy offers high speed, low light exposure, high penetration range, and low levels of photobleaching. However, the field of view (FOV) of light sheet microscopy is limited as the Gaussian beam has less focal depth. Another limitation is that the light-sheet images get deteriorated in quality due to scattering problems. Bessel light sheet microscopy, Structured Illumination Microscopy are the potential solutions for achieving confocal level resolution (Allahabadi 2016; Fahrbach et al. 2013).

Confocal In confocal microscopy, a spatial pinhole is utilized to blur the defocused information. The optical components used for both illumination and detection focus the light on a diffraction-limited spot and scan the specimen to make a complete image. The main advantage of confocal microscopy is the ability to control depth of field, and elimination of background noise from the focused plane. Its major application is in cell biology that relies on imaging both fixed and living cells and tissues. Furthermore, it has a resolution in the range of 1 nm, which is much better compared to conventional light microscopes. The main limitation of confocal microscopy is the narrow range of excitation wavelengths. This problem can be easily overcome by cost-shared microscope systems having different applications (Mccormick 2007; Shotton 1989).

Widefield Widefield microscopy refers to the imaging technique where the whole sample is illuminated with light. It is mostly used for capillary abnormality measurements in tissues and live cell imaging. The most common benefit of widefield

imaging is that field of view is enlarged as full aperture of the objective is used for imaging with same numerical aperture. The limitation of widefield imaging is its limited axial resolution and cannot image highly scattered thick samples. Usage of adaptive optics can improve axial resolution in widefield microscopy (Grubb 2012).

Fluorescence In this technique, the specimen is illuminated (excited) with a short wavelength light. It observes live cells in situ without the need for toxic and time-consuming staining processes. The high degree of specificity is possible in fluorescence microscopy. Despite the diverse range of probes available, fluorescence microscopy is limited by its dependence on probes. Also, prolonged exposure can bleach the sample and fluorescence intensity can be lost. To overcome this, epi-illumination is employed in which the light used for excitation is reflected onto the specimen through the objective (Mir et al. 2012).

Deconvolution Deconvolution microscopy is an analytical method in which the diffracted light is reallocated to its original place using calculations for the recorded image stacks. In comparison to traditional microscopic techniques, it has a better resolution, sensitivity, and dynamic range. It is mostly used in application areas of confocal and fluorescence microscopy along with 3D imaging of thick biological tissues and samples. The main limitation is that the computational complexity gets increased due to high processing and highly sensitive detectors are required for acquiring the images. Usage of high speed processors and automated scanning can increase the speed of measurements using deconvolution (Mir et al. 2012; Orth and Crozier 2012).

Interferometry-Based Microscopic Metrology Techniques (Quantitative Microscopy)

Background: Why Quantitative Microscopy?
Optical microscopes' resolution and magnification performance have significantly improved thanks to advancements in optical lens manufacturing methods. Ernst Abbe developed the scalar diffraction theory, which was widely used for many years to describe how optical microscopes operate in terms of imaging and resolution. However, in this theory, the effect of light polarization on microscopic images was not discussed and it was limited only to planar structures, i.e., two-dimensional structures, to be imaged. A conventional microscope is limited to providing only two-dimensional images of the sample at test. Therefore, conventional microscopes are not suitable while profiling 3D microscopic structures and high-end nanostructures used in semiconductor industries. This limitation necessitates the introduction of the third dimension, which is the height/depth of the microstructure. For the imaging of a third dimension, specific microscopy techniques like interference microscopy need to be used. The advanced diffraction theories like vectorial diffraction models consider the object's three-dimensionality. They calculate the light–matter interaction numerically, which is the fundamental for quantitative

microscopy. Primarily, the interference-based microscopic techniques are used in quantitative microscopy to extract the third dimension or phase of the object to provide the structural information. These are discussed as follows:

Phase Contrast (PCM) It is an optical microscopy technique that uses the changes in phase of the light transmitting through a transparent specimen and maps them to brightness changes in the captured image. It is highly used for imaging transparent thin samples and the most common benefit is that sample staining is not required. The capacity to produce visual contrast from materials that do not absorb light, such as cells and tissues in culture, is its major benefit. One drawback of phase contrast is that it does not work well with thick specimens because phase shifts from regions above and below the specimen defocus the resulting image. A phase plate can be used to reduce the contribution of the background light (Barty et al. 1998; Rodrigo and Alieva 2014).

Interference Reflection Interference reflection microscopy (IRM) is an optical microscopy technique that creates an image of an object on a glass surface using polarized light. It is mainly used to image cell adhesion on glass, cell mobility on glass coverslip. The main limitation is that a high power source needs to be used due to the presence of multiple optics (Verschueren 1985).

Differential Interference Contrast (DIC) It is also called Nomarski interference contrast (NIC) microscopy. It is used to improve the contrast in unstained, transparent samples by producing contrast image using interferometry. It is most used in the imaging of nanoparticles, surface slope measurements, etc. The main disadvantage is that the optical system becomes complex and specialized optics is needed (Mir et al. 2012).

Digital Holographic Microscopy (DHM) It works on the principle of digital holography applied to optical microscopy. The concept of holography was first introduced by Dennis Gabor (Gabor 1948). Digital holographic microscopy distinguishes itself from other microscopy methods as it does not capture the projected image of the object. It records the wavefront information originating from the object as a hologram and then uses numerical reconstruction algorithms to reconstruct the object amplitude and phase images (Kim 2011). DHM is a type of quantitative microscopic metrology and is mostly used for quantitative imaging of cell and tissue structures, in-flow imaging, particle tracking, imaging of engineered microsurfaces, etc. (Barak et al. 2018). The schematic of a basic digital holographic microscope is shown in Fig. 3. The key advantages of DHM are that it is a label-free, noninvasive, and nondestructive technique and its resolution ranges in the order of subnanometers (Kim 2011). Also, numerical refocusing can be performed to reconstruct out-of-focus information without mechanical scanning. One limitation of DHM is that numerical refocusing can be performed only within the recorded DOF of the objective. To image information outside the DOF and for gathering accurate

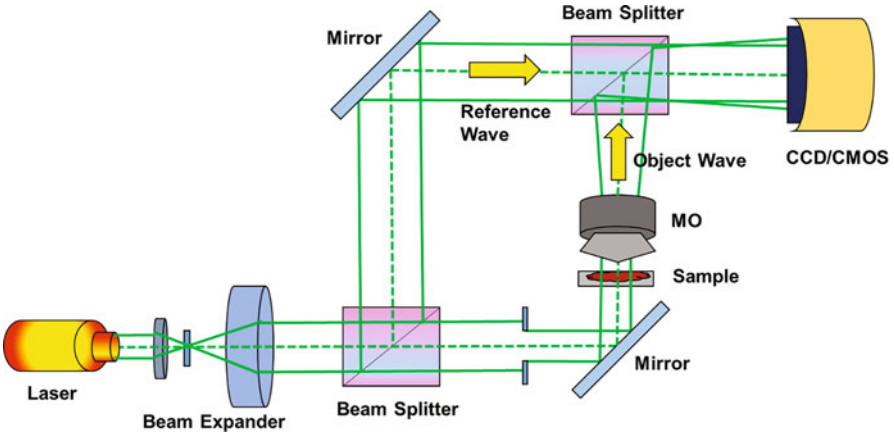

Fig. 3 Basic schematic of digital holographic microscopy

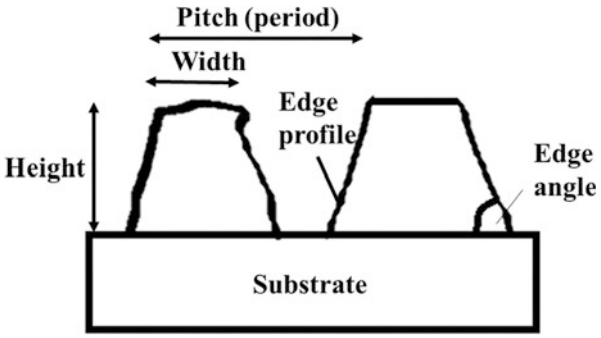

Fig. 4 Schematic representation of measurands in quantitative microscopy (Osten and Reingand 2012)

quantitative information of samples thicker than the DOF, extended depth of focus techniques need to be applied.

Application Areas of Quantitative Microscopy

Quantitative microscopy, as previously stated, measures the structural information of object having dimensions in the range of micro- and nanometers. The most important parameters of measurement in micro- and nanostructures are the widths and heights of the structure along with the distance or pitch between separate entities. Fine quantities like surface profile, edge angles/shapes or the length of a line, and shape/diameter of aperture are also some important measurands that can be of interest in quantitative microscopy. Figure 4 shows the schematic representation of important measurement entities in quantitative microscopy.

Depth of Focus and Field of View Challenges in Quantitative Microscopy

Microscopes have a limited depth of focus, therefore viewing a complete image of a three-dimensional (3D) object in a single view is unachievable. Because the magnification capability of microscopes is inversely proportional to the depth of field, this is the case. Because the specimen in a 3D scene is usually thicker than the microscope lens' allowable focal depth, obtaining a focused image of the whole sample is difficult. The numerical aperture, objective magnification, object distance from objective, objective working distance, and other parameters all influence the depth of field/focus of a microscope objective. The magnification of the objective is the most crucial limitation for expanding the depth of focus. In order to increase the depth of field of the objective, the magnification must be lowered down, thus lowering the resolution of the system. Therefore, it is a trade-off between the extended focal depth and the magnification and resolution of the microscopic system. To increase the axial range, a lot of researchers have worked on the development of extended depth of focus algorithms for obtaining complete structural information of optically thick microscopic samples (Pan 2013; Zalevsky 2010; Valdecasas et al. 2001; Dowski and Cathey 1995).

Techniques for Expanding the Depth of Focus in Quantitative Microscopy

Microscopic systems offer high lateral resolution in the axial range of the system, which called the depth of field or the depth of focus, depending on the object or image space measurements, respectively. While imaging outside this axial range, i.e., imaging optically thicker samples, the image becomes blurred because of the presence of additional phase in the pupil function of the system. This blur function introduces errors in the quantitative measurements due to alteration in phase. Various strategies have been proposed to circumvent this constraint and provide expanded focus depth. They are as follows:

Wavefront Coding

One of the earliest methods used in extending the focal depth of microscopic imaging systems was Wavefront coding (Dowski and Cathey 1995). In this method, the noncoherent optical system was altered by introducing an additional phase mask. This phase mask modulated the point spread function of the objective so that it became insensitive to blur. This alteration in phase allowed wider range of depths of the sample. The sampled intermediate image was reconstructed using digital signal processing by using phase deconvolution. Although this technique proved to be a fast technique and was sensitive to noise, it required modifying the optical hardware of the microscope, which made it a complex process.

Aperture Apodization

Aperture apodization is another technique used for extended focus imaging. The process is done by introducing an additional binary mask in the aperture plane, which performs blocking/transmitting (Zalevsky 2010). This technique provides large number of axial planes but it has the limitations of aperture size. While using small aperture, the system's resolution decreases as the light reaching the image plane gets decreased in intensity.

Image Fusion

Image fusion is another interesting approach utilized in extending the depth of focus. In this technique, different images of the specimen are obtained with different specimen portions in focus of the objective. To accomplish this, either the specimen stage, objective, or detector are scanned to obtain a focal stack. The focal stack contain images recorded at different focal depths of the objective corresponding to different axial planes. The stack is then merged into a single output image that includes all of the input image stack's in-focus sections. The information density and quality of the extended depth of focus image are improved by utilizing image fusion (Zalevsky 2010; Valdecasas et al. 2001). However, limitations associated with image fusion include high computational intensity and a large volume of data being required to form the input stack. Moreover, the scanning speed makes the process very slow, which limits its use in real-time scenarios.

Multiple Focal Plane Microscopy

In order to avoid mechanical scanning of the image plane, another option is to split the illumination beam into numerous fixed beams that are refocused concurrently on different imaging sensors placed corresponding to different axial planes in the extended focus. Another name for this method is Image plane sharing microscopy. Its key benefit is that it eliminates the need for physical scanning (of sample, objective, or imaging sensor). The extended focus images are captured all together in this mode, which allows for high-speed image collection. However, since the imaging beam is divided into many beams, the available optical intensity at each imaging sensor is diminished, thus, lowering the optical data signal-to-noise ratio (Tahmasbi et al. 2014). Another limitation is that the number of axial focal planes available is also limited to the number of times the illumination beam is split.

Multiple Focus Microscopy

For single shot acquisition of extended focus images, another solution is multiple focus microscopy (MFM). It allows rapid and concurrent acquisition of extended

depth of focus images. This is attained by the combination of a multifocus grating (MFG) (placed at the Fourier plane) along with a chromatic correction grating (CCG) and a prism (Pan 2013). This combination separates the principal image into several extended focus images and then projects them on the imaging plane altogether. In this technique, the imaging camera is segregated into different squares, which collect differently focused images (multiple focus images). This technique is limited by the sensor size as the imaging camera can collect a limited number of extended focus images in a single shot.

Wavelength Scanning Method

In the microscope objectives which are not achromatic, various wavelengths produce different focal spots due to chromatic aberration. The sample stage and the chromatic aberrated objective are both fixed in this technique. Light of various wavelengths is employed to illuminate the sample, allowing for prolonged focus image acquisition (Attota 2018). The wavelength scanning technique provides more mechanical stability than traditional stage-scanning optical microscopes because the position of the sample stage is not scanned. The expense of multi-wavelength/tunable wavelength sources is the primary constraint. Furthermore, the detector's wavelength range also restricts the range of extended focal depth.

Artificial Intelligence-Based Methods

Another option for extended focus imaging is to use learning methods to assess the activity function, such as artificial neural networks. To categorize the in-focus and out-of-focus portions of a picture, a decision map is trained. Using proper merging procedures, a mosaic of the in-focus areas is created. The processing time required to train the algorithm to differentiate between blur and in-focus regions is very high and limits the usage of this method. Furthermore, accurate projections need a vast amount of data for training the algorithm (Wei et al. 2021).

Numerical Refocusing Using Digital Holographic Microscopy

Digital holography microscopy is digital holography combined with microscopy. The numerical refocusing property of digital holography is utilized to numerically extract the refocused extended focal images from a single experimentally recorded hologram. This technique avoids the movement of sample physically to different focal regions. Extended focus images are obtained numerically refocusing the amplitude images to different z distances based upon the reconstruction technique used (Anand et al. 2014; Samsheerali et al. 2014). DHM improves the speed of microscopic image acquisition and provides single shot quantitative information

(Pandiyan et al. 2021). The reconstruction distance may be mathematically altered and made as minimal as required (Singh et al. 2014). However, digital refocusing in DHM is limited only within the DOF of the microscope objective. Therefore, it is possible to reconstruct images at positions lying within the DOF range. To extend imaging to further axial planes outside the microscope objective's DOF, other techniques in DHM have been implemented. These include:

(a) **Extended Focused Image (EFI)**: In digital holographic microscopy, the EFI concept has been further explored by P. Ferraro et al. (Ferraro et al. 2006). They emphasized the extended focus image as a combined image from variously focused subareas (EFI). The in-focus regions of each image stack were correctly selected using distance information given by the phase image. As a consequence, the final EFI was built with precision. The fact that this digital holographic EFI technology only works with a single object with an axial dimension bigger than the DOF is a common limitation of this methodology.
(b) **Optical Scanning Holography**: The use of optical scanning holography for EDOF has been provided in reference (Kim 2006). The solution of sectioning is found via Wiener filtering or iterative methods. However, because the complex phase information is not retrieved during processing, this technology can only offer amplitude information and cannot be used for only phase objects.
(c) **3-D Deconvolution**: In reference (Latychevskaia and Gehri 2010), the utility of 3-D deconvolution methods in DHM is presented. The accurate 3D distribution of microsamples is reconstructed by utilizing 3D Point spread function. The basic limitation of 3-D deconvolution is the requirement of large amount of memory. Also, data resampling is a necessity in this method; thus, spatial resolution is degraded.

Adaptive Optics for EDOF Imaging

Recently, the use of adaptive optical elements has been explored for EDOF quantitative microscopic imaging. Tip/tilt, deformable mirrors, spatial light modulators (SLM), are some examples of adaptive optics that can be utilized for EDOF image collection. These adaptive optics are used to change the phase of illumination and shift the focal spot. These types of optics have multiple applications in extended depth imaging (Ho et al. 2017; Salter et al. 2013), autofocusing (Gao et al. 2013), creating optical tweezers for 3D stacking of particles (Dasgupta et al. 2012; Xavier et al. 2012), etc. Another technique for EDOF using an axicon lens is stated by Ong et al. (2013). The use of axicon lens for cone shell imaging to achieve extended focal depth has been presented. A key advantage of these methods in EDOF imaging is high-speed image collection. Adaptive optics technologies and equipment are widely accessible, with biological applications being the most typical use. The

aberrations created in the wavefront owing to modulations are an often cited restriction with adaptive optics.

Extended Focus Quantitative Microscopy Using Liquid Lenses

With the advent of adaptive optics, the evolution of liquid lens also took place. The basic idea behind the liquid lens was to provide a lens with a variable focal length. At first, the idea of a variable focus lens was given by Berge and Peseux (2000), where the efficacy of a transparent drop was studied as a variable focus lens by applying electrowetting effect. A lens can be made from the meniscus of two immiscible liquids with different refractive indices. Electrostatic regulation of the solid/liquid interfacial tension causes a change in the meniscus' curvature, resulting in a change in focal distance.

The concept of variable focus liquid lens was introduced by Oku et al. (2004). They proposed a compact, high-speed variable-focus liquid lens using acoustic radiation. An annular piezoelectric ultrasonic transducer and an aluminum cell filled with degassed water and silicone oil constituted the lens. By applying sonic radiation force from the transducer, the profile of the oil–water interface may be rapidly changed, allowing the liquid lens to be used as a variable-focus lens. Electrically tunable lenses (ETLs) were introduced using similar techniques. These lenses have curvature-changing capabilities that allow for fast axial shifts of the focal plane, allowing for acquisition rates in the order of milliseconds. These liquid lenses are inspired by the human eye and can focus quickly. They have been used in a number of cell biology experiments (Note, Optotune Application 2013). The liquid lenses are made up of an optical liquid that can change its shape by application of external current/voltage or mechanical pressure. Based upon the type of actuation, the liquid lenses are broadly classified as: Mechanically actuated and electrically actuated liquid lenses. Different commercially available variants of tunable focus lenses are available in the market with different nomenclatures. These include electrically tunable lenses (Optotune), tunable acoustic gradient lens (Mitutoyo), etc. A photograph of electrically tunable liquid lens manufactured by Optotune is presented in Fig. 5.

The ETL provides major benefits like:

- High speed focus tuning
- Covers a wide focal range
- Fast control of Z-axis
- No mechanical movement required in Z-axis
- High Axial scanning range
- Compatible with finite and infinite objective lenses
- Vibration-free
- Broadband

Fig. 5 Electrically tunable lens (Optotune n.d.)

Liquid Lenses in Microscopy

Recently, the technology of adjustable focal length lenses or liquid lenses has advanced quickly. Liquid tunable lenses or variable focus lenses have been categorized as: Electrowetting (Berge and Peseux 2000; Hendriks et al. 2005), piezo-hydraulic actuation (Oku et al. 2004), and acoustic radiation force tunable lens (Koyama et al. 2011). Liquid lenses can be easily introduced into microscopic setups to serve a wide range of applications, including extended-depth-of-field imaging (Liu and Hua 2011). Developing high-speed adjustable lenses for quick focusing is another application (Oku et al. 2004), along with speeding up the procedure of axial focus changing in two-photon microscopy (Lee et al. 2010), and spherical aberration compensation caused by refractive index mismatch in tissues (Tsai et al. 2007).

As discussed earlier, extending the depth of focus of a microscope objective is a tedious procedure and requires different complex algorithms or mechanical movement of microscopic components to achieve larger depth of focus. Such procedures are time-consuming and cannot be implemented in real time. A liquid tunable lens or a commercially available electrically tunable lens provides a compact and fast solution for extended depth of field imaging. Recent researches have shown a huge interest of researchers for exploring the application of liquid lenses in microscopic imaging (Fahrbach et al. 2013; Jabbour et al. 2014; Haslehurst et al. 2018; Grewe et al. 2011; Jiang et al. 2015). Most researchers have focused on the use of tunable lenses to extend the depth of focus, depth of field, axial scanning range, and field of view of microscopic systems using liquid lenses. Rapid axial traversing,

autofocusing, and increased depth of field can all be done by incorporating an electronically tunable lens (ETL) in a microscope.

One of the earliest realizations of ETL in microscopic setup was implemented by (Grewe et al. 2011). They presented a combination of liquid tunable lens with a conventional microscope for in vivo two-photon imaging of neuronal populations. After that, ETL was introduced in confocal microscopy setup in reference (Jabbour et al. 2014; Jeong et al. 2016) for optical axial scanning and high speed quantitative measurements with a large field of view. The advantage of ETL over traditional z-scanning for fast axial measurements has been demonstrated. In another application, tunable lens has been employed in multifocal fluorescence microscopy for depth-sensitive epithelial cancer measurements (Zhu et al. 2014). Color imaging has been done at multiple depths by using a tunable lens with a microlens array and the benefit of vibration-free multiplane imaging has been explained. ETL has also been employed in light sheet microscopy in reference (Fahrbach et al. 2013; Haslehurst et al. 2018; Zhai et al. 2019; Hedde and Gratton 2018). The usage of ETL has been explored for improving axial resolution, and imaging in fluorescence light sheet microscopy. Also, fast selective plane light sheet microscopy has been presented where the uniformity of light sheet is maintained using ETL. The efficacy of ETL has been shown for rapid light sheet microscopy and no involvement of mechanical scanning has been implied upon. ETL has been employed in phase imaging in microscopy (Rodrigo and Alieva 2014; Zuo et al. 2013) for high speed and rapid quantitative phase measurements. Image stacks have been acquired by scanning using ETL and through-focus images have been acquired to extract phase information. Apart from that ETL has been employed in temporal focusing microscopy (Jiang et al. 2015) for fast 3D measurements and for in vivo multifocal photoacoustic microscopy (Li et al. 2014). Here, the speed of ETL has been utilized for rapid measurements and for fast focal point tuning. A comparison of extended depth of focus techniques in microscopy based upon their scanning speed, performance, axial range has been presented in Table 1.

The utility of liquid lenses in conventional microscopy has been described in the previous section. Apart from this, application of the electrically tunable liquid lenses has been explored in DHM for quantitative microscopic imaging. In (Schubert et al. 2014), the electrically tunable liquid lens has been used in a self-interference configuration in DHM where it has been employed to modify the amplitude and phase of the illumination light entering the objective. This is done to reduce the effects of coherence of illumination light on quantitative phase images. In another application, ETL has been used for modulating the phase of the reference wave to cope up with the phase changes in the object wavefront (Deng et al. 2017). Here, the phase of the reference wave is changed to match with the curvature of object wave so as to compensate any phase distortions. This is helpful in compensation of the curvature changes in the two arms. Furthermore, ETL has also been employed in digital holography to test aspheric lenses by producing deformed wavefronts (Wang et al. 2017). In this context, the ETL produces an adjustable deformed wavefront that

Table 1 Comparative analysis of various extended depth of focus techniques in quantitative microscopy

Extended DOF techniques in quantitative microscopy	Mechanical scanning	Quantitative information	Image extraction	Speed (in ms)
Wavefront coding (Dowski and Cathey 1995)	No	No	Computational	Hundred ms
Image fusion (Valdecasas et al. 2001)	Yes	No	Direct	Few hundred ms
Wavelength scanning (Attota 2018)	Yes	No	Direct	Few hundred ms
Multifocal plane microscopy (Tahmasbi et al. 2014)	No	No	Direct	High-speed (instantaneous)
Machine learning based (Wei et al. 2021)	No	No	Computational	Few ms
Adaptive optics (Salter et al. 2013)	No	Dependent	Direct	Few ms
DHM only (Colomb et al. 2010)	No	Yes	Direct	Few ms
Sectioning and merging (Colomb et al. 2010)	Yes	Yes	Computational	Few seconds
Optical scanning holography (Kim 2006)	Yes	Yes	Computational	Few seconds
3D deconvolution (Latychevskaia and Gehri 2010)	No	Yes	Computational	Few seconds
Tunable lens (Grewe et al. 2011)	No	Dependent	Direct	A few ms

helps in the reduction of aspheric lenses' high gradient. A double-exposure measurement can be used to estimate the absolute phase of an aspheric surface by decomposing it into two resolvable ones. Different ETL curvatures corresponding to ETL control currents can be used to test different aspheric lenses. In another application of ETL, it is employed to acquire out-of-focus holograms to retrieve the object's phase by employing synthetic aperture imaging in (Lee et al. 2015). Instead of using a mechanical translation stage, ETL is used to defocus images and perform synthetic aperture imaging. A calibration algorithm has been generated to register images, correct the image for different magnifications, and compute the axial locations of the image planes. Apart from these, ETL is used for autofocusing in DHM. Here, ETL focuses the out-of-focus plane information extracted using DHM reconstructions. For evaluation of focused image, a contrast-based autofocus criterion using sharpness metric is described (Kim and Lee 2019). However, the main limitation is that such autofocus algorithms lack efficiency when dynamic specimen is being imaged. A novel method of quantitative imaging of human red blood cells in a volumetric space has been presented in (Barak et al. 2020). Here, ETL has been used to image RBCs present at different focal depths in a volume and their quantitative profile has been obtained. Another method in DHM utilizing variable magnification zooming with ETL has been presented in (Sanz et al. 2020). Here, the

application of ETL for variable zooming in holographic microscopy is explored and presented. ETL is used to reconstruct images at different z-planes using numerical refocusing with different magnifications. However, using a single ETL provides extended plane imaging and multiple ETLs need to be used for zooming into extended planes. An application of ETL with variable aperture controlled objective is presented in (Barak et al. 2021a; Barak et al. 2021b), where a single platform is used to provide telecentricity and zooming in microscopic domain. Tables 2 and 3 show the biological and industrial applications of ETL, respectively, in microscopic domain.

Evaluation of Uncertainty of Measurement

Measurement uncertainty is defined to be a "non-negative parameter characterizing the dispersion of the quantity values being attributed to measurands, based on the information used." Here, a quantity value is defined to be a "number and reference together expressing magnitude of a quantity," and a measurand is defined to be the "quantity intended to be measured" (Joint Committee for Guides in Metrology (JCGM/WG 2) 2006). The "*Guide to the Expression of Uncertainty in Measurement*," or GUM for short, is the generally accepted guide to all things measurement uncertainty related. All measurements are subject to measurement uncertainty. This is for the simple reason that one cannot be infinitely precise or accurate.

Hence, there are certain factors that always influence the measurement and these may be considered as Type B components. Before making any measurement, it has to be ensured that the system has the proper traceability and the record of environmental conditions is mandatory. To start with, first evaluate the Type A uncertainty, which is normally called the repeatability. For this, normally ten readings are taken at a single point of measurement and its mean is calculated dividing it by number of readings. Then standard deviation and standard uncertainty is evaluated as in Eq. (1).

$$S(x) = \sqrt{\frac{1}{n-1}\sum_{j=1}^{n}\left(x_j - \bar{x}\right)^2} \tag{1}$$

where, $S(x)$ is the Estimate of std. deviation, n *i*s the no. of elements, $\bar{x}$ is the mean value, and x_j is the value at *j*th reading.

After that, all of the unknowns should be combined together. To do so, however, one must first convert all previously observed uncertainties into standard deviations. Standard uncertainty is applied in the following phases. In a measurement uncertainty distribution, this is effectively one standard deviation. After then, using the equation of uncertainty propagation, one may aggregate all standard uncertainties (GUM-2008 2008). For this, Eq. (2) must be applied:

$$u(y) = \sqrt{\sum_{i=1}^{n} c_i^2 u(x_i)^2} \tag{2}$$

Here, $u(y)$ is the "combined standard uncertainty," c_i is a sensitivity coefficient, and x_i is an uncertainty component.

Expanded Uncertainty Although the combined standard uncertainty $u(y)$ is commonly used to express the uncertainty of many measurement results, for some commercial, industrial, and regulatory applications (for example, health and safety), a measure of uncertainty that defines an interval around the measurement result y within which the value of the measurand Y can be confidently declared to lie is often

required. Expanded uncertainty, recommended symbol U, is the measure of uncertainty used to achieve this criterion, and it is calculated by multiplying $u(y)$ by a coverage factor, indicated symbol k. This is given by Eq. (3)

$$U = k.u(y) \tag{3}$$

where U is the Expanded Uncertainty, $u(y)$ is the consined uncertainty, and k is the constant (Coverage Factor).

However, quantifying type B occurs in a somewhat different way compared to type A. In comparison to the normal distribution of measurements caused by type A uncertainities, a measurement distribution due to type B uncertainities often takes the form of a rectangular or triangular distribution, with the distribution width upper and lower limits being estimated by the experimenter. This is due to the fact that the type B distributions create errors that tend to remain constant throughout all measurements. A rectangular distribution is used if it is believed that it is equally probable for the uncertainty value to fall anywhere between the upper and lower limits. This is often used as the default distribution for type B uncertainties. A standard deviation can then be obtained from the type B distribution. In order to find the standard deviation of a rectangular distribution, Eq. (4) is used as follows:

$$s = a/\sqrt{3} \tag{4}$$

where "s" is the standard deviation, and "a" the limits of the rectangular distribution. A triangular distribution should be used if it is believed that the uncertainty value is more likely to fall in the middle of the upper and lower limits and less likely to fall near each limit.

The uncertainty parameters for extended depth of focus microscopy using ETL have been mentioned in the next section followed by the uncertainty budget. In the uncertainty budget, some of the parameters are not taken as their contribution is negligible.

Factors Affecting Measurement and Leading to Uncertainty of Measurement

There are several factors that affect the accuracy of measurements. These are called the uncertainity factors that affect the system parameters like repeatability, reproducibility, etc. The Type B uncertainty factors considered for the microscope system with a tunable lens are provided as follows:

(U1) **Resolution**: All optical microscopes are limited to a maximum resolution of around 200 nm. The microscope camera, for instance, has its own finite resolution. The resolution of a microscope is measured using the Rayleigh resolution criterion expressed as in Eq. (5):

$$d = \frac{0.61\lambda}{\text{N.A.}} \tag{5}$$

$$\text{N.A.} = n^{*}\text{Sin}(\mu) \tag{6}$$

where, "d" is the spatial resolution, λ is the imaging wavelength, N.A. is the numerical aperture of microscope given by Eq. (6), n^{*} is the Index of refraction, and μ is the 1/2 of angular aperture.

(U2) **Imperfect optics and sensor**: Imperfect optics may blur the edges of the object and an imperfect sensor might not pick up on the contrast that the measurand has compared with its surroundings.

(U3) **Image analyzer software**: It's also important to consider the level of uncertainty involved with any image software analysis. Perhaps the software has trouble differentiating the microsphere from its surroundings, or it isn't built to handle microspheres larger than a specific size. All of these issues must be considered.

(U4) **Contrast**: Only imaging dark objects with large index of refraction.

(U5) **Reproducibility**: When a microscope's experiment findings are repeated, the results gained through an experiment, a should be attained with a high degree of reliability yet again.

(U6) **Temperature effect**: The temperature variations due to heating of ETL and due to changes in external environmental conditions both lead to uncertainty in measurements.

(U7) **Coma error due to gravity**: When ETL is placed vertically with respect to the optical axis, the coma error gets introduced in the microscope due to displacement of lens liquid by the effect of gravity.

(U8) **Wavefront error**: The wavefront error produced by ETL is 0.5λ at 0 mA, 525 nm, which is another factor for uncertainty.

(U9) **Optical retardance**: The other uncertainty factor is optical retardance produced by ETL. It provides an optical retardance of 6.1 nm at 590 nm.

(U10) The microscope parameters like NA, FOV, magnification, DOF, working distance, resolution get distorted due to introduction of ETL in the microscopic arm. This is because ETL disrupts the conventional telecentricity of the microscope. This leads to type B uncertainty in microscopic measurements.

Combined Uncertainty							$u_t(y)$	v_e	
Expansion Coefficient (k)							1.633	22.6	100.0%
Expanded Uncertainty [$ku_t(y)$]							2.074		
							3.39		

Conclusion

In summary, a survey of extended depth of focus algorithms techniques has been presented for extending the axial range in quantitative microscopy. Various computational and experimental methods have been discussed to extend the focal depth of a microscope ranging from decades old to recently developed new methodologies. The study concludes the advantage of using liquid lenses over other conventional techniques in microscopy for extending the axial depth range. It has been presented that liquid lenses prove to be a fast and vibrationless solution for imaging in the extended focus regions. Various applications of tunable liquid lenses in microscopy have been presented at length ranging from biological to industrial and dynamic scenarios. The discussions are provided in such a way that the reader might get familiar with the usage of liquid lenses in microscopic systems as well as can have a better understanding of what technique must be applied for a certain application area. We have discussed most of the utilities and benefits of liquid lenses in microscopy, however, there are certain limitations and precautions that need to be taken care of while introducing tunable lens in microscopic setups. These include the problem of telecentricity, image shift, poor resolution, coma aberrations, wavefront errors, gravity factors, etc. Most of the researches have proposed some potential solutions to these challenges; however, all the approaches that have been used in microscopy using liquid lenses are still exploring their utilization with better imaging quality. Further improvements in fabrication technologies of liquid lenses and advancements in extended depth of focus techniques is still a matter of research. In the final section of this chapter, an example has been quoted to evaluate the uncertainty of measurement by taking into account the various factors affecting the measurements as Type B components and the uncertainty budget is also presented.

stated that atoms work like a transducer, converting microwave E-Field and H-Field strengths into observable changes in optical signals. A real-time application of microwave in this domain was first investigated by Christopher and their group, where they have sensed RF electric field strength by measuring the frequency split of electromagnetically induced transparency signal in the presence RF field applied between the Rydberg states (Holloway et al. 2014a). The beauty of this experiment was that the RF E-Field strength could be made directly traceable to Planck's constant thus reducing the uncertainties associated with other methods of measurement of E-Field using various classical probes. After that, numerous research was done by various researchers and still undergoing utilizing the optical and microwave field interaction with Rydberg atom-based systems, such as broadband RF E-Field sensing, frequency modulation, frequency up-conversion, frequency down-conversion, etc. The interaction of electromagnetic field with atomic system results in specific phenomena such as EIT and ATS (Boller et al. 1991; Marangos 1997; Anisimov et al. 2011), which also form the basis of all these applications. Therefore, in this chapter first we will discuss basic properties of Rydberg atoms, followed by the interaction of electromagnetic field with two-level atomic system. Later, EIT and ATS phenomena in a three-level system and applications will be discussed. Some of the devices based on these phenomena such as electric field sensors, microwave mixers as well as receiver for communication purposes will also be discussed in detail. As Rydberg atoms are the heart of the Quantum Microwave Measurements, different methods of fabrication of atomic vapor cells with their advantages and disadvantages will also be discussed in brief.

Introduction

The term quantum microwave measurement stands *for the measurement of microwave parameters by exploiting the properties of atomic energy levels and related transitions in presence of optical/laser signal. In other words, it can be stated* that atoms *work like a transducer, converting microwave E-Field and H-Field strengths into observable changes in optical signals. A real-time application of microwave in this domain was first* investigated *by Christopher and their group, where they have sensed RF electric field strength by measuring the frequency split of Electromagnetically Induced Transparency signal in the presence RF field applied between the Rydberg states* (Holloway et al. 2014a). *The beauty of this experiment was that the RF E-Field strength could be made directly traceable to Planck's constant thus reducing the uncertainties associated with other methods of measurement of E-Field using various classical probes. After that, numerous research was done by various researchers is still undergoing utilizing the optical and microwave field interaction with Rydberg atom-based systems, such as broadband RF E-Field sensing, frequency modulation, frequency up-conversion, frequency down-conversion,* etc. *The interaction of electromagnetic FIELD with atomic system results in specific phenomena such as EIT and ATS* (Boller et al. 1991; Marangos 1997; Anisimov et al.

2011), *which also form the basis of all these applications. So, in this chapter first we will discuss basic properties of Rydberg atoms, followed by the interaction of electromagnetic field with two-level atomic system. Later, EIT and ATS phenomena in a three-level system and applications will be discussed. Some of the devices based on these phenomena such as electric field sensors, microwave mixers as well as receiver for communication purposes will also be discussed in detail. As Rydberg atoms are the heart of the Quantum Microwave Measurements, different methods of fabrication of atomic vapor cells with their advantages and disadvantages will also be discussed in brief.*

Rydberg Atoms

Rydberg atoms are named after Johannes Rydberg, who introduced an empirical formulation to determine energy levels of the highly excited atom (Scientists Make First Observation of Unique Rydberg Molecule 2022). Rydberg atoms are basically excited atoms having one or more electrons with a very high principal quantum number n (Gallagher 1988), where higher the value of n, larger the distance of electrons from the nucleus. This results in several distinct characteristics. First, higher value of n results in outermost electrons being weakly bound to the nucleus, making them highly sensitive to the environmental conditions of the atom. The sensitivity of atoms idealizes them to behave as ideal probe for detection of external electric (Holloway et al. 2014a, 2017) and magnetic fields (Sedlacek et al. 2012). Second, the strong interaction between the collectively excited Rydberg atoms induces dipole blockade effect (Comparat and Pillet 2010; Gallagher and Pillet 2008), which is further used in applications such as quantum information processing (Lukin et al. 2000; Saffman et al. 2009) and quantum computation (Lim et al. 2013). Moreover, the lifetime of the Rydberg state is of the order of 100 μs (Beterov et al. 2009) which is higher in comparison to low-lying excited states with the order of around 23 ns (Steck 2021). The other properties include low-ionization energy, larger transition dipole moment, level frequency spacing of the order of MHz and GHz, etc. which are proven to be quite useful for microwave and RF electrometry. These distinct characteristics of Rydberg atoms have made it a popular research topic in the field of quantum optics as well as for atom photon interaction. The dependency of the above discussed properties of Rydberg atoms on principal quantum number, n, is shown in Table 1. The size of the atom increases with the scaling of the factor of n^2

Table 1 Dependency of properties of Rydberg atoms on principal quantum number n

Property	Scaling as n
Size	n^2
Lifetime	n^3
Dipole moment	n^2
Ionizing field	n^{-4}
Polarizability	n^7

which implies as the principal quantum number of the atomic state increases, the size of the atom increases. The transition dipole moment also scales as n^2, leading to ease in coupling of two excited Rydberg states with the help of RF and microwave fields. The low ionization energy obeying the scaling law as n^{-4} suits perfectly well for sensing of external RF and microwave E-fields (Heckötter et al. 2017).

Atom-Photon Interaction

There are infinite number of energy states available for transitions in an atomic ensemble, each defined by a different energy level. Invention of lasers in 1960, by T. H. Maiman, led to the possibility of detailed study in this domain. The understanding of atom-photon interaction physics helps in manipulating the optical response of atom-based system. The interaction of excited atom and a photon can be understood in the easiest way for a single atom in two-level system. A closed two-level atomic system means that the relaxations from the other states in continuum are neglected and any population leaving the excited state relaxes to the ground state. Figure 1 shows a 2-level system coupled with a resonant laser light of frequency ω_L.The incident light excites the atom from ground state $|1\rangle$ to the excited state $|2\rangle$, and the excited state decays to ground state with decay rate γ_{21} with lifetime of $T = 1/\gamma_{21}$. Although an infinitely large number of atomic states are available for transitions in the atomic medium, the monochromatic light beam emitted by laser can couple only those two energy states which are resonant with the laser frequency, thus reducing the problem to a two-level system. A semiclassical approach can be taken to analyze this problem, where the light is treated classically and atom is treated quantum mechanically. Density matrix formulism (Blum 2012; Rand 2016) is used to treat this system mathematically. It is equivalent to using a wave function and representing the states of a quantum system, giving complete details regarding population and coherences in between the states.

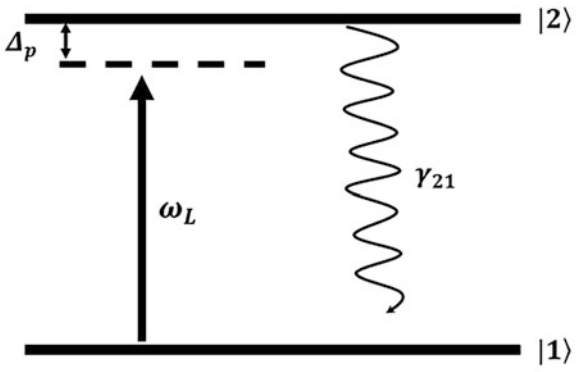

Fig. 1 Schematic representation of two-level system interacting with optical frequency ω_L

The wave function for a two-level system can be written as

$$|\psi >= C_1|1 > +C_2 \mid 2 > \tag{1}$$

Density matrix operator is expressed as follows:

$$\rho =| \psi > <\psi \mid \tag{2}$$

$$\rho = [C_1(t)|1 > +C_2(t)|2 >]\left[C_1^*(t)<1|+C_2^*(t)<2|\right] \tag{3}$$

$$= |C_1(t)|^2|1 > <1| + C_1C_2^*(t)|1 > <2| + C_1^*C_2(t)|2 > <1| + |C_2(t)|^2|2 > <2| \tag{4}$$

The density-matrix elements are

$$\rho_{11=}|C_1(t)|^2 \tag{5}$$

$$\rho_{12=}\ C_1C_2^*(t) \tag{6}$$

$$\rho_{21=}\ C_1^*C_2(t) \tag{7}$$

$$\rho_{22=}|C_2(t)|^2 \tag{8}$$

where, ρ_{11}- Probability of occupying the ground state
ρ_{22}- Probability of occupying the excited state

The diagonal matrix elements ρ_{11} and ρ_{22} give the probability of occupancy of population in level $|1>$ and $|2>$, respectively, while the other two off-diagonal elements give the coherences between the states.The same density matrix formulism can be further applied to systems having more than two atomic energy levels. In case of a multiple-level atomic system problem, the values of density matrix elements are averaged over states. In an ensemble of n systems in the state $|\psi_n\rangle$, the density matrix operator can be expressed as follows

$$\rho = \sum P_n \mid \psi_n > <\psi_n \mid \tag{9}$$

where P_n is the probability of finding a particular system in state $|\psi_n\rangle$.

This two-level system can serve as a unit for any atomic transition-based application, as it is easy to understand and mathematically analyze as well. This system can be coherently manipulated, leading to absorption of electromagnetic signal and other related phenomena.

However, the real-world scenarios involving atomic transitions in excited atom ensemble may be much more complex, varying from three-level atomic systems to six-level system or more. In case of three or higher-level system, these coherent manipulations lead to various constructive and destructive phenomena between the excitation pathways of atomic transition. The next section focuses on the phenomena of EIT and ATS in three-level atomic system.

Electromagnetically Induced Transparency (EIT)

The interplay of electromagnetic (EM) waves with a three-level atom system incites interferences in between the pathways of transition within the atom. Figure 2 shows the two, three-level models, which have been used to study EIT, by different groups (Agarwal 1997; Fulton et al. 1995; Anisimov and Kocharovskaya 2008), namely, cascade (Fig. 2a) and lambda (Fig. 2b) model. It demonstrates the two pathways of transitions between ground and higher energy states of atom due to interaction of weak (probe) and strong (pump) optical fields with the atom. When the frequency of weak coupling field (probe laser) is resonant with the frequency of transition from $|1>$ to $|2>$ atomic levels, this gives an absorption spectrum. When a stronger coupling field (pump laser) is applied in resonance with the $|2>$ to $|3>$ atomic transitions, these two states get further mixed to form pairs of dressed states, having almost equal energy. Destructive quantum interference is observed from each of these dressed states, due to opposite signs of the excitation amplitude (Holloway et al. 2014a), resulting in transparency in absorption spectra. This phenomenon of quantum interference in which transparency in absorption spectra is observed when a second stronger light of different frequency is incident on the system that has already absorbed a light of specific frequency is referred to as EIT.

Harris et al. reported EIT for the first time in 1989 (Imamoğlu and Harris 1989): Interference in between the dressed states led to zero in absorption profile. An experimental proof was reported in 1991 by Boller et al. (Boller et al. 1991) which exhibited an opaque atomic transition completely transparent at its resonance frequency.

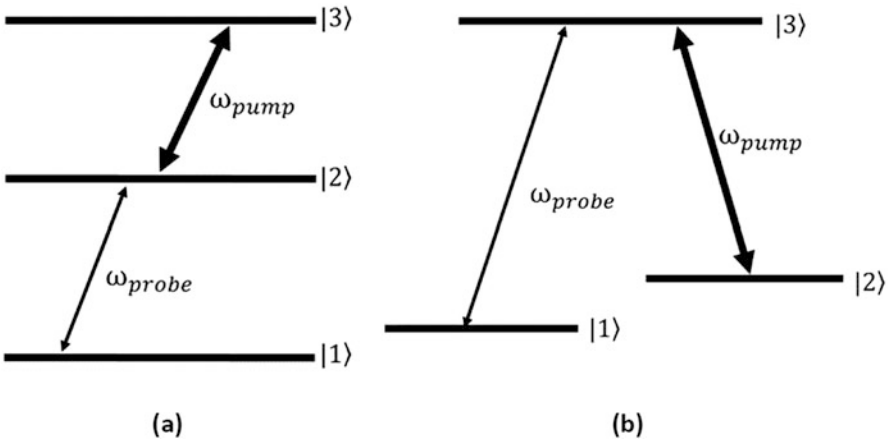

Fig. 2 Energy-level diagrams for three-level atom: (**a**) Ladder (cascade) model with weak probe light for coupling states $|1\rangle$ and $|2\rangle$, and strong pump beam for coupling states $|2\rangle$ and $|3\rangle$; (**b**) lambda model with weak probe light for coupling states $|1\rangle$ and $|3\rangle$, and strong pump beam for coupling states $|2\rangle$ and $|3\rangle$

Autler-Townes Splitting (ATS)

Autler-Townes splitting is a quite similar looking phenomenon to EIT, as both have a characteristic dip in the absorption spectra. It is very important to understand to identify the difference in between the two phenomena. The major difference lies in the parametric regime in which these two phenomena are observed. EIT is observed as a consequence of destructive interference (Marangos 1997; Fleischhauer et al. 2005) while on the contrary ATS is observed as a gap in between two resonances which is a consequence of the constructive interference (Davuluri et al. 2015). Autler and Townes (1955) reported this effect in 1995 on OCS molecule and depicted its microwave transition splitting in distinct components when a stronger microwave field is used to couple one of the resonant states with a third energy level. With the passage of time, lasers were developed and this effect had also been reported in optical regime (Hänsch and Toschek 1970). Availability of laser fields provided researchers with enormous opportunities to provide high-energy beams of fixed frequencies to study atom-photon interactions.

EIT and ATS in Three-Level Atomic System

As mentioned before, both EIT and ATS phenomena are quite similar in appearance and are also accompanied with cancellation in absorption of light, which is resultant of interferences between transition amplitudes (Anisimov et al. 2011; Anisimov and Kocharovskaya 2008; Tan and Huang 2014; Giner et al. 2013; Abi-Salloum 2010; Lu et al. 2015; Rawat and Dubey 2020); it becomes very important to realize whether reduction is observed due to EIT or ATS. Salloum (Abi-Salloum 2010) worked in this aspect and figured out the major difference between the two.

Figure 3a represents probe laser absorption curves for ladder model as shown in Fig. 2a. The Rabi frequencies of probe and pump lasers are represented as Ω_{pr} and

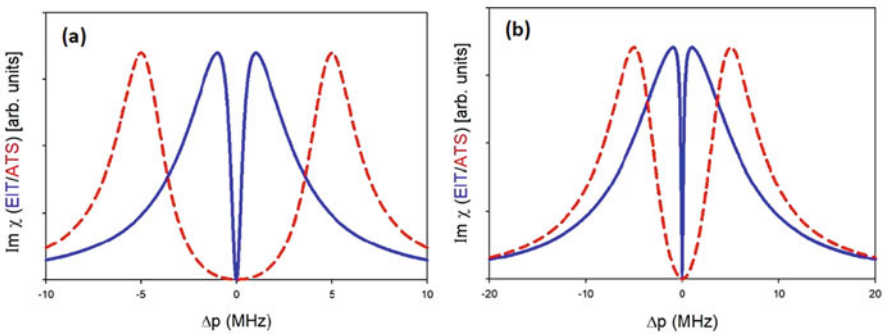

Fig. 3 The blue- and red-dashed curves represent the EIT and ATS, respectively, for (**a**) three-level ladder and (**b**) three-level lambda model. The probe laser's Rabi frequency for both is $\Omega_{pr} =$ 500 kHz. The pump laser Rabi frequency for EIT and ATS in both the models is $\Omega_{pu} = 2$ MHz and 10 MHz, respectively

Ω_{pu}, respectively. Both the curves are observed in a condition when $\Omega_{pr} \ll \Omega_{pu}$, i.e., weak probe regime, with $\Omega_{pr} = 500$ kHz and $\Omega_{\mathrm{pu}} = 2$ MHz. The blue curve, showing reduction in the value of absorption at $\Delta_{\mathrm{p}} = 0$ when Rabi frequency is less than the decay of the transition (i.e., $\Omega_{pu} \ll \gamma_{21}$), represents EIT, and given by:

$$\Delta_p = \omega_{21} - \omega_{pr} \tag{10}$$

Here, Ω_{pr} and Ω_{pu} are the Rabi frequencies for probe and pump lasers, respectively.

Δ_{p} is the detuning of the laser lights from the transitions
ω_{21} is the frequency for transition between level 1 and level 2
ω_{pr} is the frequency for probe laser
The decay rate from level $|2\rangle$ to level $|1>$; $\gamma_{21} = 6.06$ MHz
The decay rate from level $|3\rangle$ to level $|1>$or $|2>$; $\gamma_{31} = \gamma_{32} = 1$ kHz

The red-dashed curve showcases reduction in absorption, which represents the ATS effect when the pump Rabi frequency exceeds the decay of the transition, i.e., $\Omega_{pu} > \gamma_{21}$. The pump Rabi frequency for this case is 10 MHz, while keeping all other atomic parameters same. Figure 3b represents probe light absorption for lambda model in weak probe regime. The blue and red-dashed curves represent EIT and ATS phenomena for pump Rabi values 2 MHz and 10 MHz, respectively. It is quite observable that both of these effects occur in strong coupling field regime, but there lies a minimum threshold value for transition from EIT to ATS, and this threshold value is the decay rate (γ_{ji}) for the states on which probe light is tuned. In case when $\Omega_{pu} < \gamma_{21}$, the transparency in absorption is termed as EIT, whereas when the applied pump laser's Rabi frequency goes beyond this value, the transition from EIT to ATS is noticeable.

Till now, we have discussed the properties of Rydberg atom, interaction of two-level atomic system with optical field, followed by EIT and ATS phenomena in the three-level atomic system. Researchers have extended this work by exploring the various new phenomena and changes in the discussed phenomena by application of external RF/microwave fields on Rydberg atom-based system. Now, we will discuss the application of these quantum phenomena in microwave measurements.

Utilizing Advanced Laser-Atom-Interaction Phenomena in Microwave Applications

Rydberg Atom as E-Field Sensor

The conventional E-field measurement sensors are essentially antennas or probes, which operate in a designated frequency band, along with associated electronics and suitable microwave receiver or spectrum analyzer, etc. The antennas receive

the electromagnetic energy, the associated electronics converts it into received microwave power, and it can be read through the receiver or analyzer. The antennas and probe are made of metal or contain a metallic sensing element (dipole, monopole, patch, etc.) in them. The principles of EM wave reception on these antennas and probes are well established. However, the major issue with these is the fact that the metallic element of the antennas, while measuring the E-field, also perturbs the field. This results in inaccuracy to the measured field. Also, these antennas are very frequency selective and cannot cover the entire microwave spectrum and are hence needed to be designed for each different frequency band, as required. There are also size constrains, as the size of probe is quite large for lower frequencies (below 1 GHz) and very small for higher frequencies (above 30 GHz).

Rydberg atom-based sensors offer a unique solution to all above problems in the E-field sensing. As mentioned before, application of external RF field upon the atom already in higher state results in further coupling on the Rydberg states. The energy gap of the coupling Rydberg states is as per the frequency of external RF signal. As there are infinite number of Rydberg states available, the transitions/resonances can occur over a wide range of frequencies ranging from hundreds of megahertz (MHz) to terahertz (THz); this can serve as a single E-field sensor for entire frequency range in the spectra. Also, the atomic dipole moments for these frequencies range can be very large, thus making Rydberg atoms a perfect candidate for E-field sensing (Holloway et al. 2017).

Figure 4 shows a schematic of Rydberg atom-based E-field sensor. In this setup, first a weak probe beam is used to excite the alkali (Rubidium) atoms from ground state to first excited state, then a strong counterpropagating pump laser is applied, tuning the atoms from first excited state to a Rydberg state. This leads to the detection of EIT signal at the photodetector as shown in Fig. 5a.

When an external RF field is applied on the vapor cell, two Rydberg states are coupled depending upon the frequency of the RF signal applied. The EIT lines split

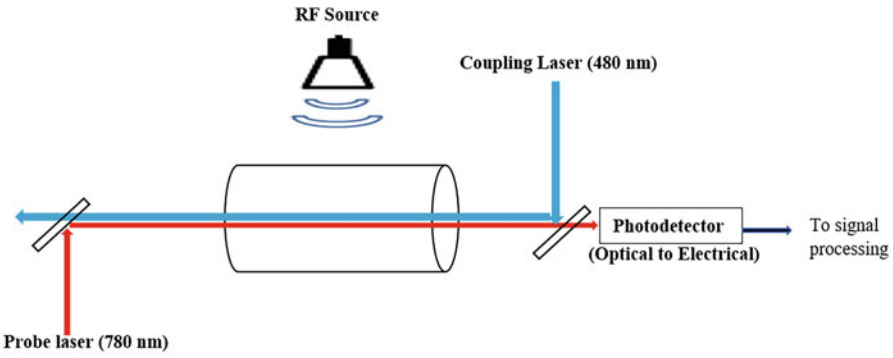

Fig. 4 Schematic of atomic electric field sensor for sensing RF fields

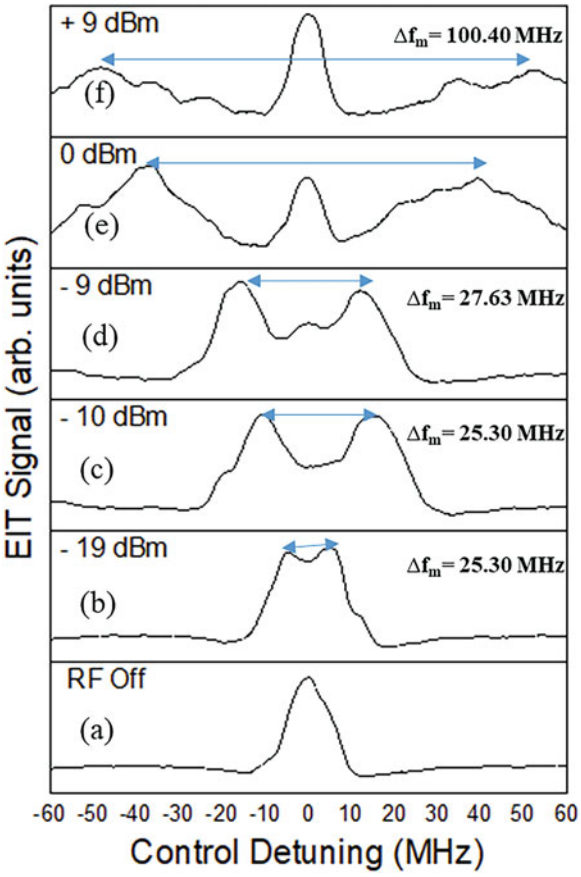

Fig. 5 Illustration of splitting of EIT peak with increasing RF power of signal generator at 15.09 GHz: (**a**) RF off; (**b**) – 19 dBm; (**c**) – 10 dBm; (**d**) – 9 dBm; (**e**) 0 dBm; and (**f**) 9 dBm. Splitting, indicated by double-sided arrow between the off-set peak, increases with increasing RF power. (Adapted from Rawat and Dubey (2020))

into a pair of two ATS lines. This splitting increases with increase in RF signal power. This is shown in Fig. 5b–e.

Rawat and Dubey (2020) have studied this for coupling $52D_{5/2}$ state to $53P_{3/2}$ using RF signal of frequency 15.09 GHz and obtained results in terms of Δf_m (frequency difference between two ATS peak) corresponding to the applied signal power (in dBm). The amplitude of electric field of RF can be calculated using the following relation (Holloway et al. 2014a):

$$| E | = \frac{h\Delta f_m}{d} \tag{11}$$

where Δf_m - is the frequency difference between two ATS peak,

d- is the electric dipole moment of the Rydberg transition,
h-Planck's constant

Table 2 Measured amplitude of RF E-field strength for various RF power levels

Power (dBm)	Δf_m (MHz)	$\|E\|$ (V/m)
19	9.61	0.44
−10	25.30	1.15
−9	27.63	1.26
0	77.12	3.52
9	9100.40	4.58

Adapted from Rawat and Dubey (2020)

These results with electric dipole moment of 1451.27×10^{-29} C-m (for $52D_{5/2}$ state to $53P_{3/2}$ transition) are compiled in Table 2.

However, this method has certain limitations. Since the Rydberg states' energy levels are quantized and not all can be coupled with each other, this phenomenon is only valid for limited range of frequencies, i.e., 500 MHz to 1 THz (Gordon et al. 2019). This problem can be resolved by exploiting the full quantum response of the Rydberg atom interaction with RF fields that even includes off-resonance AC Stark shift readout (Anderson et al. 2018), enabling direct ERMS measurement of continuous-frequency RF field frequencies over tens of gigahertz with a >60 dB dynamic range.

Also, this method becomes highly ineffective when E-field applied is too weak for ATS to occur (Gordon et al. 2019). This problem can be addressed by making use of Rydberg atom as a mixer, as discussed in the next section.

Rydberg Atom as Mixer

While using Rydberg atom as E-field sensor, it was observed that the ATS peaks in the absorption spectra split upon application of external RF field. However, this method is ineffective while dealing with weak RF signals, i.e., when the field is too weak for ATS peaks to split. The minimum detectable RF field capable of being detected with ATS and causing AT peak separation equivalent to EIT line width (Holloway et al. 2014b) is given by:

$$E_{\mathrm{AT}} = \frac{\lambda_p}{\lambda_c} \frac{2\pi\hbar\Gamma_{\mathrm{EIT}}}{\rho_{\mathrm{RF}}} \tag{12}$$

where λ_p is the wavelength of the probe laser,

λ_c is wavelength of the coupling laser,
Γ_{EIT} EIT line width,
ρ_{RF} is element of dipole matrix element of RF Rydberg transition field, and
$\hbar$ is Planck's constant

Several techniques were earlier explored for measurement of weak RF fields, such as optical cavities (Yang et al. 2018), narrow EIT line-width frequency-

modulated spectroscopy (Yang et al. 2018), homodyne detection with Mach Zehnder Interferometer (Kumar et al. 2017), etc. Simons and his group (Gordon et al. 2019; Simons et al. 2019) have suggested using Rydberg atoms as mixer for measuring phase and frequency of weak RF fields. The experimental setup is similar to E-field sensing, but an additional local oscillator is used to generate another RF field. The two signals interfere with each other in Rydberg states of the atom and generate a low- and high-frequency component. The intermediate frequency (IF) representing the difference between frequencies of two applied RF fields is detected by optically probing the Rydberg atoms (Simons et al. 2019). This IF signal modulates the probe laser intensity enabling the measurement of weak RF fields. Also, the phase associated with the IF signal corresponds to the measurement of phase of the RF field directly.

The setup for the experiment conducted is as shown in Fig. 6. The probe laser of wavelength $\lambda_p = 852$ nm (D_2 transition wavelength) excites the Cesium (Cs) atoms from ground state ($6S_{1/2}$) to first excited state ($6P_{3/2}$). These atoms are further excited to state $34D_{5/2}$ by counterpropagating coupling laser tuned to $\lambda_c = 511.148$ nm resulting in transparency in the absorption spectra for the probe laser.

In a conventional RF mixer, two RF signals are fed to the mixer. The resultant signals are sum and difference of the two input signals. RF mixers are used for up-conversion and for down-conversion of frequencies, usually in the case of transmitters. The Rydberg atom-based RF mixer setup also works in the similar way. The two different weak RF signals are incident on a vapor cell and can be represented as

$$E_1 = E_{\mathrm{LOC}} \cos(\omega t_{\mathrm{LOC}} + \varphi_{\mathrm{LOC}}); E_1 \approx E_{\mathrm{AT}} \tag{13}$$

$$E_2 = E_{\mathrm{SIG}} \cos(\omega t_{\mathrm{SIG}} + \varphi_{\mathrm{SIG}}); E_2 \leq E_{\mathrm{AT}} \tag{14}$$

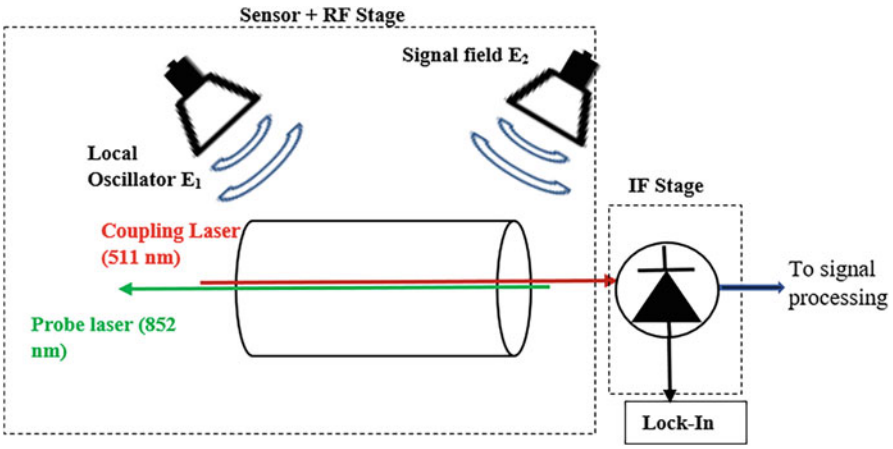

Fig. 6 Experimental setup for detection of weak electric field and measurement of phase of RF fields

Here, E_{AT} represents minimum detectable RF field (as per Eq. 12).

In experiment carried out by Gordon et al. (2019), the local oscillator is tuned to 19.626 GHz (in resonance with $34D_{5/2}$ to $35P_{3/2}$ Rydberg transition of Cs). The other RF signal to be sensed is tuned at 19.626090 GHz, so that it gets detuned by 90 KHz (intermediate frequency) from the other field.

These two RF signals interfere with each other and generate a high-frequency component and a low-frequency component. One of the electric components oscillating at higher frequency oscillates at ω_{LOC} resonant with Rydberg transition while the other component oscillates at a frequency $\Delta\omega = \omega_{LOC} - \omega_{SIG}$ resulting in modulation of probe laser intensity, which can be measured on photodiode and as EIT spectrum. Now the resulting frequency of the signal turns out to be 90 KHz which makes E_{SIG} detectable even when it is below $E_{AT.}$ The final output on photodiode is further passed to lock-in amplifier with reference same as the intermediate frequency. The lock-in output voltage is proportional to the applied weak field (Gordon et al. 2019).

The same setup can be used to detect the phase of the RF signal. The resultant second RF which oscillates at same frequency as ω_{LOC} creates a beat note which can be demodulated by the Rydberg atoms. The change in phase can now be measured as phase of demodulated signal and is directly associated with the incident RF signal (Simons et al. 2019).

Rydberg atom when used as a mixer overcomes limitations of conventional RF mixers (such as lineality, operating range, sensitivity, etc.) and also has other advantages such as tuning and narrow band frequency selection. The Rydberg mixer's ability to separate and distinguish between signals of various RF frequencies with a frequency resolution order of magnitude finer than the response bandwidth of the Rydberg transition makes it more advantageous. These characteristics indicate that the vapor cell can be used to characterize the weak RF E-field efficiently, enabling the development of quantum E-field sensors for broad frequency range and better sensitivity.

Rydberg Atom as a Receiver for Communication

Traditional antennas have been in use since a very long time for transmission and reception of signals. Different types of antennas are used for this purpose such as microstrip patch antenna, helical antenna, etc. It basically acts as a transducer which converts RF signals to electrical signals and vice versa. However, their uses are limited to the applications based on their size, frequency range, gain, and transmission requirements. Detection of time-varying and modulated RF fields using Rydberg atoms have offered new possibilities in the field of RF sensing and communication. Currently, researchers are focusing on Rydberg atom-based communication system because of its advantages over conventional antenna. A smaller single antenna can be used for a wider range of frequencies from few MHz to 100 GHz. It eliminates the necessity of demodulation circuitry as signal can be read out directly from the optical laser beam. The signal received is free from any electromagnetic interference, since the signal is received through optical laser beam.

Distinct EIT peaks can be used for locking, and message signal can be modulated over RF signals of different frequencies resulting in coupling of distinct Rydberg states. A vapor cell containing both Rb and Cs atoms can together allow multiband communication through a single atomic antenna. The communication becomes independent of the size limitation in the traditional antennas.

Different groups have worked and showed detection of various kinds of time-varying and modulated signals (Anderson et al. 2021; Meyer et al. 2018; Deb and Kjærgaard 2018; Holloway et al. 2019) using Rydberg atom-based system. Some of them include Rydberg atom-based transmission system for digital communications (Meyer et al. 2018), atom radio-over-fiber (Deb and Kjærgaard 2018), and a multiband atomic AM and FM receiver for radio communications (Anderson et al. 2021).

The basic principle for an atomic vapor cell to act as an antenna (receiver) lies in the fact that EIT observed explores a number of large differential dipole moments for different Rydberg states of an atom. H. S. Rawat, in his work (Rawat 2012), has demonstrated the use of Rydberg atom as a receiver for analog communication, and the experimental setup for the same is shown in Fig. 7.

In this setup (adapted from), counterpropagating probe and coupling laser beams are passed through vapor cell to excite the atoms to the Rydberg state. The absorption spectra is continuously monitored to observe the EIT. An audio signal is then AM modulated with a microwave source and incident on the vapor cell. The change in the quantum state of Rydberg atom due to this AM signal is observed by the detector. The detectors' output signal is directly connected to an output device (oscilloscope or speaker). Now, when both probe and coupling lasers are tuned at

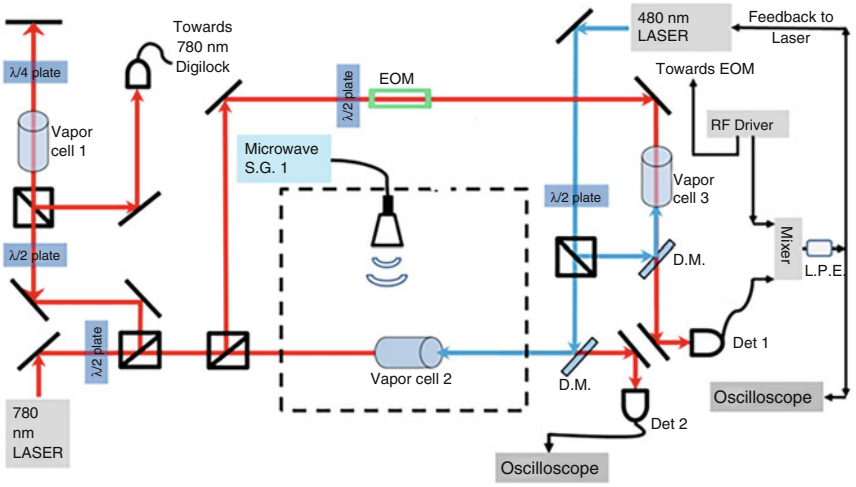

Fig. 7 Schematic of the experimental setup for atom-based receiver for analog communication. (Adapted from H. S. Rawat (2012))

specific transition frequencies, the output signal at detector will be same as the message signal in the AM-modulated signal.

In the schematic shown in Fig. 7, the probe laser (red) is locked at 780.24 nm by tuning the atomic states $5S_{1/2}$ and $5P_{3/2}$ via the frequency reference technique, achieved through "vapour cell 1." The coupling laser (blue) is tuned at 479.788 nm by coupling the states $5P_{3/2} - 61S_{1/2}$, locking at these transition levels by locking at the EIT peak detected at photodetector (Det 2), and feeding the signal to "vapour cell 3."

Afterward, ATS is observed in EIT for "vapour cell 2," by applying the AM-modulated microwave field. The microwave signal chosen for this experiment has frequency 15.175 GHz (for coupling the Rydberg states $61S_{1/2}$ with $61P_{3/2}$).

The amplitude-modulated message signal using signal generator is incident directly onto the vapor cell 2 (after the laser is locked at one of the inflection points of EIT peak obtained through vapor cell 3). The incident microwave field now interacts with the Rydberg atoms in vapor cell 2. This impacts the dc signal already observed for EIT and results in variation of the amplitude of E-field due to the presence of message signal. Since the message signal was an audio signal, the output from the detector (Det 2) is directly given to the speakers and the exact message signal was received without any delay or loss of the signal.

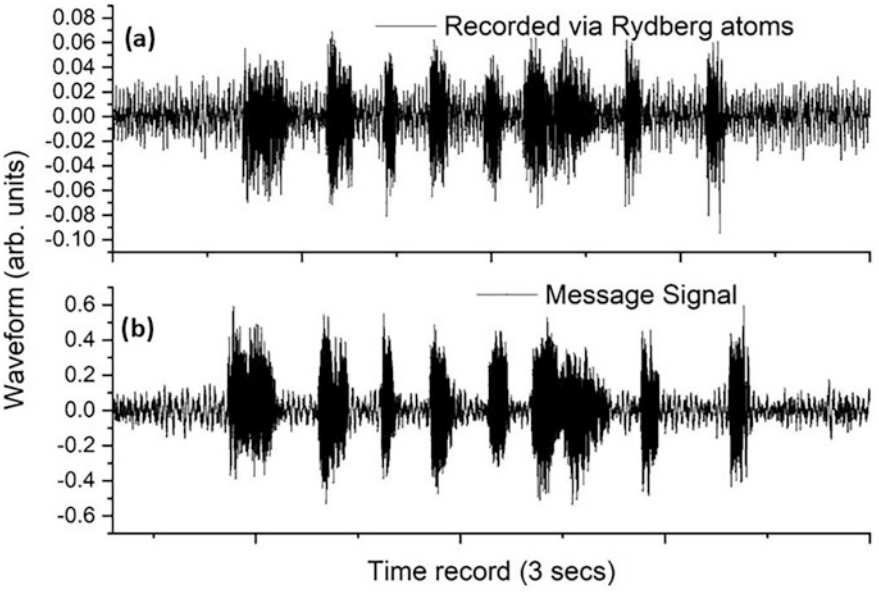

Fig. 8 The recorded waveforms of audio message signal amplitude modulated on the microwave. The message signal is "Hello mic testing alpha one check check": (**a**) The message signal recorded before modulation; (**b**) the message signal obtained via Rydberg atoms without any demodulation circuit. (Adapted from H. S. Rawat (2012))

Figure 8 shows the comparison of the output signal at detector (Det 2) (Fig. 8a) and the input audio signal (message signal) used for amplitude modulation of the 15.175 GHz microwave signal (Fig. 8b).

The important observation over here is that to receive the message signal, one does not require any demodulation and the message signal can be retrieved as it is when the atoms inside vapor cells are properly controlled.

It can be said that change in the quantum states of Rydberg atoms takes place, when a modulated signal is incident on it and that change in quantum states is heard/observed through speakers. These Rydberg atoms automatically demodulate the signal, without any extra demodulating circuitry, and one can get a direct readout of the message signal without any delay and with high fidelity.

This depicts that Rydberg atom as a receiver has major advantages over the existing conventional techniques, namely,

- It eliminates the necessity of demodulation circuitry as signal can be read out directly from the optical laser beam.
- A single receiver (Rydberg atom-based vapor cell) of such a smaller size can be used for RF signals ranging from 100 MHz to 500 GHz.

Fabrication Methods of MEMS Alkali Vapor Cells

As clear from the previous sections, alkali atoms inside the vapor cells containing the alkali atoms are at the heart of all the discussed applications and other various phenomena arising from laser-atom interactions of alkali metals. Fabrication of these vapor cells and miniaturizing them has been a task of major importance since the 1950s when absorption of microwave radiations by Cs/Rb vapors led to the discovery of atomic time and frequency standards (Lombardi et al. 2007; Sullivan 2001). Fabrication process of atomic vapor cell has always been a tedious task because

- The size of the cell has to be small.
- It should be sealed hermetically to protect vapors of alkali atoms and buffer gases from leaking.
- Moreover, the cell should be designed in a way that it allows light to pass through the atoms, and the material from which the cell has to be fabricated should neither be reactive with atomic vapors nor magnetic in nature.
- The size of the cell proved to be problematic, when the results showed instabilities of time parameters.

Several different methods are used in microfabrication of atomic vapor cell. These methods are based on three fundamental ideas:

1. Filling of pure liquid alkali metals
2. Chemical reaction of alkali compounds
3. Dispensing of alkali vapor from the solid-state dispensers

The following section discusses these in brief along with their limitations.

Filling of Pure Alkali Metals

Pipetting

Liew et al. (2004) proposed one of oldest known methods for fabrication of atomic vapor cell. The fabrication part included three main steps – first, fabricating a glass-silicon preform. Second, alkali metal is then directly introduced via pipetting in a high-vacuum chamber. Lastly, a buffer gas is then introduced at a pressure around 50 to 200 Torr, and then the second glass is anodically bonded to the silicon preform.

Pure alkali metal and appropriate mixture of buffer gases are obtained in this process, but manipulation in anaerobic condition is quite a difficult job.

Glassblowing

This process involves etching of two holes on a silicon wafer, which are connected through a channel. The second step includes anodically bonding a pyrex glass below the silicon wafer. The second glass wafer to be bonded above the silicon wafer is first drilled to have a hole, which has to be placed over one of the holes on the silicon wafer. This hole is further attached to a vacuum line for proper dispensing of alkali metal. After filling of the cell with buffer gas and alkali metal, the connectivity is cut off using a gas torch (The chip-scale atomic clock-recent development progress 2022).

Though pure cesium vapor is obtained from this method, the incompatibility of this method with MEMS technology has been a drawback in using this method (Knapkiewicz 2018a).

Chemical Reactions

Although the above discussed methods are useful, they have their limitations. The glass-blowing technique provided excellent results, but the size of the cell was not favorable for MEMS technology and pipetting method comes with negative impact of low-temperature anodic bonding (Liew et al. 2004). Hence, new methods for fabrication of atomic vapor cell were discovered by researchers and are discussed below:

On-Chip Chemical Reaction

In chemical reaction approach, silicon-glass preform is fabricated using anodic bonding method with holes etched on the surface of silicon wafer. The chemical reaction takes place inside the cavity in UHV chamber, which is as follows

$$B_aN_6 + C_sCl \rightarrow B_aCl + 3N_2 + C_s \quad (15)$$

Heating the preform at 120 °C induces decomposition of barium azide into Pure Ba and nitrogen gas. Then the silicon glass preform is covered with another layer of glass which is anodically bonded at voltage 1 kV and at a temperature about 200 °C.

Further, the final reaction takes place where elemental Cs is obtained along with barium chloride (Liew et al. 2004; Knapkiewicz 2018a).

This method offers advantage as the reactants are stable at room temperature. But, the by-product barium chloride, which is white in a color, can add difficulty in transmission of light through the cell. Although, the leftover nitrogen can act as buffer gas in this method.

Off-Chip Chemical Reaction

The same process of chemical reaction as described in the previous method was revised by Eklund et al. (2008). The major difference in two process is that, in this method, the same chemical reaction (Eq. 15) takes place inside an ampoule outside the glass-silicon preform at a temperature about 180 °C. In this way, pure Cs/Rb can be obtained and this can be filled in the form of a few drops in the preform cavity. Lastly, buffer gases are filled and another layer of glass wafer is hermetically sealed over silicon glass preform.

This method is quite advantageous since the problem produced by the presence of barium chloride is resolved. Moreover, desired mixture of buffer gases can be used and pure alkali metal can be introduced in the cell preform.

UV-Induced Chemical Reaction

Physical deposition process can also be used to deposit a thin layer of Cs/Rb azide. Researchers (Woetzel et al. 2013, 2014; Liew et al. 2007) have presented different ways to pippete the solution of Cs/Rb azide onto the inner surface of the cell. In this method first, the glass silicon preform is prepared using anodic bonding with holes already etched onto the silicon wafer. Then a thin film of cesium azide is deposited inside the preform. The second layer of glass is anodically bonded onto the silicon wafer. When the cell is exposed to UV radiation, Cs azide decomposes into pure Cs and nitrogen.

However, in this method, the layer of Cs azide lacks uniformity, which can result into variation in the amount of alkali metal produced in different cells. Besides this, it is not a very cost-effective method as well.

Off-Chip and On-Chip Dispensing

Apart from anodic bonding, other different types of bonding such as eutectic, thermo-compression as well as glass frit bonding can also be used to bond silicon with glass.

Off-Chip Dispensing Using Eutectic Bonding

The silicon wafer and glass are bonded through eutectic bonding, and then the preform along with another glass wafer, kept at a safe distance from it, is placed inside the vacuum chamber. Rb in liquid form is evaporated, so that it could condense in the cell preform resulting into deposition of droplets of Rb. Finally, the glass silicon preform is covered with glass wafer through thermo-compression bonding via a layer of indium (Petremand et al. 2010; Mileti et al. 2010; Vecchio et al. 2010).

However, eutectic bonding is not an ideal method to use because of its inability to attain proper vacuum levels and sustaining optical properties of the cell for longer periods (Knapkiewicz 2018a).

On-Chip Dispensing Using Anodic Bonding

One of the most favorable techniques for fabrication of MEMS cell is dispensing of alkali metal, when laser is irradiated inside the sealed cells. There are three major requirements for fabrication using this method, i.e., an optical chamber, a dispenser containing alkali metal (Saes Getters), and a connection channel. A cesium disperser is placed inside already bonded silicon glass preform. Irradiation of laser (near NIR regime) is used to dispense Cs out of the dispenser. With the rise in temperature to near about 720 °C, chemical reaction takes place between Cs and other reducing agents present in the dispenser. The quantity of the alkali metal produced is dependent on the laser power as well as on the time duration of radiation (Douahi et al. 2007; Knapkiewicz et al. 2010).

This method proved to be one of the best methods for fabrication of vapor cells because of the availability of micro dispensers (Knapkiewicz 2018b). The only requirement of this process is a laser in IR regime, irrespective of its wavelength. The amount produced can be directly controlled from power and time duration of irradiation. Although the size of dispenser can be one of the drawbacks, a recent research showed that this technique can be used for mass-scale production (Knapkiewicz 2018a).

Conclusion

Rydberg atom-based spectroscopic technique for the measurements of microwave parameters, driven by Electromagnetic Induced Transparency (EIT) and related phenomena, is a promising technology for microwave measurement and other applications. One of its major advantages lies in its ability to provide direct traceability to all existing microwave measurements against universal Planck constant. This technique also possesses other advantages like broadband nature, better sensitivity, no constrains related to size of device, and whether to be used as sensor, receiver, or other purpose. The tunability of the Rydberg states, based on probe and pump lasers and RF fields applied, allows for better selectivity and higher sensitivity simultaneously.

This chapter has described the role and impact of microwave in ongoing quantum physics study in term of hyperfine structure tunability which can lead to various new phenomena as well as provide platform to fine tune various experiments. The role of Rydberg atoms of alkali metals and various microwave devices such as sensors, mixers, receivers, and modulators are described in detail. Many more interesting phenomena can occur, if Rydberg series of ions, molecules, or excitons in semiconductors are used. Research involved with Rydberg atoms can have many more real applications, if cold atomic vapors are used instead of thermal or room-temperature vapors. In the recent years, cold atomic vapors have been used endlessly to produce unidentified types of novel matter, such as Rydberg molecules, cold neutral plasmas, and collective Rydberg matter. These cold Rydberg atoms have also found application in the creation of large-scale defect-free atomic arrays, the realization of high-fidelity quantum gates, the simulation of quantum spin models, and the proof of single-photon-level optical nonlinearity.

Research has also to find newer, faster ways to fabricate vapor cells. Now, even on-chip vapor cells are being fabricated to achieve portable Rydberg atom-based system. The emergence of MEMS-compatible vapor cell fabrication will lead to fast commercialization of such systems in many applications. These achievements also pave the way for continued success in Rydberg atom-based QIP and open up exciting possibilities for developing scalable quantum computation and simulation in the coming decades.

Abstract

In recent times, microwave absorbing materials have been playing crucial roles in various applications including communication, stealth, and shielding. The working of these materials largely depends on the careful characterizations that include measurement for morphological, electrical, and physical properties followed by microwave characterization. A significant amount of work has been carried out in exploring the physical, electrical, and magnetic properties of various organic and inorganic materials, polymers, nanocomposites, meta-surfaces, and meta-materials suitable for employing them as microwave absorbing material. Both intrinsic and extrinsic properties of materials play an important role in the

development of microwave absorbing materials. The design of the functional materials largely depends on the optimization of the intrinsic properties of the raw material such that required extrinsic properties can be achieved. Depending on the application, a wide range of such parameters need to be characterized to test the performance of the material in a particular frequency range. An excellent microwave absorbing material is required to possess main properties like high reflection loss, wide bandwidth, low weight, lower coating thickness, chemically inactive, and cost-effectiveness. To measure these properties, the microwave characterizations can be difficult to implement in various scenarios such as when (1) operating in wideband frequency range; (2) size, shape, and thickness of the material are not uniform; (3) the sample of material is in difficult state for microwave characterization, i.e., semisolid or liquid; (4) there is an unavailability of the specific complex instrument or software; and (5) using novel materials with poor repeatability. All these factors contribute to the uncertainty in the measurement of performance parameters of microwave absorbing materials. In this chapter, the relationship of fundamental aspects of electromagnetic (EM) materials with the performance of the microwave absorption is presented. Indicative literature is presented showing the major sources of uncertainty and their contribution in the measurement. Various applications are discussed where characterization of this relationship becomes a key factor.

Introduction

Microwave materials (MMs) have received considerable interest over the years for their applications in stealth, communications, electronics, automotive, and avionics technologies. In defense applications, one of the main objectives is to detect threats as early as possible and be undetectable to increase survivability in the area monitored by advanced radar and microwave technology. In communication, these materials are used for various requirements such as miniaturization, EMI shielding, temperature stability, thermal conductivity, etc. Worldwide, multidimensional research is going on for the development of efficient absorbers using these microwave materials, generally referred to as microwave absorbing materials (MAMs) or radar absorbing materials (RAMs) or simply microwave absorbers (MAs). After initial widespread use of Salisbury screens and Jaumann absorbers, a significant amount of work has been carried out in studying the microwave absorption characteristics of organic and inorganic materials, polymers, nanocomposites, meta-surfaces, and metamaterials. The microwave absorption behavior of grading honeycomb composites (Zhou et al. 2015), frequency-selective surface (FSS) impregnated absorbers (Lee et al. 2015), graphene structures (Xu et al. 2015;

Olszewska-Placha et al. 2015; Zhang et al. 2015), different shapes of materials (Lv et al. 2015; Liu et al. 2015), and doping elements (Hong et al. 2016) has been studied.

Due to the unique properties of graphene and oxide, a large literature is available for the development of MAMs synthesized using graphene composites (Wu et al. 2015; Wang et al. 2015; Balci et al. 2015). As an excellent representative of a carbon material, reduced graphene oxides (R-GO), the thinnest and most lightweight 2D materials of the carbon family, have also been reported to exhibit excellent dielectric properties (Feng et al. 2016; Yi et al. 2017). Recently, molybdenum disulfide (MoS_2) has also been actively investigated for their microwave absorption properties due to its unique electrical, optical, and mechanical properties (Zhang et al. 2016; Xie et al. 2016). The composites of R-GO and MoS_2 have also shown promising absorption performance; however, wideband performance has not been achieved, and repeatability is a standing issue (Ding et al. 2016). For achieving wide bandwidth, the multilayering technique using metamaterials and FSS embedding is widely being adopted and has shown considerable improvement in the absorptivity of the materials (Chen et al. 2018; Yigit and Duysak 2019). A large literature on magnetic microwave absorbers is also available (Yao et al. 2016; Yuan et al. 2016; Wang et al. 2016), but the need for frequency-selective and low-density MAMs remains a challenge. A recent study of clustered $NiFe_2O_4$-rGO nanocomposite has been carried out showing highly tunable electromagnetic properties for selective-frequency microwave absorption (Zhang et al. 2018). These studies are crucial since control of dielectric and magnetic losses can be understood which directly helps in determining the microwave absorption mechanisms in MAMs.

Most recently, high-performance, tunable MAMs required for various applications are being actively researched upon using multidimensional approaches and materials discussed above (Hu et al. 2019; Tang et al. 2019). Tunable MAMs using tailored dielectric properties are also being explored and have shown significant improvement in the absorption properties (Quan et al. 2017; Cheng et al. 2016; Pan et al. 2017). A significant amount of effort has also been made in the field of development of lightweight, textile-based MAMs which have crucial applications in camouflaging and stealth applications (Song et al. 2016, 2017). Depending on the application, such as the absorbers required in EMI and EMC applications, characterization techniques differ, and thus a separate set of properties is studied (Khalid et al. 2017). For example, infrared emissivity is the parameter to quantify the heat transfer. MAMs, having a high emissivity in the microwave spectrum, are crucial in a wide array of applications, such as electromagnetic interference mitigation, stealth technology, and microwave remote sensing and radiometer calibration (Houtz and Gu 2017). Apart from absorption characteristics, the mechanical requirements, e.g., ultrathin, flexibility, lightweight, thermal stability, etc., are to be catered for application-based products and are widely stressed upon by the researchers (Song et al. 2016; Shanenkov et al. 2017; Jia et al. 2018; Machado et al. 2019; Aguirre et al. 2018).

In this chapter, the relationship of fundamental aspects of electromagnetic (EM) materials with the performance of the microwave absorption is presented.

The focus of the chapter is to demonstrate the metrological aspect in the characterization of these materials required for analyzing the absorption performance. The major sources of uncertainty in the measurement of the MAMs are discussed in detail. The chapter also covers a large number of new methods and applications being prevalent in the modern-day systems. A large set of references related to the topic is presented in the chapter for readers to get more details. In this chapter, the considerations to be made for the accurate measurement of microwave parameters, such as reflection, transmission, insertion loss, shielding effectiveness, electrical properties, and radar cross section, required for gauging the performance of microwave materials are discussed in detail. Depending upon the application in hand, the required measurements can be set up with the minimum uncertainty by considering and evaluating the different sources of error. For example, the absorption characterization is important for realizing microwave absorbing materials, and it depends upon the dielectric, magnetic, reflection, transmission properties of the microwave material. Hence, each parameter has to be carefully measured to estimate the absorption property of the said material.

Electrical Properties of Materials

How the materials interact, intercept, and absorb the incident wave, schematically shown in Fig. 1, has to be physically and analytically defined to help the researchers to avoid the trial-and-error method in the development of MMs and their use for any application. For example, various microwave techniques can be implemented to characterize the absorption at macroscopic level. These microwave absorbing materials are widely used in various applications such as electronics, stealth, and communication technologies. While analyzing the microwave absorbing absorption, the impedance matching is critical for maximum absorption, which can be given as

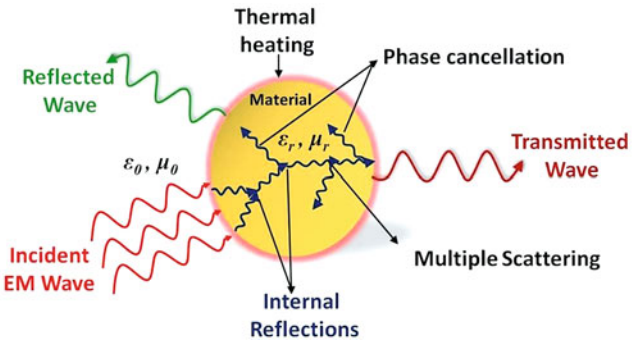

Fig. 1 Simple schematic representation of main mechanisms of EM wave and material interaction

$$\frac{Z_{in}}{Z_0} = \sqrt{\frac{\mu_r}{\varepsilon_r}} \times \tanh\left(j\frac{2\pi ft}{c}\sqrt{\mu_r\varepsilon_r}\right) \tag{1}$$

where μ_r is the relative permeability, ε_r relative permittivity, f is the frequency in Hz, c is velocity of light in m/s, and t is thickness of sample in m. The thickness of the material t is limited by the quarter wavelength cancellation law. For an ideal absorption, $Z_{in}/Z_0 = 1$, showing a perfect match between the free space and the sample. Using the characteristic impedance of the material, the reflection loss (RL, in dB) can be calculated as

$$RL(dB) = 20\,log\left|\frac{Z_{in} - Z_0}{Z_{in} + Z_0}\right|. \tag{2}$$

For 90% and 99% absorption, the return loss should be less −10 dB and −20 dB, respectively.

Depending upon how the material acts with the incident EM wave, the materials can be broadly classified as dielectric, semiconductor, or conductors. There may be more categories which again will largely depend upon the interaction with the incident wave. The major electromagnetic materials and their properties are given in Fig. 2. From the metrological point of view, the selection of characterization method, measurement setup, and corresponding uncertainty evaluation largely depends on the material under test (MUT). Therefore, once the class of the material is identified, further selections can be made accordingly. This point is further discussed in the subsequent sections, wherein the specific characterization will be employed for the specific MUT.

Moreover, the classification of the materials for microwave applications can also be based on the macroscopic properties exhibited by the material. Some examples are given in Fig. 3, which are grouped based on wave interaction, properties in different orientations, and number of constituents.

The classification of materials in Fig. 2 shows the broad categories of materials and their properties in general. The properties of any material can depend on the shape, size, geometry, propagation parameters, electrical transport properties, etc. These properties for electromagnetic materials are classified as intrinsic

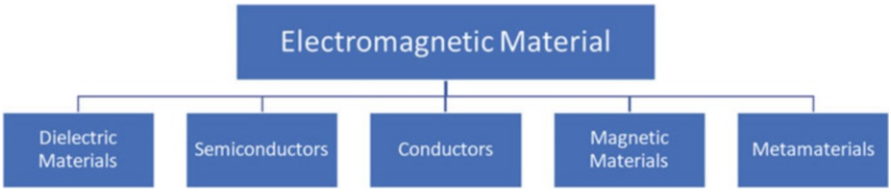

Fig. 2 General categories of electromagnetic materials based on their properties

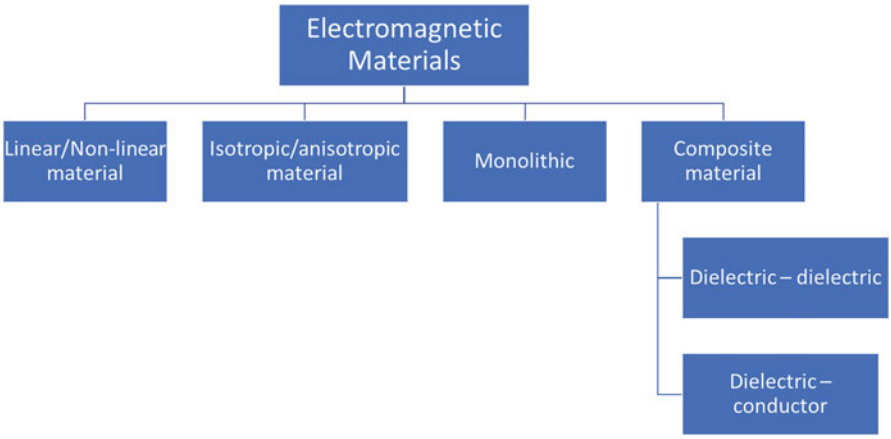

Fig. 3 General categories of electromagnetic materials based on their macroscopic properties

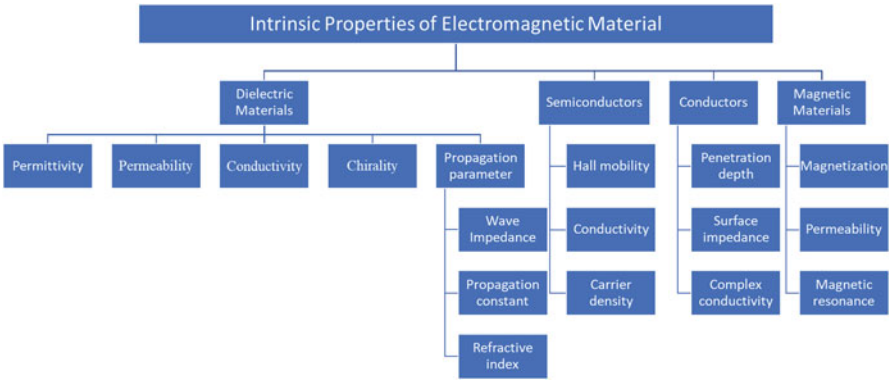

Fig. 4 Important intrinsic properties of different electromagnetic materials

(independent of size and geometry) and extrinsic (dependent on size and geometry) properties. Few of the important intrinsic properties of electromagnetic materials are given in Fig. 4. These properties play a crucial role in deciding the use of the material for a particular application and development of functional materials of desired extrinsic properties. For instance, the dielectric materials are most widely used as microwave absorbers due to their bulk parameters, and their structure and thickness can play a monumental role in achieving the desired extrinsic properties such as characteristic impedance, reflectivity, operating frequency, etc. In the next section, the use of the intrinsic properties to achieve the desired extrinsic properties is elucidated for microwave absorbing materials.

Microwave Absorption Principles

The essential principle of microwave absorption is to convert the microwave energy into thermal energy that dissipates into the environment through various absorption mechanisms. The absorption mechanisms of these materials are dependent on the intrinsic properties of the material, including:

- Heterogeneity of the composite and its effect on the wave propagation
- Electrical and magnetic properties (i.e., complex permittivity, permeability, conductivity, etc.)
- Morphological parameters such as shape, size, density, and cohesion of the composite materials
- Layered system of composites
- Thickness ratio in the multilayered system

The thickness of the material t is an important parameter while fabricating the MAM. It is limited by the quarter wavelength cancellation law and thereby can be taken as

$$t = \lambda_0/4 \times 1/\sqrt{\mu_r \varepsilon_r}. \tag{3}$$

The thickness parameter is also studied, and the lower bound for the thickness to bandwidth ratio is given (Rozanov 2000). The Rozanov limit given in the paper specifies that for the nonmagnetic MAM; the thickness to bandwidth ratio is limited to 1/17.2 at the 10-dB absorption level. Similar inequalities are given for narrow-bandwidth and magnetic materials. The Rozanov limit is computed from the inequality given as

$$|\ln \rho_0|(\lambda_{\max} - \lambda_{\min}) < 2\pi^2 \sum_i \mu_{s,i} d_i \tag{4}$$

where the operating band specified as $\lambda_{\min} \ldots \lambda_{\max}$ is the lowest possible reflectance, d_i is the thickness of *ith* layer (in case of multilayer system), and $\mu_{s,i}$ is the static permeability of *ith* layer.

Also, the absorption mechanisms in the materials are dependent on the intrinsic properties of the material such as dielectric and magnetic properties (complex permittivity and permeability) as well as the morphological parameters such as shape, size, density, and cohesion of the composite materials. The permittivity originated from electronic, ion, and intrinsic electronic and interfacial polarization can be described in terms of relaxation formula:

$$\varepsilon = \varepsilon_\infty + \frac{\varepsilon_0 - \varepsilon_\infty}{1 + (\omega\tau)^2} \tag{5}$$

where ε_0 and ε_∞ represent permittivity for angular frequency $\omega \to 0$ and $\omega \to \infty$, respectively, and τ is the relaxation time for polarization of composite. The microwave absorption can be enhanced by fabricating the effective absorbing material of favorable bulk parameters as well as by using advanced EM techniques such as multilayering, FSS imprinting, meta-surfaces, and metamaterials. However, in this chapter, the absorption enhancement techniques are not discussed, since the scope of the chapter is contained only to the metrological aspects.

Material Characterizations

The microwave material as an absorber is usually characterized using the recommendations given in IEEE Std. 1128 published in 1998 (IEEE 1998). However, the standard has limitation of the frequency range up to 5 GHz only which may not suffice for the current-day needs. Therefore, the revision to the standard is expected to address the frequency extension and may be including the modern test setups for the characterization of the absorbers. The IEEE Std 1128 focuses on the measurement methods for different levels, starting from the evaluation of (1) material bulk parameters, (2) reflectivity, and (3) practical use of the absorbers in the anechoic chambers/open area test site.

Characterization of Material Bulk Parameters

The most often used characterization techniques for measuring the bulk parameters of the materials include nonresonant and resonant methods. As the names suggest, the nonresonant methods are a characterization over a frequency range, and on the other hand, the resonant methods are specific to a particular frequency (or frequencies). The major methods under both the techniques are given in Fig. 5.

Considering the nonresonant methods, the measurement methods for the bulk parameters can be broadly categorized into frequency and time domain procedure, as shown in Fig. 6. The detailed explanation on the frequency domain method can be found in the literature and is currently the most widely adopted method. However, as discussed previously, the time domain method can be thought of as a suitable candidate to extend the frequency of operation up to millimeter wavelength. However, so far, the applicability of the free space characterization method is found to be suitable only for medium and high-loss materials (Liu et al. 2021), while free space techniques for electrical property measurements are preferred over cavity and waveguide methods for the following reasons:

- Materials such as ceramics, composites, etc. are inhomogeneous due to variations in manufacturing processes. Because of inhomogeneity, the unwanted higher-

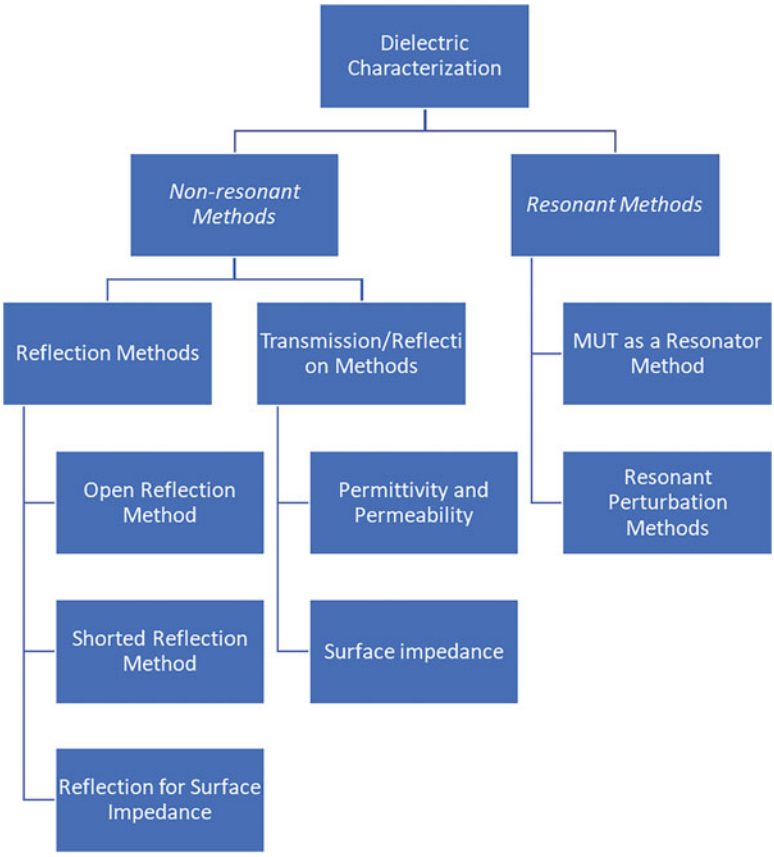

Fig. 5 Broad categories and subclassification of the prevalent dielectric characterization

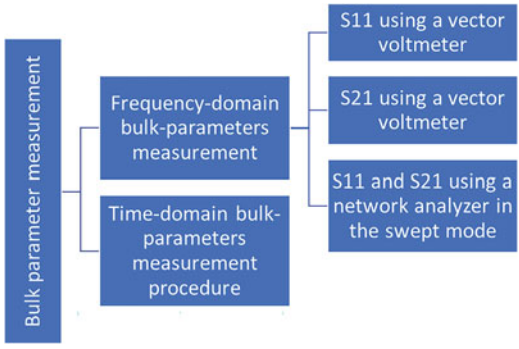

Fig. 6 The bulk parameter measurement methods

order modes can be excited at an air dielectric interface in waveguides and cavities.
- Dielectric measurements using free space techniques are nondestructive and contactless, particularly suitable for dielectric measurements at high temperature.
- In the cavity and waveguide methods, it is necessary to machine the sample so as to fit the waveguide cross section with negligible air gaps. This requirement will limit the accuracy of measurements for materials which cannot be machined precisely.

The inaccuracies in dielectric measurements using free space methods are mainly due to:

- Diffraction effects at the edges of the sample (minimized using lens antenna)
- Multiple reflections between the two horns via the surface of the sample (can be minimized using time-domain gating)

The free space method for measurement of dielectric constant ε and loss tangent (tan δ) of dielectric materials and the complex reflection coefficient $\mathbf{S_{11}}$ were measured by inserting a perfectly conducting plate behind the plate of unknown material. The metal-backed sample is placed at the focus of the transmit lens antenna. From transmission line theory, $\mathbf{S_{11}}$ for normal incidence plane wave is related to the complex relative permittivity ($\varepsilon^* = \varepsilon'(1 - j \tan \delta)$) by the following relationship:

$$S_{11} = \frac{jZ_{dn} tan\,(\beta_d d) - 1}{jZ_{dn} tan\,(\beta_d d) + 1} \tag{6}$$

where Z_{dn} is the normalized wave impedance in the unknown material.

For nonmagnetic materials,

$$Z_{dn} = \frac{1}{\sqrt{\varepsilon^*}}, \quad \beta_d = \frac{2\pi}{\lambda}\sqrt{\varepsilon^*} \tag{7}$$

where λ is the free space wavelength and d is the thickness of the sample permittivity which can be calculated with the help of iteration, and finding the zeros of error function,

$$E = |S_{11}^m - S_{11}^c| \tag{8}$$

where $S_{11}{}^m$ and $S_{11}{}^c$ are measured and calculated values of complex reflection coefficients, respectively.

Once the time domain transient response is recorded, then the bulk parameters can be extracted using the famous Nicholson-Ross and Weir algorithm, details of which can be found in various references (Nicolson and Ross 1970; Weir 1974; Smith et al. 2002).

Table 1 Few representative studies of free space method for dielectric characterization

Type of material	Application	Frequency band	Measurement technique	Calibration	Reference
Teflon, quartz, and boron nitride	High- and low-temperature dielectric characterization of materials	8–110 GHz	Free space measurement using spot-focused antenna	TRL	Hollinger et al. (2000)
Low-loss dielectric	To overcome the need of a priori information of the sample thickness in dielectric characterization	220–325 GHz	Bidirectional scattering (transmission and reflection) system using standard horns and lens	TRL with time domain gating	Kim et al. (2016)
Nanocarbon composite materials	Implementation of line-reflect (LR) error correction technique	30–50 GHz	Free space measurement using conical horn antenna	LR with time-gating	Hassan et al. (2016)
Highly conductive radar absorbing material	Iterative optimization model to extract the complex permittivity	18–27 GHz and 75–110	Free space measurement using conical lens horn antenna and frequency extenders	TRL	Vohra and El-Shenawee (2020)

It is evident from the review given in Table 1 that the through-reflect-line (TRL) calibration technique is important to establish the measurement setup. The complex electric permittivity and the magnetic permeability are calculated from the measured values of S_{11} and S_{21}. Diffraction effects at the edges of the sample are minimized by using spot-focusing lens antennas, and the errors due to multiple reflections between antennas via the surface of the sample are corrected by using a free space TRL calibration technique. The standards used in this calibration technique can be explained as follows:

- The *through* standard is realized by keeping the distance between the two antennas equal to twice the focal distance. For this standard, the common focal plane is placed at the front face sample location (reference plane).
- The *reflect* standards for port 1 (transmit horn) and port 2 (receive horn) are obtained by mounting a metal plate on the sample holder at the reference plane.
- The *line* standard is achieved by separating the focal planes of the two antennas. The distance between focal planes is approximately a quarter wavelength at mid-band.

Measurement Uncertainty

The major sources of uncertainties identified by the researchers are summarized from various references in Table 2. It is evident that the distortion in the cross section of the MUT, length of the MUT, and smoothness of the surface are some dimensional sources of uncertainties. Also, since the measurement is largely based on the S-parameters, therefore, the uncertainties are generated by the instrumentation, i.e., the VNA is another key source. The MUT orientation and placement are another factor contributing to the measurement uncertainty. The experimentalists need to overcome these sources of uncertainties. For example, for thin, flexible samples, the sample had to be sandwiched between two half-wavelength (at mid-band) quartz plates to eliminate the effect of sagging. Similar techniques need to be incorporated while executing these measurements.

Few other possible sources of uncertainty can be

- Drift: The drift in the physical system can contribute to the measurement; this can be included by taking the measurement over a period of time and evaluating the drift in the measurement results.
- Frequency: the measurands for calibration MAM are implicitly dependent on the frequency; this should be carefully incorporated when time-gating and other such software-based operations are applied during the measurement.
- Near field: Since the measurements are based on plane wave approximation, the effect of the near field should be incorporated in the uncertainty evaluation.

An example of uncertainty budget for a free space measurement of dielectric properties in the frequency range of 55–65 GHz is shown in Table 3.

Table 2 Major sources of uncertainties in the different characterization methods

Measurement method	Parameter	Sources of errors identified	±Error %	Reference
Loaded rectangular waveguide	Dielectric properties	Distortion in cross section Thickness of the material Sample preparation	>10%	Foudazi and Donnell (2016)
Free space method	Permittivity and conductivity	Instrumentation, impedance mismatch Distribution of sample thickness Interface alignment mismatch due to sagging Nonlinearity Environmental conditions	2%	Hassan et al. (2016)
Free space method	Permittivity and conductivity	Thickness Mismatch losses	5%	Singh et al. (2021)
Loaded rectangular waveguide	Permittivity	Cable stability Connector repeatability Drift, linearity Noise Dimensional uncertainty	–	Shoaib et al. (2016)
Coaxial line	Permittivity	S-parameter magnitude and phase Sample length	3%	Boughriet et al. (1997)

Table 3 Uncertainty budget of free space measurement (Singh et al. 2021)

	Elements of uncertainty				
Type	Sources	Uncertainty value (U_i)	Probability distribution and divisor	Standard uncertainty	Degree of Freedom
A	Independent repeated measurements	0.0548	Normal 1s $\sqrt{5}$	0.0245	4
B	Thickness of the specimen	0.0010	U-shaped $\sqrt{2}$	0.0007	∞
	Mismatch losses	0.0031	U-shaped $\sqrt{2}$	0.0022	∞
	Combined standard uncertainty, U_c	$U_c = \sqrt{\sum_{i=1}^{3} U_i^2}$		0.0246	
	Coverage factor, k	1.96			
	Expanded uncertainty, U_e	$U_e = k \times U_c$		0.0428	

Applications of Microwave Materials as Absorbers

Ultra-wideband (2–18 GHz) microwave absorbing materials in particular are extensively used for RADAR and applications such as camouflage nets and radar cross-section (RCS) reduction of planes for which stealth is of utmost importance. The MAMs are also required for civil applications such as reduction of electromagnetic (EM) pollution from mobile communication devices, electromagnetic interference shielding, radomes, etc. In the age of high electromagnetic (EM) pollution, the conventional MAMs, such as Salisbury screen; Jaumann absorber; coating of magnetic materials such as Fe_3O_4, $NiFe_2O_4$, $BaFe_{12}O_{19}$, $ZnFe_2O_4$, and $CoFe_2O_4$; and coating of dielectric materials such as ZnO and SiC, have limited practicability due to the narrow bandwidth, low dielectric or magnetic losses, thermal stability, high density, poor flexibility, and coating thickness. Significant efforts are being made by different research groups to overcome these limitations to serve various kinds of applications of MAMs. Till date, the majority of microwave absorbers prepared by the researchers for broadband application are thick sheets (>3 mm) and are made up of ferrite materials. The thickness of the layers is to be minimized, keeping the performance intact. Another technique of multilayering for enhanced microwave absorption is widely used, but this also suffers with thick coating and has low strength. With the incessant growth of the EM pollution and advanced engineering requirement in military stealth applications, the need of high-performing MAMs is indispensable. Considering the different applications of MAMs in the civil and defense sector, there is a vital need for cost-effective synthesis and fabrication of effective microwave absorbers using low-cost raw materials and less complex fabrication techniques. Thereby, in this section, few notable studies are discussed for various applications of MAMs.

EMI/EMC

The ever-increasing use of electronic equipment in our day-to-day life along with significant scientific advancements in the electronic area has led to increased EMI that is harmful to both the user and other electronic equipment. The basic EMI/EMC tests carried out for the aeronautics and space applications include the radiation and susceptibility tests. These tests are responsible to ensure that the radiation/conduction to and from any electronic unit will interfere neither with its operation nor with the other units. These tests can be further categorized as (Mallette and Adams 2011; Mathur and Raman 2020):

- Radiated emission test
- Conducted emission test
- Radiated susceptibility test
- Conducted susceptibility test
- Immunity test

Recently, a lot of promising approaches have been reported by several groups in EMI shielding with respect to different types of materials ranging from metallic, polymeric, nanomaterial-based, nanocomposite-based, porous systems, alloys, high-temperature shields, etc. Depending on the application, such as the absorbers required in EMI and EMC applications, characterization techniques differ, and thus a separate set of properties is studied. For example, infrared emissivity is the parameter to quantify the heat transfer. MAMs, having a high emissivity in the microwave spectrum, are crucial in a wide array of applications, such as electromagnetic interference mitigation, stealth technology, and microwave remote sensing and radiometer calibration. Apart from absorption characteristics, the mechanical requirements, e.g., ultrathin, flexibility, lightweight, thermal stability, etc., are to be catered for application-based products and are widely stressed upon by the researchers. Few applications where EMI/EMC studies are crucial and the use of microwave materials has been demonstrated are:

- Densely packed integrated circuits in telecommunication systems
- Aeronautical and space applications
- Printed circuit boards

EM Shielding

An EM disturbance or noise that degrades the performance of the equipment or even causes the failure of equipment is called electromagnetic interference (EMI). The problem of EMI can be eliminated by using EMI shielding materials. The shielding effectiveness (SE) is a number that measures the amount of dissipated energy or attenuated energy by a shielding material. SE is the ratio of the incident energy to the remaining energy. SE is expressed as:

$$SE(dB) = 20\,log\ \ \log\left(\frac{E_t}{E_i}\right) = 20\,log\ \ \log\left(\frac{H_t}{H_i}\right) = 10\,log\ \ \log\left(\frac{P_t}{P_i}\right) \tag{9}$$

where E, H, and P are the electric, magnetic field, and power intensity, respectively, and "i" and "t" represent the incident wave and transmitted wave, respectively.

Three mechanisms contribute to the SE of the material for any EMI. Some part of the incident wave is reflected by the shielding material, a part of it is absorbed, and the left part undergoes multiple internal reflections. Therefore, the total shielding effectiveness (SE_T), given in Eq. (10), of shielding material is equal to the sum of shielding effectiveness due to absorption (SE_A), shielding effectiveness due to reflection (SE_R), and shielding effectiveness due to multiple reflections (SE_M) in thin shielding material:

$$SE_T = SE_A + SE_R + SE_M \tag{10}$$

The study of the shielding effectiveness again depends on the MUT. A large database of materials is available in the literature where shielding effectiveness is used as the only parameter for a particular application (Mehdipour et al. 2011; Gupta and Tai 2019; Wu et al. 2021a, b). For example, the use of composites showing high shielding effectiveness in the high frequency is critical for aeronautic applications. Researchers have shown the material preparation and high shielding effectiveness of up to 90 dB using the highly conductive composites wherein the shielding effectiveness can be given as (Mehdipour et al. 2011)

$$SE(dB) = 20\,log\ \ \log\left|\frac{(\eta_0+\eta_m)^2}{4\eta_0\eta_m}\right| + 8.686\left(\frac{d}{\delta}\right) \tag{11}$$

where skin depth (δ) << thickness of the material (d) and η_0 and η_m are the intrinsic impedances for the TE10 mode for air and material, respectively. It is evident from Eq. (11) that the SE is dependent on the thickness of the material since there is a direct proportionality between SE and d.

Radar Absorbing Materials for RCS Reduction

Many researchers have suggested microwave absorbing materials as radar absorbing materials (RAMs) for RCS reduction in various configurations such as for stealth aircrafts (Jayalakshmi et al. 2019) and antenna (Genovesi et al. 2013; Wang et al. 2014) and most recently in automotive radar systems (Chipengo 2018). RCS quantifies the reflective strength of object terms of the normalized power flux density of the field scattered by the object in the direction of the receiving radar. The various types of RCS are pictorially shown in Fig. 7. The direction of the reflected and scattered field is used to categorize the RCS as monostatic (or backscatter), forward scatter, or bistatic. Mathematically, RCS σ is given as (IEEE Std 1502–2020):

$$\sigma = 4\pi \lim_{R\to\infty} R^2\left(\frac{|E_s|^2}{|E_i|^2}\right) \tag{12}$$

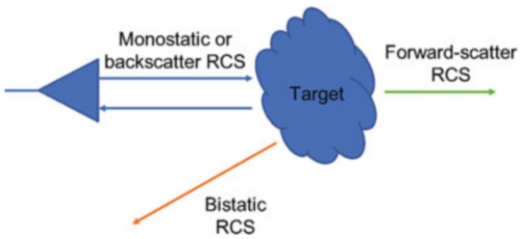

Fig. 7 Types of RCS based on the direction of reflected or scattered energy

where R is the range of the target, E_s is the electric field strength scattered by the target, and E_i is the incident electric field strength. The derivation of the equation and other details can be found in Richards (2014).

The basic technique employed for RCS reduction is coating a surface of any object with MAM of high-loss factor such that the incident wave can be reduced to heat or absorption, thereby minimizing the scattered fields and thus the RCS. There are MAMs that exhibit electric and magnetic losses and are used for RCS reduction. Few examples of such materials used in RCS reduction are summarized in Fig. 8.

Predominantly, RCS reduction was first desired in stealth applications where the invisibility of the aircraft or ships on the radar was envisaged as a countermeasure of radar detection. With the outset of new applications such as automotive radar systems, the use of RAMs is proposed in a few recent papers for cruise control and other autonomous driving requirements (Chipengo 2018; Kim and Kim 2019). The application of MAMs in automotive radar systems is an ambitious project which is still in its nascent stage. The most commonly researched MAMs for the automotive radar systems are given in Fig. 9 with their basic properties. The MAMs can play a crucial role in dictating the scene of the traffic for the efficient adaptive cruise control. For example, the RCS reduction of guardrails is an important task such that low RCS targets can be visible to the radar sensor on the autonomous cars (Chipengo 2018). However, employment of MAM on the guardrails may require coating of low cost, uniformity, and homogeneity of the material. Other studies have proposed the employment of MAMs for reducing the ghost targets produced due to the close proximity of the automotive radars (Kim and Kim 2019).

Conclusion

In this chapter, the microwave absorbing materials and their electrical properties are introduced. The most frequently used metrology techniques for the characterization of microwave absorbing materials used for various applications are presented. The recent progress in the field of MAM is driven by improvements in both materials,

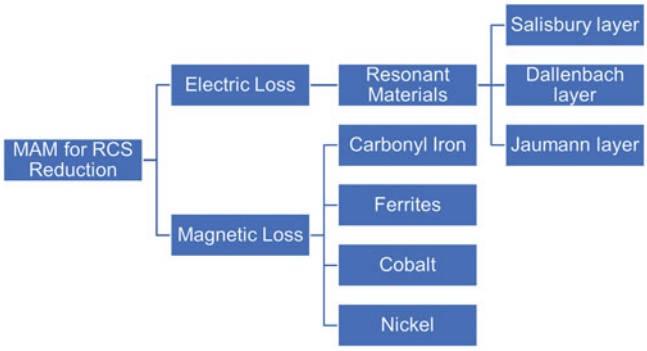

Fig. 8 Commonly used materials for RCS reduction application

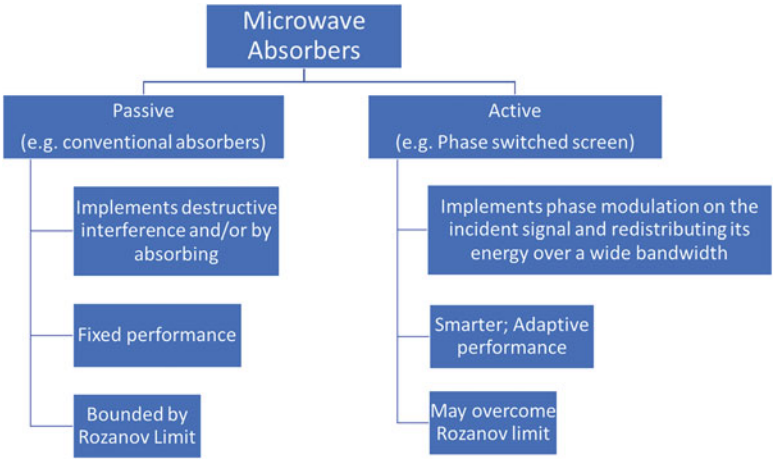

Fig. 9 Characteristics of the active and passive microwave absorbers used for RCS reduction

algorithms, and measurement techniques. Interestingly, methods and system designs vary substantially in terms of a number of antennas, measurement strategies, use of matching medium, algorithms, and so on. Therefore, it becomes essential to understand the applicability of a measurement system and its constraints and performance depending upon the material under test and its application. The major challenges and properties of the measurement setups are presented including the calibration techniques adopted by the researchers for a particular application. Majority of applications lie in the frequency range from 2 to 18 GHz. However, the important techniques of characterization of MAM bulk properties from 1 to 300 GHz is reviewed and presented from the metrological point of view. Major sources of uncertainty include the instrumentation, mismatch, sample dimensions, nonlinearity, and in some cases poor repeatability. In the end, the applications of MAMs are discussed and related with the characteristics of materials.

Abstract

Phased array antenna (PAA) systems have emerged as the state-of-the art technology providing a solution to almost all of the modern-day communication requirements like 5G mobile system, upcoming 6G mobile system, Massive MIMOs, focal plane arrays, radars, SatCom, driverless vehicles, weather monitoring, air traffic control, etc. Phased array antennas are system of systems comprising of smaller subsystems being integrated to realize the whole system. Thus, the design and development of these requires a meticulous approach taking care of the needs of the end user, performance of the whole system, system life cycle, and environmental eventualities during the design cycle. PAA involves various subsystems such as antenna array, transmit receive modules, beamformer

architecture, power supplies, cooling systems, etc. PAAs are complicated and costly systems due to involved active circuitry and fabrication expenditures; however, with the advent of the cheaper and more efficient semiconductor technology, the system cost is manageable. Henceforth, the use of these is extended for commercial applications as well. This class of antenna systems require specialized measurement techniques for assessment of their operational capabilities. These are called as array calibration techniques.

The chapter briefly discusses the phased array antennas, beamforming principles, system architecture for phased array antennas, and the various technologies involved and finally concludes by the measurement and calibration techniques specifically for radar applications. The chapter aims at providing the basic information to the readers about the phased array antennas with their applications focused toward radar applications.

Introduction

A Little Bit of History

The term Radio Detection and Ranging (Radar) was coined during World War II. In 1886, Heinrich Hertz demonstrated the reflection of radio waves for metallic objects. At the same time, similar investigations were reported by Sir J. C. Bose in India as well. Later in 1897, A. Popov developed an apparatus demonstrating a communication between the two ships in the Baltic Sea and noting an interference beat due to an interfering ship between the two ships. The German inventor, Christian Hulsmeyer, known as father of the radar, for the first time used radio waves for detecting the presence of a distant metallic object (see Fig. 1). He had shown that it is feasible to detect a ship in a dense fog and got a patent in 1904 and later got a patent on full radar system, called "telemobiloscope." In 1915, Robert Wattson-Watt also used radio direction for detection and worked further on shortwave transmission. *A. Hoyt Taylor* and *Leo C. Young*, US navy researchers, located a transmitter and receiver on the opposite sides of River Potomac and observed a fade in and out of the received signal due to interference by ships passing in between the beam. They suggested the phenomenon's usage for detecting the presence of ships in low visibility conditions. Later, *L.A. Hyland* at the *Naval Research Laboratory* (NRL) observed similar phenomenon, which led to a patent application leading to the further intensive research at NRL, where Taylor and Young were based at the time. The first radar systems developed in the USA were the SCR-268 (operating at 205 MHz) for antiaircraft gunfire control and the SCR-270 (operating at 100 MHz

Fig. 1 World war II radar produced by Germans. (Source: Internet)

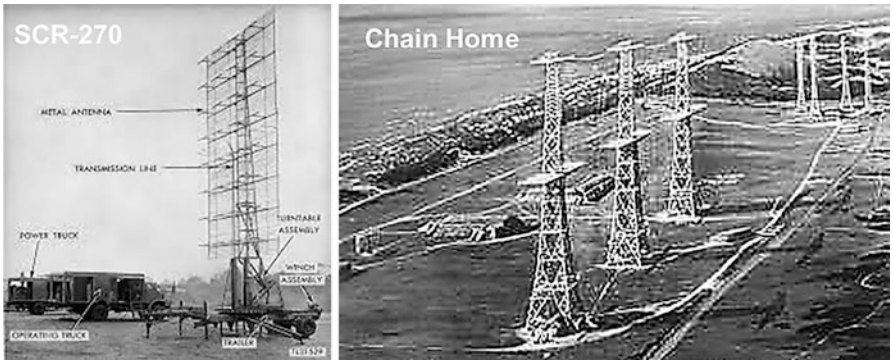

Fig. 2 First few radar systems. (Source: Internet)

frequency) for aircraft detection (see left-hand figure in Fig. 2). SCR-270 detected the approach of Japanese warplanes toward Pearl Harbor, near Honolulu, on December 7, 1941. In September 1938, the first British radar system, the *Chain Home* (see right hand figure in Fig. 2), was operated over a full day. It remained operational throughout the war, and it operated at about 30 MHz, i.e., the shortwave or HF and was invented by Sir Robert Watson-Watt. Thus, the title "father of radar" can be jointly shared by Hulsmeyer and Wattson. At the same time, similar research took place in Great Britain. The USA, Britain, Germany, France, the Soviet Union, Italy, the Netherlands, and Japan were the initial countries which started the work during WWII days on radar systems. A chronological detail of the various events is summarized in Fig. 3.

Year	Achievement
1886	Hertz tested maxwell's theories and demonstrated the similarities between light waves and electromagnetic waves and found that EM waves are reflected by mettallic and dielectric bodies
1904	Patent of obstacle detection and ship navigational aid by Hulsmeyer, a German Engineer
1922	Use of short waves for radio detection
1925	Principle of pulse ranging by US scientists for height measurement of ionosphere
1930	Pulsed radar systems into operation in US
1940	Modern radar development in the WAR years, development of high power magnetron in UK, MTI,MOPA etc.
1950	Long Range radars, Computer techniques
1960	Electronic scanning arrays concept
1970	Developed wide Bandwidth electronic scanning array Radars

Fig. 3 Chronological achievements

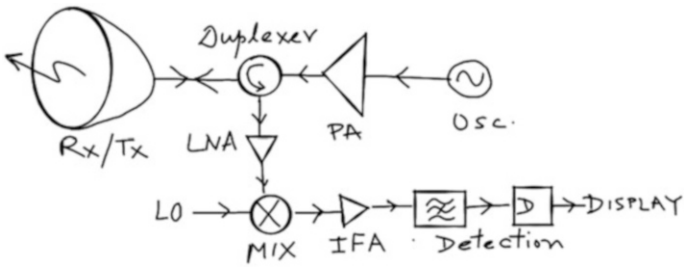

Fig. 4 Radar-functional block diagram

Radar Principle of Operation

A radar, in principle, radiates electromagnetic (em) energy in the space and receives the scattered and reflected echoes from the space, process it further to get the desired target information (Sarkar et al., 2006; Skolnik, 2008). Figure 4 shows the functional block diagram of the radar illustrating the various components comprising the overall system. The front end consists of the receive (Rx)/transmit (Tx) antenna which serves as "eyes and ears" of a radar, followed by a duplexer which isolates the Tx and Rx portions of the radar from each other. The Tx portion consists of a power amplifier (PA) which amplifies the signal from a signal generator "osc" to the necessary level required for transmission or radiation by antenna of a radar system

to achieve desired range. The Rx portion consists of a low noise amplifier (LNA), which removes the unwanted noise interference from the scattered/reflected signals received from space, followed by a mixer (MIX) which translates the radio frequency (rf) signal to intermediate frequency (IF) base band level, which is further amplified by an IF amplifier and detected through 2nd level detector and display on a video terminal. Thus, a radar may be considered as a "*system of systems"* requiring a team with vivid expertise ranging from electronics to electrical systems along with computer science experts to develop an efficient radar system.

Types of Radar

Radar can be classified broadly into three categories – *mechanically scanned radar (MSR)*, *passive electronically scanned radar (PESAR),* and *active electronically scanned radar (AESAR)* based on the *antenna type* used in the radar system (Kedar, 2020a) (see Fig. 5). The antenna type classifies the radar based on the beamforming and scanning strategy as adopted in it. MSR has a got a fixed antenna mounted on a pedestal fitted with a servo motor. The rotating mechanism rotates the antenna at fixed revolutions per minute (rpm) rate which in turn decides the scanning rate of the radar. *MSR* suffers from the problems such as slow reaction times, inertia in the servo motor mechanism, etc. *PESAR* overcomes this issue by providing the phase shifters at the element level leading to electronically controlling the phase shifts provided to the antenna elements, which in turn scan the antenna beam electronically. This increases the reaction time of the radar and eliminates the inertia factor. However, the power source or transmitter in MSA and PESAR is single source and may act as a source of complete failure of radar in case of any failure.

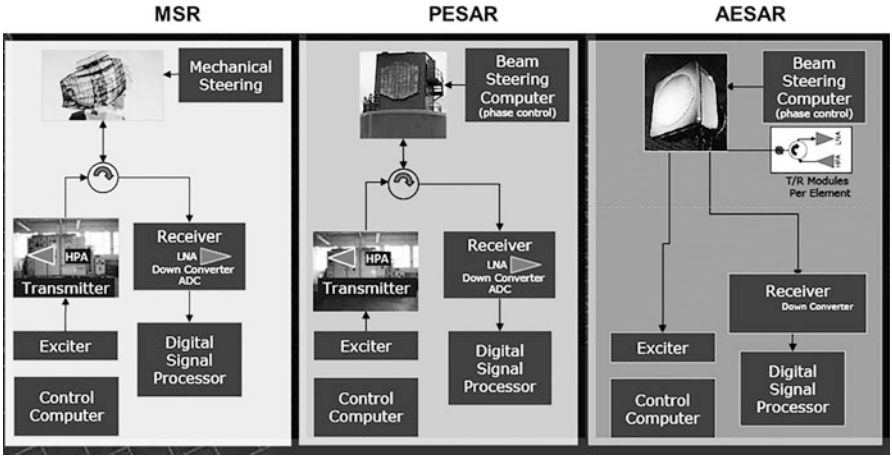

Fig. 5 Classification of radar systems

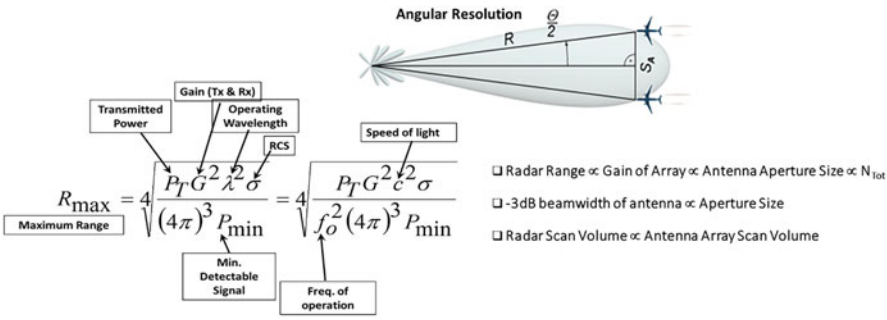

Fig. 6 Radar range equation and its characteristics

Henceforth, to take care of this issue the transmitter is distributed into small transmitters at the element level leading to the generation of *AESAR* class of antennas. Thus, the distributed transmitters provide a feature called as graceful degradation in AESAR, which means even in case of failure of these transmitters by 10–12% the AESAR will still operate with slightly degraded performance. Thus, antenna forms an important part of radar system controlling its overall performance and nomenclature of the radar system. Henceforth, *the antenna systems for radars form the theme of this chapter.*

A radar needs to illuminate the space for various surveillance and tracking applications. The important characterizing parameters of a *radar* are, namely, *radar range*, *angular resolution*, and clutter cancellation, which are totally dependent on the antenna system performance (Skolnik, 2008) (see Fig. 6). In addition, a radar needs to *cover or view* the complete hemisphere (360° of coverage) in a limited time which can be accomplished only by the movement of antenna beam throughout the hemisphere.

Figure 6 Illustrating the *radar range equation* and the radar parameters shows that radar range is mainly dependent on the *total power radiated* (P_T), *gain of antenna (G),* and *frequency of operation* ($\sim\lambda=c/f$). The *Gain, G,* of antenna depends upon the *number of elements*, N_{ToT} being collocated in an antenna array aperture in a definite geometric pattern decided by various design configurations, and the power radiated in turn depends upon the N_{ToT} *times the power fed to each of the antenna element*, P_{in}. The spatial coverage of radar depends upon the *grating lobe* (GL) free scan volume offered by the antenna array system (Skolnik, 2008; Kedar, 2020a; Balanis, 1997). Further, the radar spatial coverage requires *antenna beamforming*, which implies formation of customized antenna beam shapes like pencil beam, fan beam, multiple beams, cosecant squared beams, etc., as shown in Fig. 7 for surveillance and tracking applications (Skolnik, 2008; Kedar, 2020a; Brookner, 1991). Thus, the importance of antenna arrays is clear in design of radars and forms the theme of this chapter.

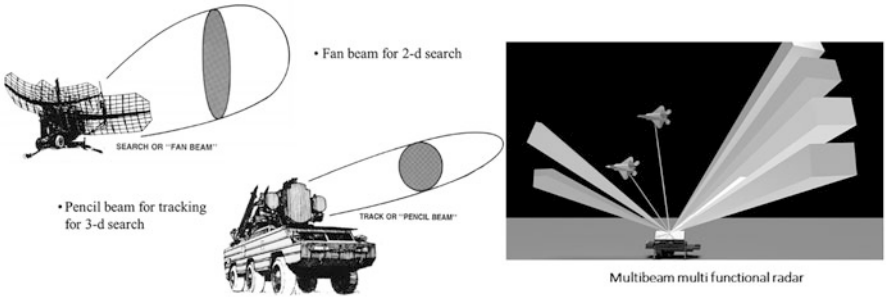

Fig. 7 Types of beamforming (source: Internet)

Antenna

Antenna in a radar does not contain a single element; however, it contains a group of elements, called as an *antenna array* as the *overall gain* of an antenna system is directly proportional to N_{ToT}, i.e., the number of elements in an ideal sense, which also decides the *range* of radar (Brookner, 1991; Kedar, 2022). Referring to Fig. 7, an antenna (actually an antenna array) covers the entire *area of interest* for radar either *mechanically* or *electronically* by the virtue of single or multiple beams (Jeffrey, 2008). The mechanical coverage is by the means of physical rotation of antenna system in a radar using servo-motor system, i.e., *MSR* or electronically by inputting *phase delay* at the element level through some *phase shifters* or *time delay units*, i.e., *PESAR* or *AESAR*. Based on this operational mechanism, the antenna is also characterized as *mechanically scanned antenna* (MSA) and *phased array* antenna (*PAA*) or electronically scanned antenna (*ESA*). The focus over here is on *PAAs* or *ESAs* which forms the integral part of the modern-day radar systems (Brookner, 1991; Jeffrey, 2008).

Phased Array Antenna

A *phased array antenna* (*PAA*) is a *group of radiating elements* in which *the relative phase shifts* of the respective signals fed to the individual antenna elements are varied in such a way that the *effective beam* (a planar wave front) formed by the array is reconstructed in a desired direction (at an angle, θ) and suppressed in undesirable directions (Kedar, 2022) as shown in Fig. 8. Figure 8 shows a phase lag $\alpha = (N-1)\phi$ being fed to n^{th} element in an N-element array. Thus, necessary phase delays are introduced in the antenna elements' input resulting in to the respective wave fronts emitted by individual radiator to interact constructively to form a primary planar wave front at an angle, θ. This phase delay can be provided either by using *phase shifter* or *true time delay* (TTD) lines (Sreenivasulu et al., 2020; Kedar et al., 2020a; Fourikis, 1997; Sturdivent et al., 2019).

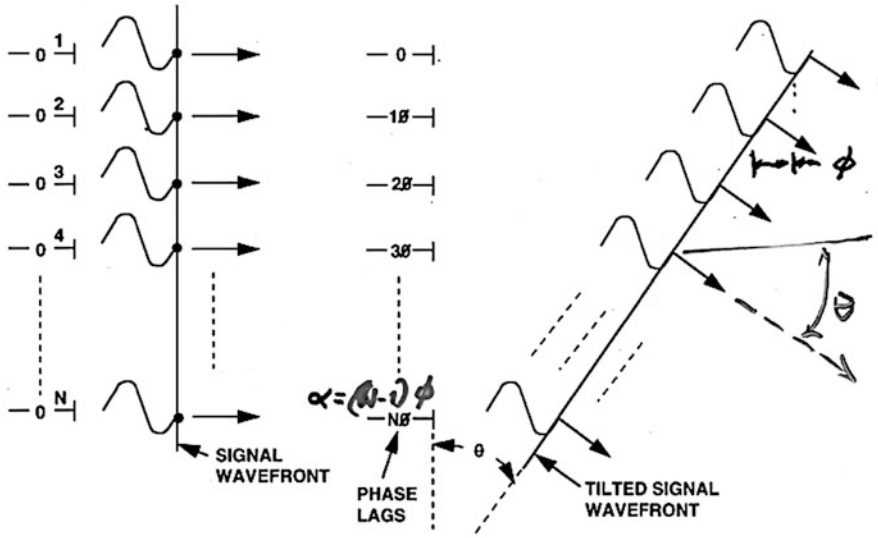

Fig. 8 Planar wave front formation in phased array antenna

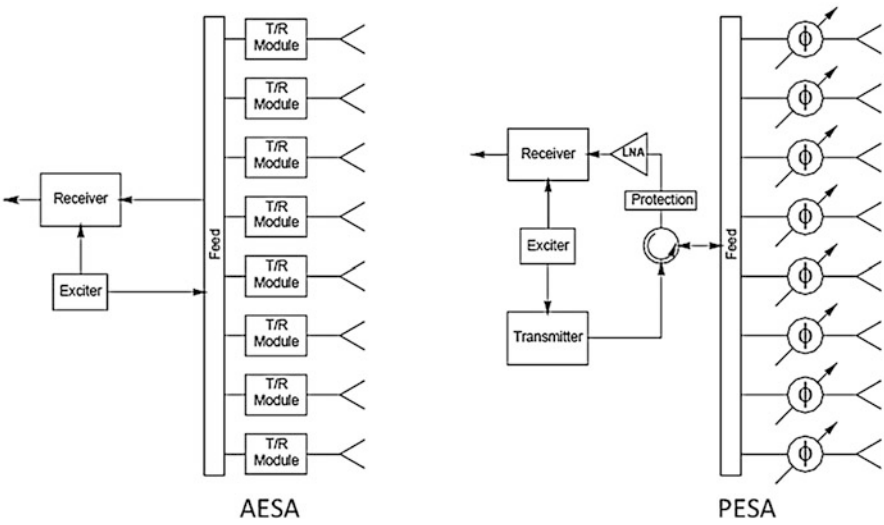

Fig. 9 AESA versus PESA

Figure 8 shows the comparison between active ESA (AESA) and passive ESA (PESA). In PESA, only the phase control is taken at the element level (see Fig. 9) whereas in AESA the amplitude as well as phase controls (together called as T/R module or TRM (Sreenivasulu et al., 2020; Kedar et al., 2020a; Fourikis, 1997; Sturdivent et al., 2019; Sturdivent & Harris, 2015)) is distributed at the element level

(see Fig. 9). Thus, AESA have better detection sensitivity and possess high reliability (i.e., *graceful degradation* (Fourikis, 1997), which implies continual operation of AESA even in the presence of few failures of the modules). In addition, the advent of digital analog to dc convertors and vice versa (i.e., ADCs or DACs) have made it possible to convert active electronics beyond power amplifier (in Tx chain of TRM) and low noise amplifier (in Rx chain of TRM) by the digital circuits (Sturdivent & Harris, 2015). These are called as *digital beamforming* (DBF)-based AESAs or *digital AESAs* (Sturdivent & Harris, 2015; Shang et al., 2017; Talisa et al., 2016). Thus, the present state-of-the-art technology and research trends for the radars are centered on AESAs.

An AESA has several advantages over MSAs and PESAs as given below:

- AESA provides an Inertia Free Beam Steering & Control (no physical movement).
- AESA facilitates multifunctionality, i.e., search, track, track while scan capabilities, etc.
- Adaptive Beam Pattern Control (dynamic beamforming, adaptive nulling, and multiple beam formation).
- Efficient use of radiated energy.
- Highly modular architecture (scalable architecture).
- High reliability and maintainability (good thermal management and repeatability in performance).
- Graceful degradation over time (operational even with few failed modules).
- Reduction of radar cross section.

Figure 10 shows the functional block schematic of active phased array antenna system or AESA showing prime constituent submodule comprising it. AESA may

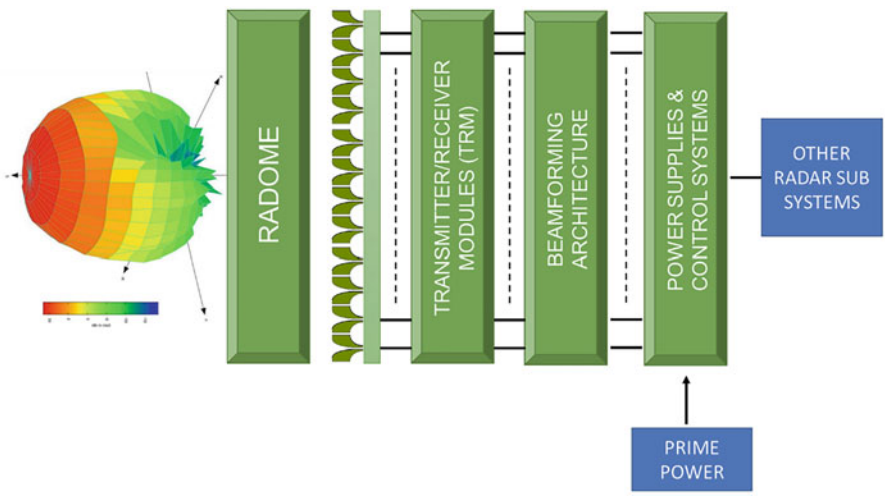

Fig. 10 Functional block schematic of active phased array antenna system

be considered as a system of systems which involves various technologies as listed below:

- Radome
- Antenna Element Technologies
- Transmit/Receive Modules
- Thermal Design, Reliability and Heat Transfer Technologies
- Array Beamforming
- Engineering Aspects (Mechanical Chassis and Integration)

Hence, an AESA designer or rather system designer shall be aware of these technologies to derive the overall specifications and guide the design and development team for AESA toward successful realization of submodules of an AESA, their integration, and evaluation (Fourikis 1997; Sturdivent et al. 2019). The next section discusses the most important technologies involved in the AESAs development.

Involved Technologies In AESAs

Radome

A Radome is a structure and weatherproof enclosure which protects an antenna from the effects of environmental exposure and conceals it from the public view, specifically in defense applications. The material used shall be RF transparent, having low dielectric constant and low-energy reduction. The technology spinoff for Radome occurred during World War II (Kozakoff 1997). The system bandwidth is limited by the *radome's bandwidth,* and the *Radome depolarization* limits the *dynamic range* in a frequency reuse application. *Radome transmission efficiency* (RTE) and *Insertion phased delay* (IPD) are the two main characterizing parameters of a radome.

A radome may have various designs based on its deploying platform like airborne, shipborne, or ground-based platforms which puts different specifications' stringency from the system perspective (see Fig. 11). Radome materials have continued to develop in two main areas: (a) ceramics, used primarily for hyper velocity missile radomes and (b) high-strength organic materials for sandwich composite radomes. The parameters that affect the radome's broadband performance are the following:

- Wall thickness (thinner radome is generally better)
- Wall design that includes the number of layers, thickness, and permittivity of each layer (more layers is better)
- Shape of the radome (flatness is desirable)
- Selection of low loss materials (small loss tangent is required)

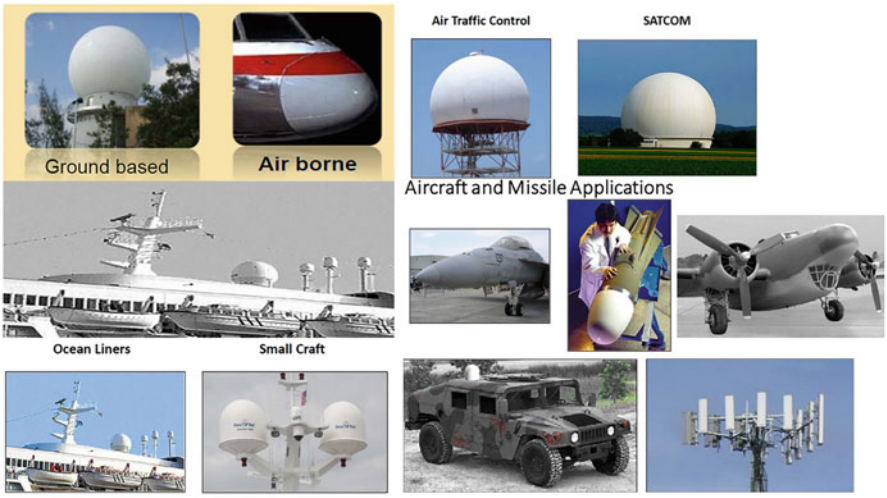

Fig. 11 Different platforms for the deployment of radome (source: Internet)

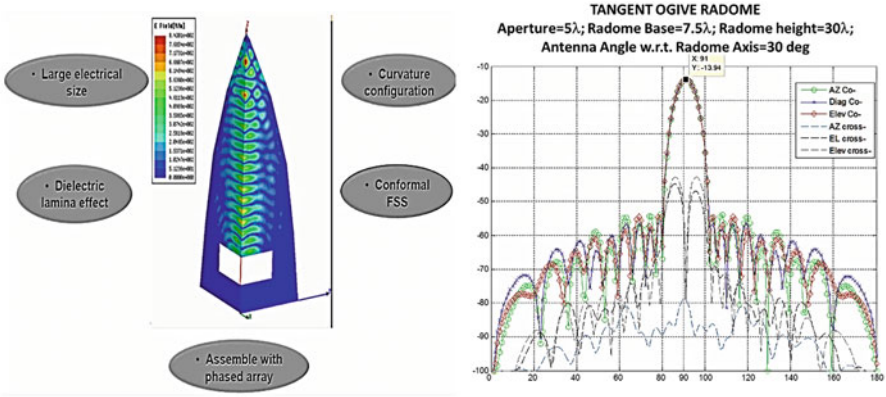

Fig. 12 Design challenges in radome

Figure 12 (left-hand side) illustrates the various constraints in design process of a radome. Figure 12 (right-hand side) shows the *em* simulation of a tangent ogive-shaped radome. A radome may affect the antenna far field radiation behavior in terms of 3 dB beam-width (HPBW), Side lobe level (SLL), and Axial ratio (AR). It may introduce Boresight error (BSE) and Boresight error slope (BSES) and may increase depolarization or the folding of energy from one polarization sense to the other. A radome may result into an increase in antenna VSWR and the insertion loss (IL) due to its presence. A radome design requires a proper choice of material, shape modeling as per curvature of antenna and mounting platform (conformability), and its modeling along with the phased array antenna (Kozakoff 1997; Kedar and

Revankar 2006; Kedar et al. 2020b). The performance of a radome affects the antenna performance as:

- Influences the antenna's far field radiation behavior in terms of HPBW, sidelobe level (SLL) of antenna array's radiation pattern, and axial ratio (AR). SLL generally increases inside radome due to the distortion and wall transmission effects as a wavefront propagates through a radome wall. This is a great hindrance in the design of low-sidelobe-level antennas.
- Boresight error (BSE), is the bending of the angle of arrival of a received signal relative to its actual angle of arrival due to distortions of the electromagnetic wavefront as it propagates through a dielectric radome wall and boresight error slope (BSES), is the rate of change of BSE as a function of the antenna scan angle within the radome. BSE depends upon the frequency, polarization, and antenna orientation. BSES can cause severe degradation for modern guidance systems. The radome manufacturing tolerance affects the BSES characteristics of the radome. The maximum allowable BSES is determined by the manufacturing tolerances of the radome.
- Power Transmission Coefficient
- Introduction of a registration error: Registration error is the difference in uplink frequency and downlink frequency, and it should be sufficiently small to assure that both the transmit beam and receive beam peaks are coaligned on the same satellite.
- Increased depolarization: It is the folding of energy, i.e., the change in the sense of the primary antenna polarization, for instance, the RHCP signal after reception transforms to LHCP signal. This is due to the radome wall curvature and difference in complex transmission coefficient between orthogonal polarized vectors.
- Increase in antenna VSWR: The antenna VSWR can greatly increase from RF power reflected from the inner radome wall surface. The VSWR increase from this radome reflected power will represent an additional gain/loss that can be critical to, for example, SATCOM communications systems.
- Insertion Loss due to the Presence of the Radome

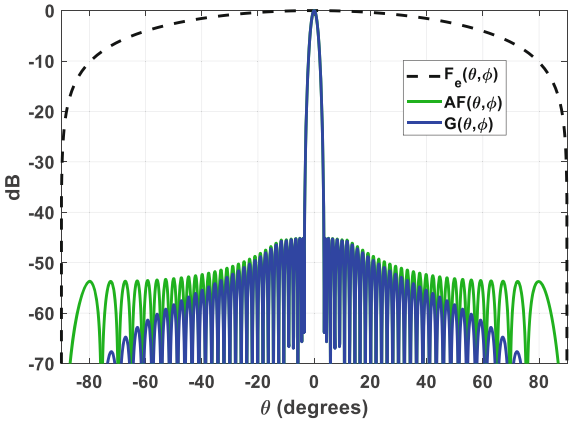
Figure 12 shows the performance of an antenna array in the presence of tangent ogive radome. The left-hand side shows the electromagnetic propagation inside radome as captured using electromagnetic simulations using Ansys HFSS. The right-hand side figure shows the antenna radiation pattern (co- and cross polarization field) in the presence of tangent ogive radome whose physical and electrical parameters are shown on the top of the plot. There are various classes and types of radome, and for the details of these one can refer to the ref (Kozakoff 1997). Thus, the choice of proper radome to ensure the minimally degraded performance of an antenna array is very important. The next important technology is antenna which is discussed in the next subsection.

Antenna Technology

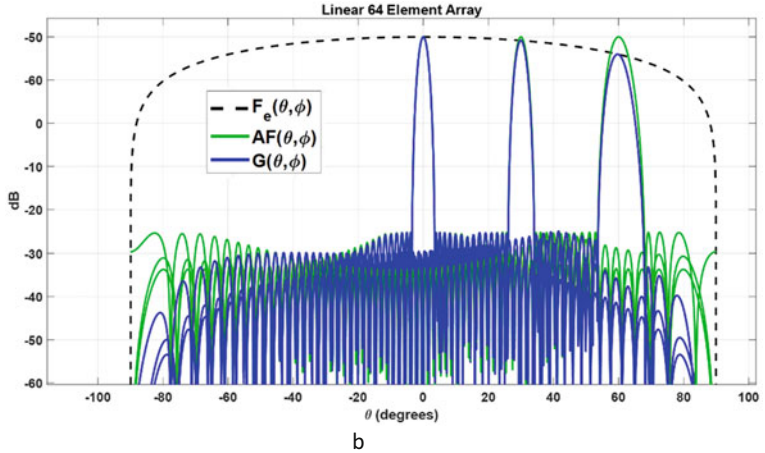
The radiation pattern, $G(\theta, \varphi)$, of an AESA's phased array antenna depends upon the design of the *antenna element* ($F_e(\theta, \varphi)$ is the element pattern) and the chosen *array configuration* (quantified by array factor, AF) (Kedar 2020a, 2022; Balanis 1997; Brookner 1991) given as in (1) (Kedar 2022).

$$G(\theta, \varphi) = F_e(\theta, \varphi) \times AF(\theta, \varphi) \tag{1}$$

In (1), F_e is the element pattern, AF is the array pattern, and (θ, φ) are the spatial direction of observation for sampling the respective radiation patterns. Figure 13 shows computed radiation pattern of a 64-element array with half a wavelength spacing between the elements in an array. Figure 13a shows the respective plots, F_e,



a



b

Fig. 13 Radiation pattern of a 64-elements antenna array (**a**) at boresight (**b**) scanned performance

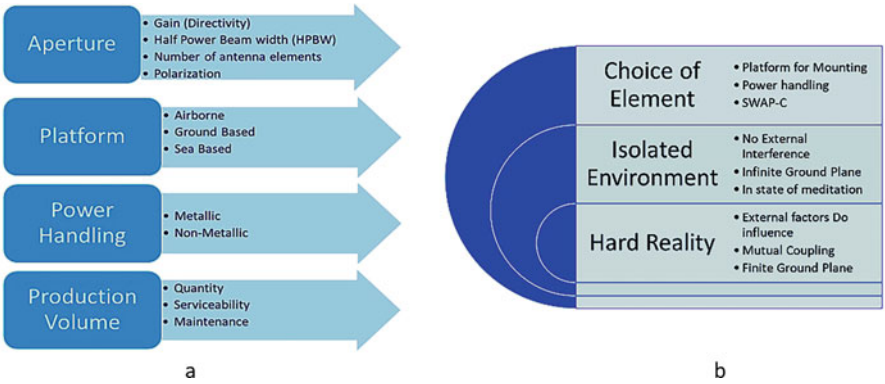


Fig. 14 Design challenges in antenna array

AF, and *G*. The effect of F_e is clearly visible in the far angles where the sidelobes of *AF* are suppressed in *G*. It is further clearly visible from the plot in Fig. 13b that the *AF* varies with scan angle in its pointing direction but with no change in its maximum gain and HPBW. However, the variation in gain and HPBW of overall radiation pattern is seen due to the variation in the element pattern with respect to the scan angle. Thus, the choice of element pattern is very critical to decide overall performance and the control over the variation in gain of the antenna array (Sreenivasulu et al. 2020). In the above example, $F_e = \cos^n(\theta, \varphi)$ is chosen which represents an isotropic antenna element's pattern (n = 1). However, in real life, n≠1.

Figure 14a shows the relationship between array's design parameters based on the design constraints. Figure 14b shows some real-life constraints which need to be accounted for while designing an antenna element for phased array applications (Brookner 1991; Kedar 2022; Fourikis 1997; Sturdivent et al. 2019; Sturdivent and Harris 2015). The practical design constraints while designing an antenna array are inclusion of the *mutual coupling* and *mounting platform effects* on the antenna performance (Kedar et al. 2020b; Singh and Jha 2013; Kedar 2021). The Eq. (2) describes mathematically the inclusion of these design constraints on the array pattern of the element chosen for the array realization. In (2), $\Gamma(\theta, \varphi)$ accounts for the mutual coupling effects from the neighboring elements in an array, A is the array's aperture area, λ is the operational wavelength, and (θ, φ) is the scan angle (Kedar 2020b, 2022).

$$F_{e,\,active}(\theta, \varphi) = \frac{4\pi A}{\lambda^2} \cos\theta \left[1 - |\Gamma(\theta, \quad \varphi)|^2\right] \tag{2}$$

The subscript "*active*" implies the value of element gain in the presence of the surrounding environment including other antenna elements in an array (Bhattacharya 2006).

The performance of an antenna elements is vividly different from its performance when it is surrounded by neighboring elements. Ideally, the design of an element starts in isolated environment assuming it is situated on an infinite ground plane with total isolation from the surrounding environment. The practical scenario is totally opposite where the element is affected by its surroundings due to the finite ground plane and the mutual coupling (Singh and Jha 2013; Kedar 2021; Bhattacharya 2006). Thus, to design an element for phased array antenna application the effect of mutual coupling needs to be taken care of (Kedar et al. 2020b). The various design challenges may be summarized as:

- Mutual coupling effects: effect of one antenna element on another in array environment. The gain, beam shape, and radiation impedance change due to coupling, and it may cause scan blindness.
- Antenna impedance matching over full scan volume.
- Active element pattern beam width optimization.

There are various ways to analyze an element's performance in array environment (Kedar 2022):

- Unit cell approach (Floquet mode approach) which considers:
  - It assumes an infinite array containing the element.
  - No array's finite edge affects.
  - Pairs of Perfect Es or Perfect Es and Perfect Hs surrounding the element.
  - Periodic boundaries – Linked Boundary Conditions (LBC).
  - It is a fast solver within few minutes.
- Finite array approach which considers:
  - Finite array.
  - Finite edge affects.
  - It is computationally expensive and time consuming.

Figure 15a shows a unit cell consisting of a dipole antenna over a metallic reflector on the left side. The right-hand side plots in Fig. 15a show the effect of mutual coupling on single element performance (SEP) embedded in an antenna array environment in E- and H- planes and also show the effect of scanning. It can be seen that in Fig. 15b SEP varied in a finite array (real-life scenario with fixed number of elements in an array) as compared to an infinite array (assuming infinite number of elements surrounding the element) environment. Thus, effect of the mutual coupling and finite edges of antenna array are apparent. Thus, a proper design of an antenna element accounting for all these considerations is crucial for the desired performance of an AESA.

Another example of antenna technology chosen for active phased array radars is shown in Fig. 16a. Usually, the printed patch antennas suffer from dielectric losses resulting into loss of antenna efficiency, which in turn reduces the overall array efficiency (Kedar 2019). A metallic antenna is completely devoid of substrates or any dielectric in turn resulting into removal of dielectric losses. Figure 16a shows the photograph of a metallic Vivaldi antenna (Kedar 2019) which is completely made

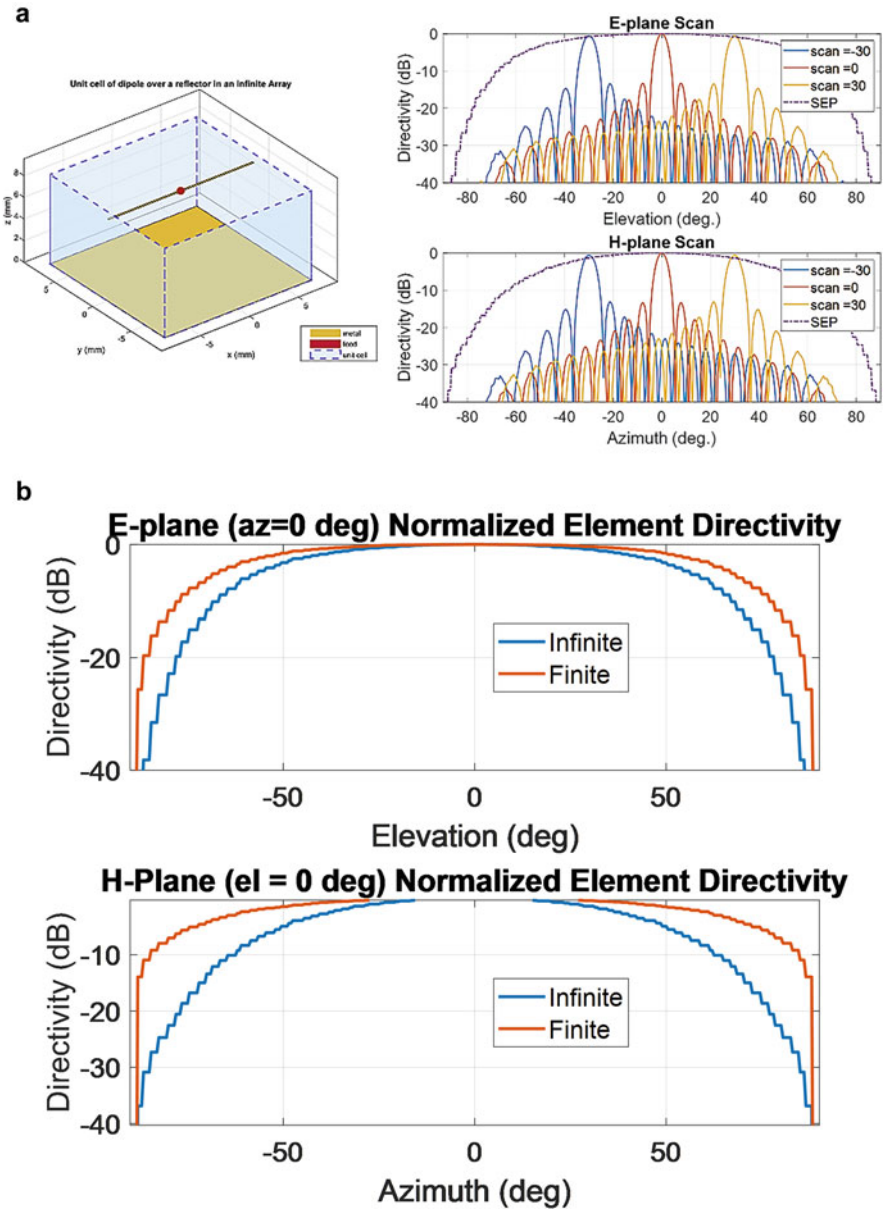

Fig. 15 Element performance in an array environment

from a metallic block by wire-cutting technology within precision of 50 μn. A 64-element (8 × 8) array is fabricated arranged in a triangular grid with Fig 16b showing the numbering scheme of the elements. Table 1 shows the comparative

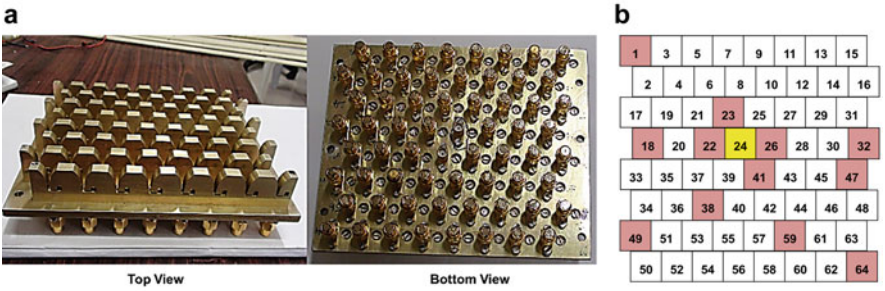

Fig. 16 Metallic Vivaldi antenna (MVA): (**a**) photographs of the top and bottom views; (**b**) numbering scheme for elements in an array

Table 1 Comparison of MVA pattern at 10 GHz

Case	Gain (dBi)	HPBW (deg)			x-pol (dB) over ±60° scan volume		
		E	D	H	E	D	H
Isolated	2.3	131	131.5	121	−19.3	−9.6	−22.8
Infinite array	4.7	141	125	93	−9.5	−32	−14.4
8 × 8 Array (measured)	3.2	118	–	95	−18	–	−22

summary of isolated element with infinite array and finite array (measured) in terms of gain, HPBW, and cross (x-) polarization levels. A substantial difference is observed in the HPBW and x-pol levels between isolated element and the element in the array environment. A variation is observed in the finite array and infinite array environment as expected because of the finite edge effects, as expected. Figure 17 shows the measured co- and cross-polarization radiation pattern plots over 9–12 GHz bandwidth in finite array environment.

The antenna element design is crucial, and once it is done, the next design aspect in PAA is the design of transmit receiver modules discussed next.

T/R Module Technology

The T/R module (TRM) (Sreenivasulu et al. 2020; Kedar et al. 2020a; Sturdivent and Harris 2015) forms a key element of an AESA which comprises of *distributed transmitter* and *receiver* providing necessary *amplitude* and *phase* coefficients to the array elements. It makes an extensive use of the semiconductor technology to provide necessary transmit power and low noise reception of *rf* signals to/from an antenna array in AESAs. It decides the desired power output and receiver sensitivity of the radar system. TRMs have necessarily four functions:

1. Provides gain and RF output power during transmission of PAA
2. Provides low noise reception during reception through PAA

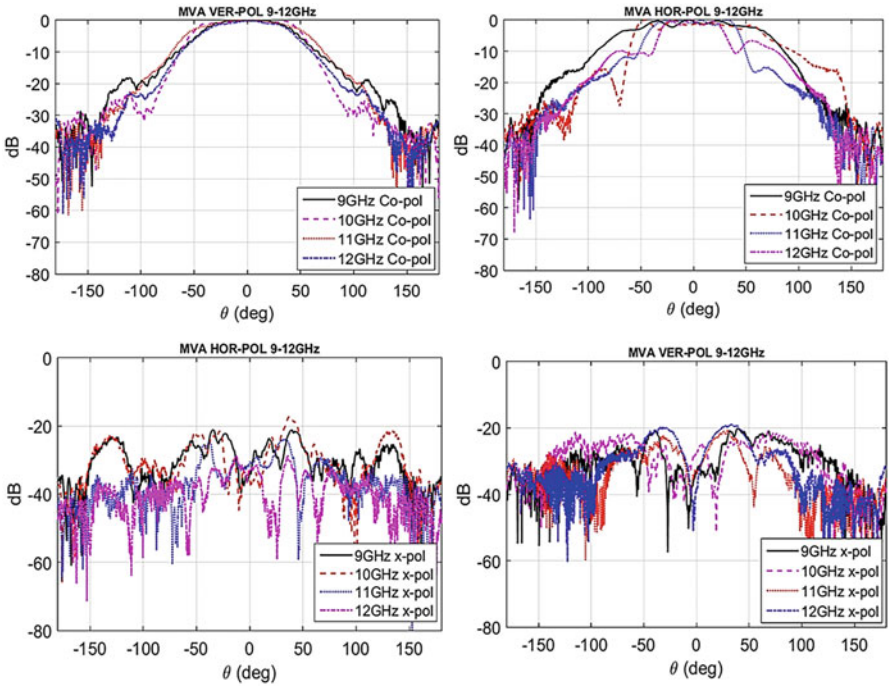

Fig. 17 Measured co- (top side) and cross- (bottom) radiation pattern plots of element in the finite array environment over 9–12 GHz

3. Provides dynamic switching between transmit and receive chains of PAA
4. Provides dynamically phase shifts and attenuation to the elements in PAA

The total power output, P_{out}, of radar is equal to the number of elements multiplied by individual TRM output. Figure 18 shows a typical design flow chart of a TRM with a functional block diagram of TRM shown as an inset. Figure 19a shows typical common leg functional bock diagram which is commonly employed in PAAs. This allows only half duplex operation, i.e., either TRM operates in Tx or in Rx mode only at an instant as shown in Fig. 19b.

The various semiconductor technologies available for the realization of monolithic microwave integrated circuits (MMICs) are based on Si, SiC, GaAs, LDMOS, or GaN processes (Sturdivent and Harris 2015). The choice of the particular technology depends upon the trade-off in the form factor of TRM, power output, module efficiency, operational bandwidth, and the cost. GaAs and GaN are the most suitable and utilized semiconductor technologies used for the realization of MMICs for wide band and high-power output TRMs in today's scenario. Figure 20 shows the comparison of these two technologies. GaN is the latest current semiconductor technology extensively used for high-power and high-gain applications in TRMs (Kedar et al. 2020a; Sturdivent and Harris 2015). Typically, considering a 4–6-inch

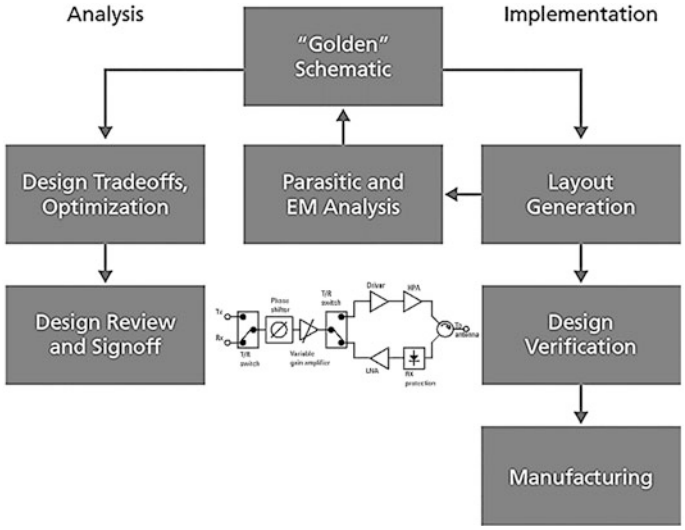

Fig. 18 TRM design realization flowchart

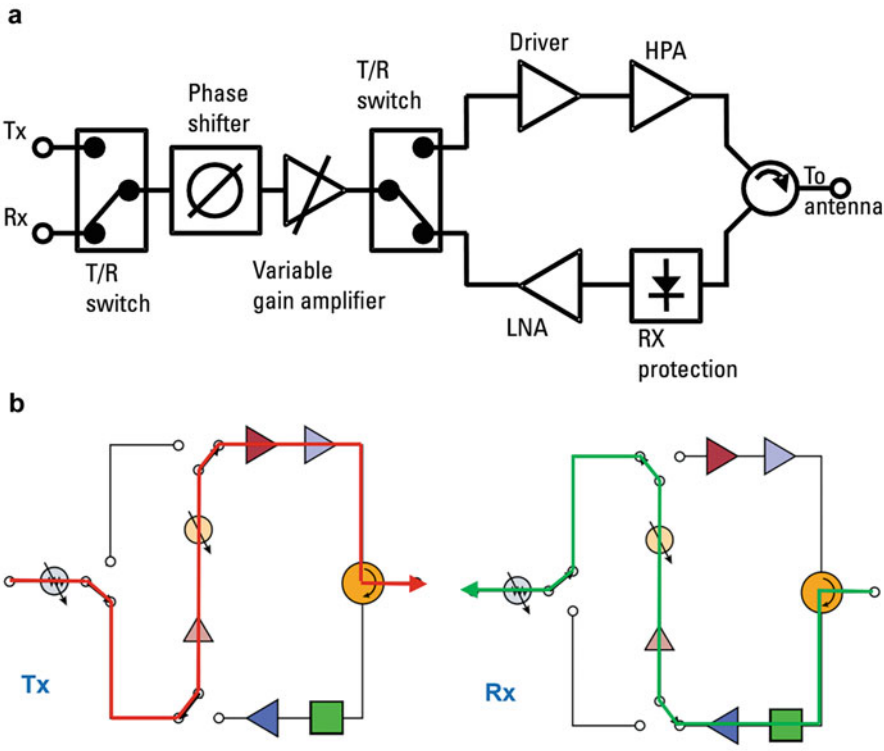

Fig. 19 (**a**) Typical common leg TRM design functional block diagram; (**b**) half duplex operation

Parameter	GaAs	GaN
Power Density	0.5 to 1.5W/ mm	>10W/mm
Operating Voltage	5-20V	25-50V
Max. Breakdown Voltage	~40V	>100V
Maximum Current	~0.5A/mm	~1A/mm
Thermal Conductivity (W/m-K)	47	390/490, SiC
Efficiency	>20-40%	>50%

Fig. 20 Comparison of GaAs and GaN technologies

wafer the power levels obtained from GaN technology are 2–3 times more than corresponding GaAs wafers (Sturdivent and Harris 2015).

The advantages offered by GaN over GaAs technology are the following:

- High-energy bandgap (2.5 times more)
- High breakdown field-strength (10 times more)
- High RF power densities (5–10 times more) on small chip sizes
- Broadband amplifier applications (multioctave design)
- High bias supply voltages
- High thermal conductivity ($\times 3$ (GaN), $\times 8$ (SiC))
- Radiation hardness

The specifications of TRM are derived from PAA-based radar specifications. Radar range determines power-aperture product of antenna (Kedar 2022), which in turn determines the output power radiated per element and henceforth, the power output of TRM. Total power-aperture product determines the number of TRMs and elements in PAA. For example, in C-band if 20 kW power is required to be radiated from an array, it can be served by choosing 1000 numbers of 20 W GaN-based TRMs, each feeding an element in PAA. However, if GaAs-based TRM is chosen, a maximum of 10 W is possible, and henceforth the number of TRMs will be doubled. Thus, the technology and the quantity of TRMs are determined from the radar requirements. Thus, size, power, noise figure, efficiency, phase and amplitude controls, and connectors for inter-connections in TRMs, all of these are derived from radar requirements. The size of TRM is determined by the inter-element separation in an array (Kedar 2022; Sturdivent and Harris 2015; Kedar et al. 2020b). The noise figure and receive chain gain of TRM determines the front-end noise figure of overall RX chain of PAA-based radar and thus is very critical and needs to be minimized (Kedar et al. 2020a; Sturdivent and Harris 2015; Kedar et al.

2020b). Thus, overall dynamic range of cascaded receiver chains is dependent on the noise figure and receive gain.

Phase shifter is another critical technology which determines the dynamic application of desired phase shifts for beam steering and forming single or multiple steered beams from PAA-based radar. It should provide 360° of phase control across the operating bandwidth while allowing minimum insertion loss, switching time, rms errors, etc. With the advent of digital phase shifters comprising of PIN diodes, MESFETs, etc. with phase increments dependent upon the least significant bit (LSB), it is possible. The typical 6bit phase shifter allows an LSB of 5.625° error. It will give a total of 2^6 states of phases across 360°. Thus, greater the number of bits, better is the performance but with the increase in cost and complexity due to intricacies of technologies involved (Sturdivent and Harris 2015). Similarly, attenuators control the amplitude of the signal fed to array elements and thus control the sidelobe level (SLL) of PAA. The number of bits of digital attenuator controls the minimum attenuation that is possibly fed to the element. Currently 6- and 7- bits attenuators and phase shifters are in use in radars arena. The power amplifier decides the power output as explained in the above text and again decides the semiconductor technology to be used, LDMOS, GaAs, GaN, etc. The circulator provides isolation between receive and transmit chains before antenna element, and limiter switch protects receive chain from high power leakage from transmit chain. Low noise amplifier (LNA) determines the noise figure and maximum rf signal that can be received by the TRM. The details of TRM constituents can be had from ref (Sturdivent and Harris 2015).

The concept of PAA is critically dependent on the availability of compact and minimum weight, low consumption, and high reliability T/R Modules. The large number of individual T/R Modules, integrated with the respective radiating elements, ensures a great degree of redundancy (Graceful Degradation). It decides the generation of Transmit Power, Low Noise Amplification of the Received Signals, Required Phase Shift in the Transmit and Receive Mode for Electronic Scanning, Variable Gain Setting for Aperture Weighting, and Proper Interface to the Array Beam Steering Controller as well as Array Beamformer and Radiating Elements. T/R microwave modules are thus the key elements of the active phased arrays.

Thermal Design, Reliability, and Heat Transfer Technologies

The involved MMICs in TRMS and transmission lines for carrying *rf* signals lead to practical issues such as thermal management and signal integrity. Thus, design of AESA is not complete without carrying out proper thermal management and signal purity analysis to mitigate any cross talk or heat buildup inside the TRMs. Further, TRMs involve multilayer printed circuit boards glued together involving interconnects binding multilayer boards' traces. Thus, design of TRMs involves careful consideration of these using *em* analysis based on the full wave techniques like method of moments (Sturdivent and Harris 2015).

Beamformer Technology

PAAs need to compute the progressive phase shifts, compute number of beam parameters, etc., digitally at a down level hierarchically in the PAA-cascaded chain. Usually these are relying on field programmable gate arrays (FPGAs) or application-specific integrated circuits (ASICs) technologies. Beamformer circuits are essentially digital PCBs which form the beams as per the radar requirements. Each beam input is split according to the number of elements, and amplitude and phase weights applied. The input to each element includes a power combiner which order is equal to the number of beams. The number of gain and phase control points is the product of the number of beams and number of elements. In order for the array to constructively beamform in the direction theta, the elemental paths must introduce a progressively increasing time delay of n*d*sin(theta) or an equivalent phase delay (only correct at one frequency). These converts rf received from TRM into digital signal using analog-to-digital convertors (ADCs) or converts digital to rf while transmitting the power to TRM using digital-to-analog convertors (DACs). The number of ADCs/DACs depends upon the number of channels in the receiver, which is again determined from radar requirements mainly beam switching time, cost, complexity, and the number of beams required by radar to be formed. There are various possible beamformer architectures available in literature (Sturdivent and Harris 2015) but not dealt with here due to limited scope of this chapter.

Phased Array Calibration and Assessment

The realization of AESAs is an engineering challenge involving assembly of different submodules, thermal management, power distribution, and compact framework housing these subunits. The integrated AESA needs to be calibrated and evaluated for the desired performance. It requires beam collimation and calibration inside an *anechoic chamber* isolated from surrounding noises (Balanis 1997; Brookner 1991; Rensburg et al. 2020) based on near field measurements. An optimal performance of an AESA is only achievable by employing suitable calibration techniques to mitigate the nonuniformities observed in the radiation pattern of the radiating elements due to the various factors such as mutual coupling, the amplitude and phase sensitivities observed in the associated active electronics (TRMs, beamformer hardware, etc.), and near-field scattering phenomenon.

Collimation Procedure for Active Array: The instrument calibration loop inside anechoic chamber is used to perform three distinct functions. First of all, it characterizes the instrument transfer function during the measurement modes, followed by the characterization of the individual TRMs and lastly the special external characterization mode.

Calibration: The amplitude and phase characteristics of the passive circuit viz., probe sampling the energy from AESA, Built In Test Evaluation (BITE) Feed Network inside the AESA, and cables in the RF injection path of each of the TRM are measured as *calibration ratio (CR)* in an antenna chamber, also called as *near*

field test range (NFTR) during the pattern measurement of an AESA. The CR measurement setup is shown in the Fig. 21.

$$\text{Calibration ratio} = \text{Probe value} - \text{Injection value} \tag{3}$$

In NFTR, CR measurement is carried out at a fixed temperature (room temperature) for multiple spot frequencies of operation for AESA (typically 11 or more) in all the operational modes of an AESA, i.e., *transmit (Tx)* as well as *receive (Rx)* modes.

The basic concept in calibration of TRMs is to Switch "ON" only one selected module out of "N" Modules with rest of N-1 Modules in OFF State in an AESA. Then, sample the amplitude and phase values of the "ON" Module through Sum/CAL Receive Channel of Central Unit by injecting the appropriate BITE/CAL RF Signal through BITE/CAL Feed Network.

Transmit path calibration: During Tx mode calibration as shown in Fig. 22, TX drive signal from exciter is fed as an input to TRMs through RF feed network. The selected TRM, i.e., its Tx chain, is "ON," amplifies the Tx drive signal, and radiates, while keeping other TRMs in "OFF" state (i.e., in Rx mode with proper isolation).

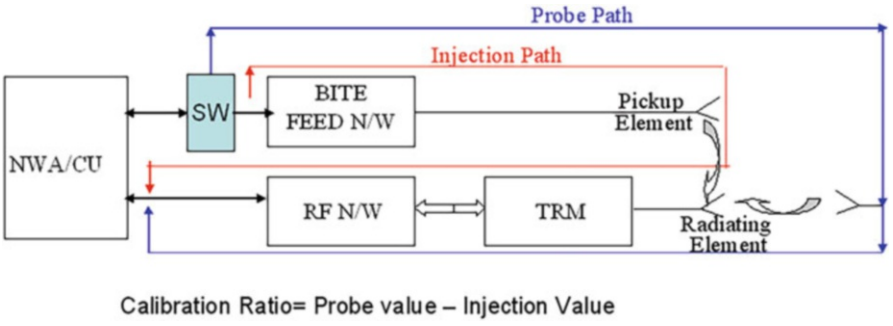

Fig. 21 Calibration ratio measurement setup

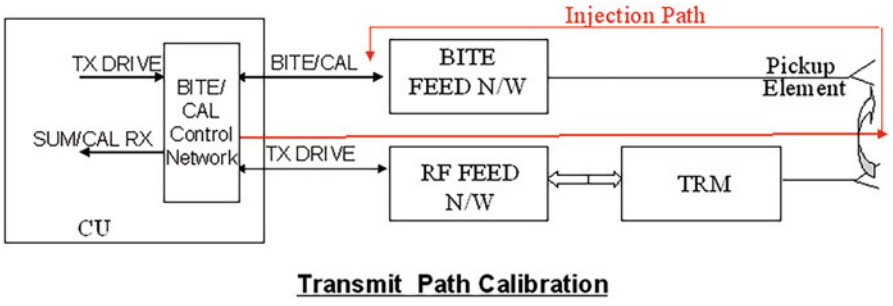

Fig. 22 Transmit path calibration

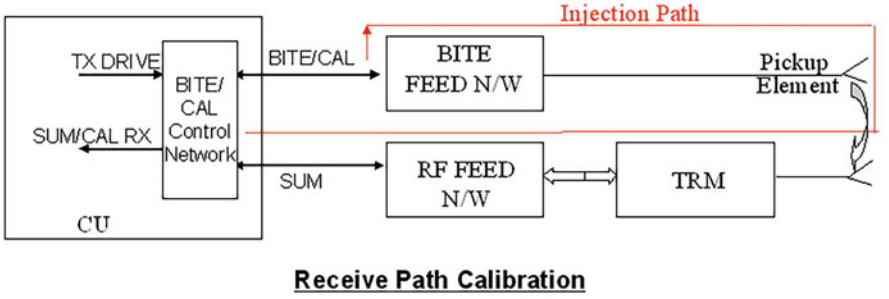

Fig. 23 Receive path calibration

This radiated signal is received by the pickup element of the radiating segment and passed through BITE feed network to the input of Rx channel in the receiver. Further, it is digitized as "I" and "Q" data and sent to the Radar Controller (RC) for computing the amplitude and phase values of the selected TRM. The module to be calibrated is set for 0 dB attenuation, 0° phase state during transmit mode at the first iteration. The amplitude and phase values are computed by adding this sampled (injection path) value to the respective CR value. As the Tx amplifiers are saturated, phase calibration only required to cophase all TRMs within 1 LSB of 0° phase value.

Receive Path Calibration: The Rx mode calibration is shown in Fig. 23 below, where Tx drive signal is fed to the pickup element of the AESA's radiating segment through BITE feed network. The selected TRM, whose receiver is "ON," amplifies the signal received through its antenna from the pickup element's radiation, while other TRMs are in "OFF" state (kept in Tx mode with proper isolation). This amplified signal passes through RF feed network, Sum channel of the beamformer unit, and is fed to the input of the receiver-exciter unit of radar. The sample is further sent to the RC for computing the amplitude and phase values of the selected TRM. The module to be calibrated is set for attenuation state and corresponds to distribution value, 0° phase state at the first iteration. The amplitude and phase values required for calibration are computed by adding this sampled (injection path) value to the respective calibration ratio value. As the receive amplifiers are linear, all TRMs need to be calibrated to their respective distribution values within 1 LSB and phase calibration is required to cophase all TRMs to within 1 LSB of 0° phase value. It is to be mentioned that the calibration network thus explained should conform to the dynamic range of the receiver exciter unit of the radar. Typically, the dynamic range is around −50 dBm to −70 dBm during in-system calibration for transmit and receive states. The noise level at the input of Sum/CAL receive channel is −90 dBm. Thus, *signal to noise ratio* (SNR) during calibration is >20 dB which is easily obtainable in AESAs.

The in-system calibration of TRMs is performed on request basis in the field either periodically over 100/200 h of system usage or after replacement of faulty

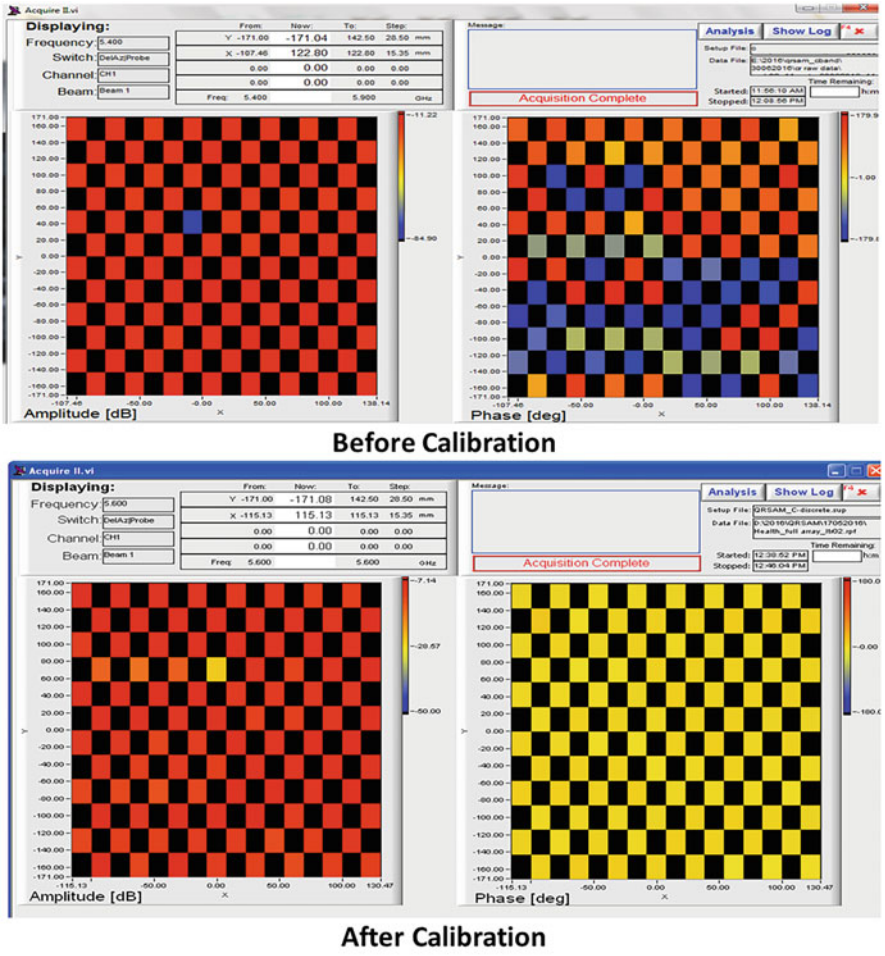

Fig. 24 Receive path calibration

modules in AESA. If there is a large variation in T/R Module parameters during Power on BITE or On-line BITE, array calibration can be performed for the randomly selected T/R Module or for all the T/R Modules based on the operator request. Figure 24 shows the amplitude and phase distribution in a 64-elements AESA before and after calibration process. It is clear that after calibration the amplitude and phase distribution over the radiating aperture of AESA is within 1 LSB of amplitude and phase distribution. Figure 25 shows the pattern performance of an AESA during the iterations involved in calibration process. A clear beam formation is visible after the completion of calibration process involving 2–5 iterations at a maximum.

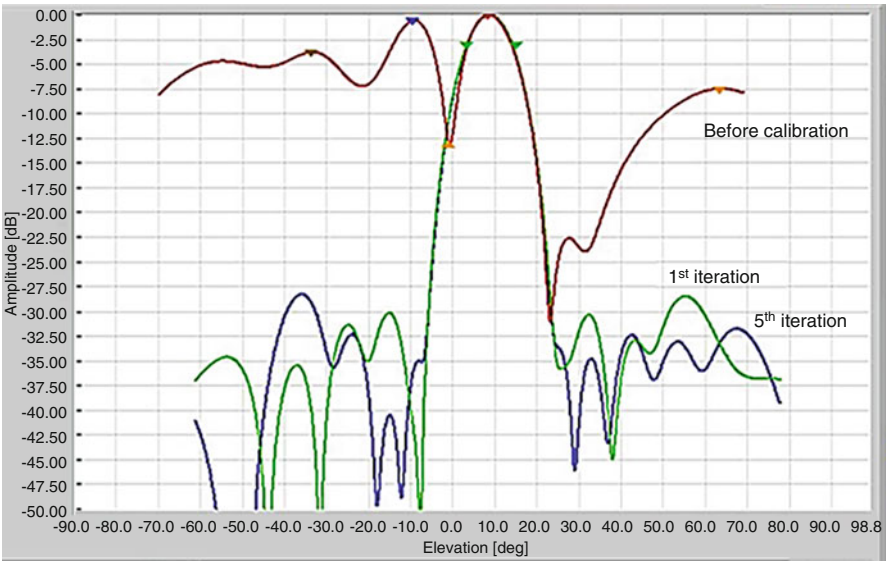

Fig. 25 Radiation pattern performance of AESA

Conclusion

The present chapter discusses the phased array antenna technology for radars and presents various involved technologies like radome, antenna, T/R modules, thermal integrity, calibration processes, etc. It presents a brief historical perspective of radar and the importance of an efficient design of phased array antenna to ensure desired performance of phased array radar. Phased array antenna is system of systems involving various subsystems involved in its buildup like radome for external environment protection without giving any hindrance to its performance, antenna array serving as eyes and ears of radar, T/R modules giving necessary power output and noise-free reception, and various technologies involved in developing these technologies. The various involved technologies are discussed briefly familiarizing the reader about them and a platform to start the detailed investigations on the topic of interest. A brief of operational constraints, characteristic parameters, and working mechanism of various technologies is presented. The chapter concludes with the calibration and collimation techniques for characterizing AESAs.

Abstract

Multiple-input Multiple-output (MIMO) antennas are one of the key enabling technologies for the modern (4G-LTE, 5G) cellular communication base stations/hand-sets/wireless access points (WAPs) and will continue to dominate the implementation of future generation wireless technologies (6G and Beyond). MIMO systems provide significant advantages over conventional SISO (Single-input Single-Output) systems, especially in combating multipath fading effects in NLOS (Non-Line of Sight) propagation scenario, leading to enhanced channel capacity (data-rate), lower bit-error probability, and better signal-to-interference-noise ratio (SINR). Transcending from cellular and WLAN (Wireless Local Area Network) domain, research on MIMO techniques are currently emerging significantly in the context of RADAR (Radio Detection and Ranging) systems as well. While the classical RADAR technology has been well-established in the context of defense applications (since World War II) and weather-monitoring systems, its integration with MIMO technology has opened new directions for RADAR usage in many industrial and civilian applications.

In this chapter, we first describe the standard operating principles of MIMO RADARs and elaborate upon their advantages over conventional phased array

RADARs. Among the various application environments, MIMO RADARs have assumed a crucial role, especially in automotive applications like advanced driver assistance systems (ADAS). Subsequently, we describe the state-of-the-art mm-wave MIMO antennas available in the open literature for automotive systems. Besides highlighting the antenna design aspects, we also critically examine the different integration challenges when a RADAR antenna system is installed inside a vehicle.

MIMO RADAR · Automotive · ADAS · Virtual array · Antenna

Introduction

Automotive RADAR systems, first introduced in the late 1990s, show a steady trend from safety-oriented vehicle functions (Active Safety: AS) to comfort (Advanced Driver Assistance System: ADAS). Nowadays autonomous vehicle is a reality and a very challenging research topic. As we all know, most of the high-tech, sophisticated, and luxurious automotive industries such as Daimler Mercedes-Benz, BMW, Tesla, etc. working proactively on future advanced driver assistance systems (ADAS), driver-less vehicles, or self-driven cars. The component or device, which is the basic building block to accomplish this concept, is the automotive MIMO RADAR sensor or collision avoidance RADAR. Automotive MIMO RADAR is the key component in autonomous driving and safety systems including a diverse range of applications shown in Fig. 1. RADAR-based systems tend to address scenarios of growing complexity, targeting urban or city traffic along with highway scenarios,

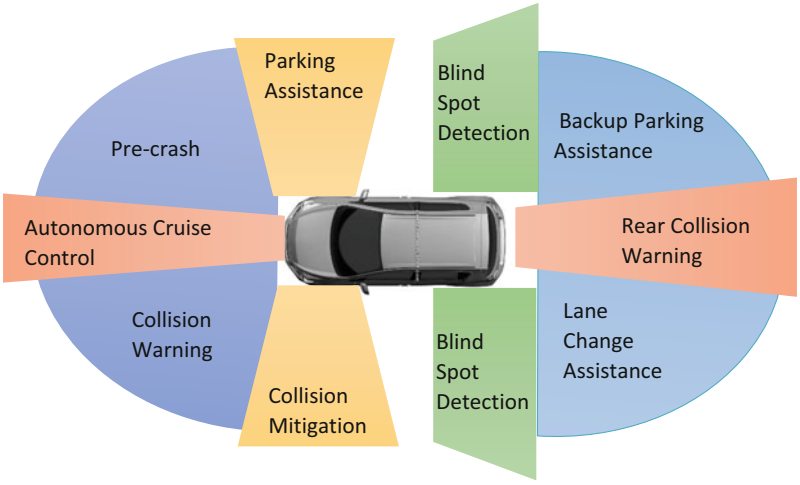

Fig. 1 Applications of automotive collision avoidance RADAR

which are the main application in recent years. In general, frequency-modulated continuous wave (FMCW) radar technology is used for this purpose. Resolution in range, azimuth angle, and target velocity are the key features to deal with demanding scenarios of high complexity and high dynamics (Rasshofer 2007). European Union has replaced the previously used 24 GHz ultrawideband RADAR sensors with a new frequency band from 77 to 81 GHz to enable future ADAS and AS systems. However, there are certain basic advantages of the 77 GHz band over 24 GHz as far as the radar antenna properties are concerned as listed in Table 1 (Viikari et al. 2009; Ramasubramanian et al. 2017).

The European-funded project "RADAR on Chip for Cars" (short RoCC) started in the fall of 2008 (RoCC press release 2009) in order to start the development of 79 GHz band technology. The main advantages of the 77 GHz to 81 GHz frequency range (79 GHz band) are that RADAR devices can be much smaller, and that a single technology can be used for all applications along with a greater capability for distinguishing between objects.

Further, as the degree of automation has reached levels 4 and 5 (Merlo and Nanzer 2022), situational sensing is an utmost priority in an autonomous vehicle, necessitating the rapid development of sensor technologies (Marti et al. 2019) with high-resolution mapping. Generally, this high-resolution sensing is achieved by using various sensors such as LIDAR (Light Detection and Ranging), camera, ultrasonic SONAR, and automotive RADAR, which have paved the path for the realization of fully autonomous vehicles or self-driving cars. In addition, it is supported by advanced monolithic microwave integrated circuits (MMICs), computer vision techniques, artificial intelligence, and improved signal processing (Engels et al. 2017). The optical sensors such as LIDAR and camera provide high angular resolution and visual representation of the target, respectively, but fail in low light conditions and face high attenuation in bad weather conditions such as rain, fog, dust, snow, etc. (Jokela et al. 2019). The SONAR sensor is suitable for low-speed and short-range target avoidance; however, its spatial resolution and maximum range are restricted for dynamic driving conditions and at the same time get attenuated in adverse weather conditions. On the other hand, RADAR is one of the most efficient sensors among others which is unaffected by weather conditions and independent of lighting conditions. Due to the development of mm-wave, MMICs automotive industries are now capable to realize the complete RADAR on a single chip (RoC) or system-on-chip (SoC). For example, a fully integrated 65-nm CMOS technology 77 GHz frequency-modulated continuous wave (FMCW) RADAR system for an automotive application is proposed in (Kucharski et al.

Table 1 Basic comparison between 24 GHz and 77 GHz automotive radar antenna parameters

Parameter	24 GHz	77 GHz
Frequency range (bandwidth)	24 GHz–24.5 GHz (250 MHz)	76 GHz–81 GHz (5 GHz)
Size	Higher	One-third the size of 24 GHz
Resolution	Lower detection range with resolution	Higher resolution and excellent detection range than 24 GHz

2019). In (Lee et al. 2010), a 79 GHz scalable RADAR based on a transceiver system having a single channel is proposed. Similarly, Usugi et al. (2020) propose another fully integrated 77 GHz LRR (Long-range RADAR) transceiver in 40-nm CMOS technology. Further, the MIMO (multiple-input multiple-output) concept in the RADAR system provides an additional degree of freedom to improve the angular resolution without increasing the physical antenna aperture. The MIMO technique increases the RADAR angular resolution by introducing the formation of a virtual array of receiver antenna that contains more number of antenna elements and a larger virtual aperture than the physical antenna through the use of waveform diversity (i.e., transmitting orthogonal waveform from transmitter antennas) and reduces the cost of LNAs and other active components present in the receive chain (Li and Stoica 2007). More information on angular resolution improvement concepts using MIMO RADAR can be found in (Dash et al. 2021a; Rao 2017; Vasanelli et al. 2017).

The design and analysis, present in the open literature on 77 GHz automotive RADARs, deals with the RADAR performance in free space. However, these automotive RADARs, in the practical application scenario, are integrated behind a bumper material having multilayered paint materials (Dash et al. 2019). The bumper produces additional path loss thereby affecting the sensitivity of the receiver and detection latency, consequently affecting ranging. In addition, the bumper distorts the antenna radiation pattern that causes ambiguity in the direction of arrival (DoA)/ departure (DoD). Therefore, a systematic study on the electromagnetic effects on the MIMO RADAR antenna performance due to the presence of bumper material property is essential for the automotive industry to choose a proper bumper material to achieve robust and uncompromised RADAR functionality.

MIMO RADAR Working Principle

MIMO RADAR system contains multiple transmitter antennas and multiple receiver antennas which generate multiple EM waveforms and provides the capability to access multiple degrees of freedom (Fishler et al. 2004). This feature has attracted automotive RADAR engineers. MIMO RADAR is of two kinds such as MIMO RADAR with collocated antennas (Li and Stoica 2007) and MIMO RADAR with widely separated antennas (Haimovich et al. 2008). The schematic representation of these two MIMO RADAR types is shown in Fig. 2. Automotive applications focus on the MIMO RADAR with the collocated antennas. This RADAR system contains multiple transmitter and receiver antennas on a single substrate placed at a few wavelengths apart. The signal transmitted by each antenna is different from each nearby antenna. Further, the reflected signal from the target belongs to each transmit antenna and can be separated easily due to signal orthogonality. This feature allows the formation of a virtual array that contains the signal information from each transmitter antenna to the receiver antenna. Figure 3 shows the schematic of the virtual array. Thus, the M transmit antennas and N receive antennas in the MIMO RADAR form the M.N independent transmit-receive pair, where each pair acts as a single monostatic RADAR. The M+N number of physical antennas form M.N signal pairs. This allows the advantage of wide FoV, high angular resolution, and compact

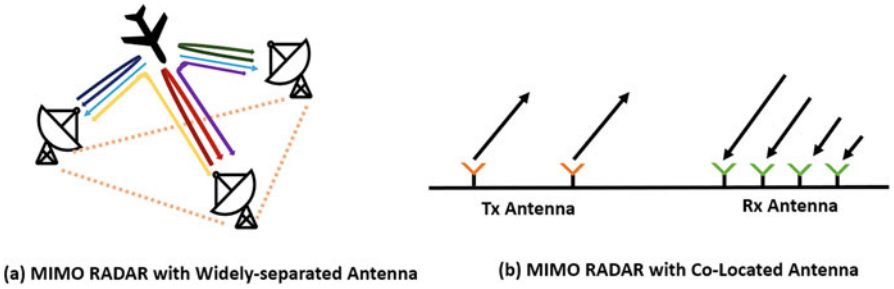

Fig. 2 Schematic representation of two different types of MIMO RADAR based on the antenna placement

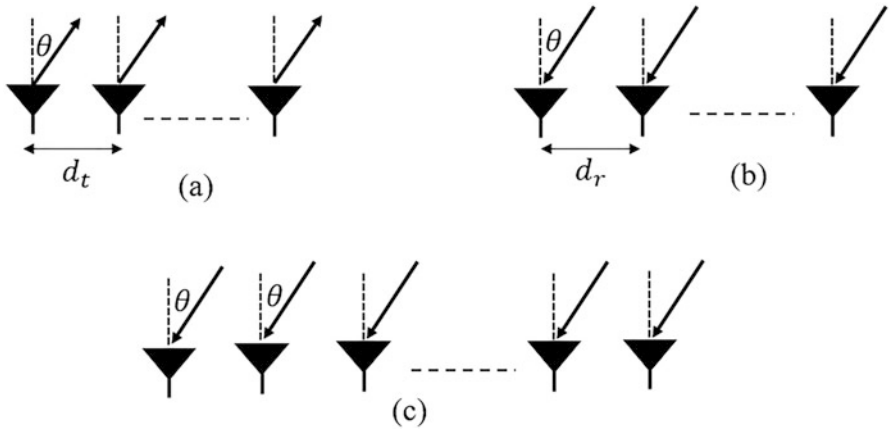

Fig. 3 Schematic to represent virtual array for MIMO RADAR with collocated antennas: (**a**) M transmit antennas; (**b**) N receive antennas; and (**c**) MN × 1 virtual array

size. Equations 1, 2, and 3 (Qu et al. 2008) represent the signal model for MIMO RADAR as shown in Fig. 3.

$$A_t(\theta) = \left[1, e^{-jkd_t \sin(\theta)}, e^{-j2kd_t \sin(\theta)}, \ldots\ldots\ldots, e^{-j(M-1)kd_t \sin(\theta)}\right]^T \quad (1)$$

$$B_r(\theta) = \left[1, e^{-jkd_r \sin(\theta)}, e^{-j2kd_r \sin(\theta)}, \ldots\ldots\ldots, e^{-j(N-1)kd_r \sin(\theta)}\right]^T \quad (2)$$

$$V(\theta) = A_t(\theta) \otimes B_r(\theta)$$

$$= \left[1, e^{-jkd_r \sin(\theta)}, \ldots\ldots, e^{-j(N-1)kd_r \sin(\theta)}, \ldots\ldots, e^{-jkd_t \sin(\theta)}, e^{-jk(d_t+d_r) \sin(\theta)}, \ldots\ldots,\right.$$
$$e^{-jk(d_t+(N-1)d_r) \sin(\theta)} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots, e^{-j(M-1)kd_t \sin(\theta)}, \quad (3)$$
$$\left. e^{-jk((M-1)d_t+d_r) \sin(\theta)} \ldots\ldots, e^{-jk((M-1)d_t+(N-1)d_r) \sin(\theta)}\right]^T$$

where $A_t(\theta)$, $B_r(\theta)$, and $V(\theta)$ are the steering vectors for the transmit, receive, and virtual arrays, respectively. d_t and d_r are the inter-element spacing in the transmit and receive array and $\otimes$ represent the Kronecker product.

Though it is quite possible to get high range and Doppler resolution from a stationary RADAR, it suffers from low angular resolution due to the smaller number of physical channels. Angular resolution is directly proportional to the antenna's physical dimension. The virtual array, produced by the MIMO RADAR, bears a larger effective dimension that increases the angular resolution within the small physical size. This unique feature of achieving higher angular resolution through the virtual array implementation has drawn the attention of automotive industries to perceive advanced driver assistance systems (ADAS) using MIMO RADAR for current and future autonomous vehicles. According to the Rayleigh criterion, angular resolution ($\Delta\varphi$) can be defined as $1.22\lambda/d_v$ (Hasch et al. 2012), where λ = free space wavelength and d_v represents the MIMO RADAR virtual array dimension. MIMO RADAR having a 3-transmitter and 5-receiver configuration showing the angular resolution of 5.82° is described in (Dash et al. 2021a).

Overview of Antenna System for Automotive RADAR Application

Automotive MIMO RADAR is classified into long-range RADAR (LRR), medium-range RADAR (MRR), and short-range RADAR (SRR) based on the maximum attainable range and field-of-view (FoV). Nowadays, automotive RADARs are commercially provided by several companies such as Autoliv, Continental ADC, Hitachi, Delphi, Bosch, Fujitsu Ten, InnoSent, Hella, Mitsubishi, TRW Autocruise, and Valeo (Menzel and Moebius 2012). These commercially available RADAR sensors are a complete transceiver module. The antenna system in this RADAR module is the main differentiating factor, because the standard antenna performance parameters such as gain, bandwidth, impedance matching, and the number of antennas used in a RADAR module decide the FoV and the angular separation between the target objects. A brief overview of four antenna system concepts for automotive RADAR application based on the beamforming properties is found in (Hasch et al. 2012) such as (a) quasi-optical beamforming, (b) digital beamforming, (c) analog beamforming, and (d) mechanically scanned array, though it does not address any antenna structure or type of antenna for an autonomous vehicle. However, the antenna type affects the system integration, performance, overall size, and cost of any RADAR module. Moreover, antenna design also decides the RADAR range and the coverage area, i.e., a mid or short-range RADAR requires a wide beam and low-gain antenna. There are certain general antenna types available in the literature (Menzel et al. 2002) for millimeter wave-automotive applications, broadly reflector antenna and planner antenna. Apart from that antenna-in-package and antenna-on-chip are a few state-of-the-art technologies to develop integrated antenna-on-chip, which requires advanced fabrication facility along with the selection of low loss substrate material at 77 GHz millimeter wave application.

Initially, Robert Bosch developed a 77 GHz RADAR lens antenna for automotive applications (Binzer et al. 2007). However, this antenna structure was quite bulky in size to integrate into a vehicle. Instead of complex lens structure planner, reflect array design using periodic or quasi-periodic structure is reported in (Menzel et al. 2002) to focus incident spherical wave and to produce a polarization conversion to the incident wave. An antenna concept for automotive RADAR sensor using planner end-fire Yagi-Uda radiators with cylindrical parabolic reflector is proposed in (Beer et al. 2009). This antenna is designed on an RF substrate while pointing the antenna toward the parabolic reflector. It reflects the EM beam in the desired direction perpendicular to the board in the elevation plane. Though the antenna configurations like reflector or lens are some of the good performance structures, the planner or microstrip structures outperform when the system integration and compatibility come into the picture. Simple structure, low profile, lightweight, low manufacturing cost, and easy to integrate behind the car bumper or fascia patch antenna arrays have been widely used in the automotive application at 76–81 GHz frequency band (Blöecher et al. 2012; Bloecher et al. 2009). A 18×8 element series-fed antenna with Taylor array pattern synthesis is proposed in (Shin et al. 2014) for short- and long-range automotive RADAR application. The sidelobe levels of this proposed antenna are 20.19 dB in the elevation plane and 25.08 dB in the azimuth plane, and a waveguide to microstrip transition is designed to feed the antenna. A transmit array in a two-layer printed circuit board (PCB) with Coplanar patch unit-cells etched on opposite sides of the PCB and connected by through-via is proposed in (Yeap et al. 2015) for automotive RADAR applications. To generate a high gain beam for automotive application, the proposed transmit array is combined with four-substrate-integrated waveguide (SIW) slot antennas as the primary feed. A patch array with a double coupled feeding structure is proposed in (Yoo et al. 2020). The antenna is designed to achieve wideband matching and gain bandwidths for automotive RADAR applications. The antenna consists of a microstrip line with a rounded rectangular radiator with a waveguide feeding. Two arrays having 1×18 and 4×18 elements are presented in (Lee et al. 2020) for millimeter wave application. These are capacitively coupled microstrip comb-line (CCMCA) array antennas for the millimeter-wave band having a low sidelobe level. An efficient leaky-wave antenna (LWA) based on a half-mode substrate-integrated waveguide is proposed in (Front RADAR sensor 2020) for 24 GHz-automotive RADAR application. The prototype exhibits 25% impedance bandwidth with 12.5 dBi gain and 85% efficiency at 24 GHz application frequency. The antenna has a half-power beamwidth of 12°. Apart from that, Table 2 provides more information on the various antenna design aspects at the 77 GHz operating band for automotive radar applications available in the open literature.

The antenna designs available in the literature for automotive RADAR applications are restricted to the design of individual antenna elements and lack discussion of RADAR implementation viewpoint. A modified binomial series-fed microstrip antenna with 3 Tx and 5 Rx MIMO configuration for 77 GHz-automotive RADAR application is provided in (Dash et al. 2021a). The antenna exhibits low sidelobe level ($<$16 dB), low cross-polar level ($<$30 dB), and 80° half-power beamwidths.

Table 2 Antenna types for 77 GHz automotive radar application

Reference	Antenna type	Substrate material	Dielectric constant (thickness: mm)	HPBW (degree) (E/H plane)	Cross polarization (dB)
(Yeap et al. 2015)	Dual-layer transmit array	RO4003C	3.38 (0.203)	15	–
(Hallbjorner et al. 2012)	Lens antenna	Taconic Taclam Plus	2.1 (0.1)	4/4.4	<-19
(Wang and Stelzer 2013)	LTCC patch array antenna	Low-temperature cofired ceramic	7.3 (0.27)	7	–
(Artemenko et al. 2013)	Integrated lens antenna	RO4003C	3.5(−)	18 (12.5 mm lens) and 27 (7.5 mm lens)	<-25

(Arnieri et al. 2018)	Planar grid array	Roger 3003	3 (0.254)	5	<-22

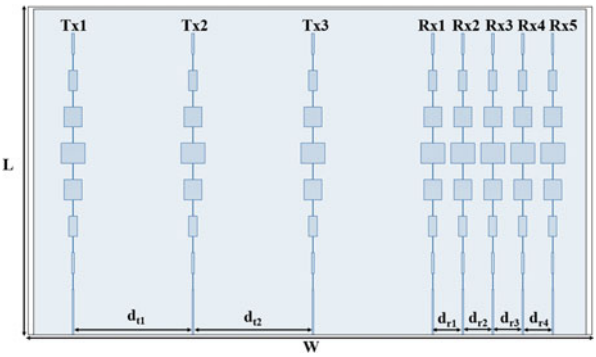

Fig. 4 Schematic of 3Tx-5Rx MIMO RADAR antenna. Dimensions in mm: L = 37.3, W = 22.65, $d_{t1} = d_{t2} = 8$, $d_{r1} = d_{r2} = d_{r3} = d_{r4} = 2$. (See Dash et al. (2021a) for more details). (© IEEE 2021)

Further, the proposed MIMO RADAR antenna configuration provided 5.82° angular resolution. The MIMO RADAR antenna prototype at 77 GHz operating is shown in Fig. 4. Fig. 5 shows the S-parameter curve and the 3D radiation pattern of the individual antenna element in Fig. 4.

More specifically, the antenna design shown in Fig. 4 is a one-dimensional (1D) MIMO RADAR antenna configuration. Note that the 1D MIMO RADAR antenna defines the nature of the formation of the virtual array (see Fig. 3) due to the antenna arrangement as shown in Fig. 4. This antenna arrangement is limited to azimuth angular resolution using 1D MIMO RADAR virtual array as shown in Fig. 3c. In order to support autonomous driving and better capability, angular resolution in both azimuth and elevation is required in addition to the range and

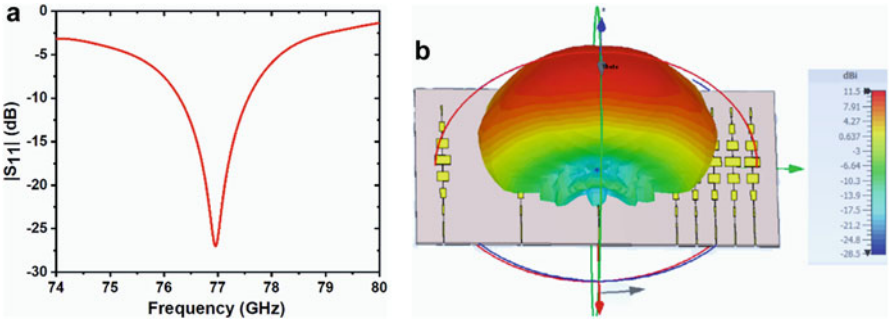

Fig. 5 (**a**) Simulated S_{11} magnitude versus frequency for the series-fed array Tx-1 in Fig. 4; (**b**) simulated 3D radiation pattern of Tx-1 in the MIMO RADAR antenna configuration at 77 GHz. (See Dash et al. (2021a) for more details). (© IEEE 2021)

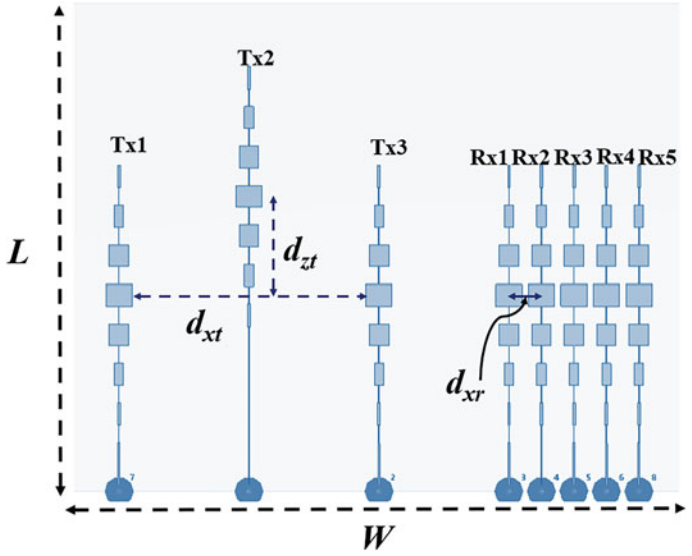

Fig. 6 Schematic of 3Tx-5Rx MIMO RADAR antenna. Individual antenna dimension in mm: L = 30.14, W = 37.3, d_{xt} = 16, d_{zt} = 6.1, d_{xr} = 2. (See Dash et al. (2022a) for more details). (© IEEE 2022)

velocity estimation. The angular resolution in both azimuth and elevation creates the 3D snapshot of the target\cite{cm}. 2D MIMO radar antenna supersedes the 1D MIMO radar antenna configuration by fulfilling the requirement of a 3D image capturing a target/object (Ma et al. 2011). However, the 2D array configuration needs more antenna elements which eventually increases the cost. A 3Tx-5Rx 2D MIMO RADAR antenna configuration is proposed in (Dash et al. 2022a). The schematic of the antenna is shown in Fig. 6. The individual antenna element in Fig. 6 has the identical property as in Fig. 4. Though the antenna type and arrangement for 1D and 2D MIMO RADAR configurations are looking similar, the offset design of Tx2 in

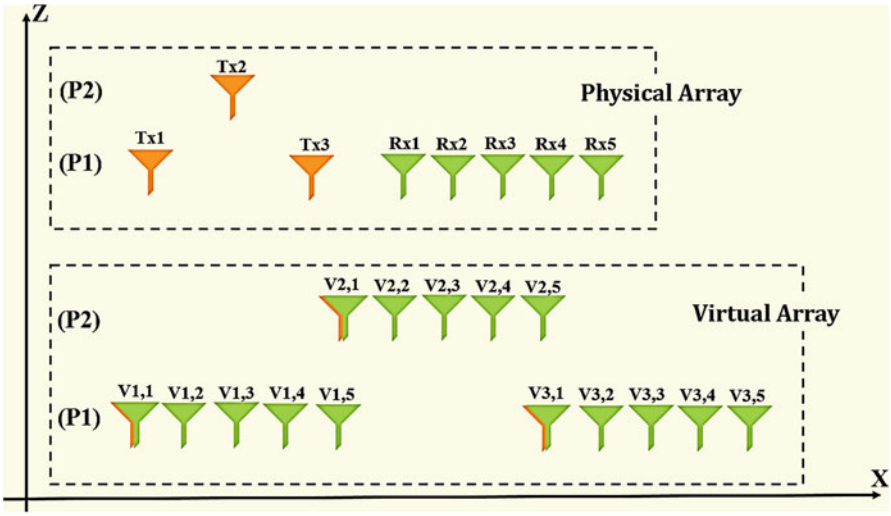

Fig. 7 Pictorial representation the virtual array formation for 2D antenna arrangement of Fig. 6. (See Dash et al. (2022a) for more details). (© IEEE 2022)

Fig. 6 creates the actual difference between 1D and 2D MIMO by providing an additional degree of freedom in elevation plane resolution. The 2D virtual array formation (as shown in Fig. 7) enables the elevation angular resolution of 44.8° and uninterrupted azimuth angular resolution of 5.82°.

Further, in commercial RADAR sensor, Bosch announced its third-generation RADAR sensor called MRR in 2011 (Hasch et al. 2012) and its 5th generation sensor in 2020 (Front RADAR sensor 2020). Compared to the earlier versions, it had different transmitter and receiver antennas on the same module. Instead of a combination of antenna patched and dielectric lens, planner antennas are used comprising four receivers and two transmit antennas. In (Waldschmidt et al. 2021), an MIMO sensor antenna studied by Toyota Laboratories is provided. The antenna consists of six subarrays, three for the transmitter and three for the receiver. Each antenna subarray consists of two series-fed arrays. All subarray provides a relatively wide azimuth beam, and a good angular resolution is achieved by beamforming. However, the issue of the RADAR integration inside a car is not addressed in these articles, which is one of the most critical segments of vehicle manufacturing that severely affect the RADAR performance along with other sensors.

Integration Challenges of Automotive MIMO RADAR Antenna in a Vehicle

Generally, automotive RADAR sensors are integrated behind the bumper, which contains multiple paint layers. Without disturbing the aerodynamic profile and outer body look of the vehicle, the RADAR sensors must be mounted behind the bumper,

which is a significant challenge. When the sensor antenna radiates the EM wave, the wave passes through the bumper painted with multiple paint layers. Hence, the wave must propagate through the bumper and then through the painted media in the transmitting mode and vice versa for receiving mode. The bumper with layers of paint can be considered as a stratified medium where each layer has its thickness, dielectric constant, and loss tangent. These painted bumpers affect the EM radiation of the RADAR and thereby affecting the RADAR range and velocity estimation.

In the simulation stage of the RADAR antenna and bumper-integrated system, these painted layers affect the overall simulation time and system memory. More specifically, it is well known that the vehicle-integrated system is electrically very large. On the other hand, at a 77 GHz millimeter wave band the EM simulator generates billions of mesh cells which require a very high simulation time as well as a large memory requirement. A high-power computing facility could be helpful to solve this kind of simulation requirement. However, to simplify this problem an alternative solution to this issue is provided in (Dash et al. 2019), which deals with the reduction of overall simulation time of the RADAR antenna and bumper-integrated system without affecting the accuracy. The technique uses the modeling of multilayer media to a single-layer equivalent media using the effective medium theory. The equivalent modeling of stratified media considers two different model approaches such as (a) parallel plate capacitor model, and (b) model based on the same transmission and reflection coefficient. Again, these models consider two simulation implementations. A simplified rectangular bumper with six paint layer model is considered for the validation of the proposed model, where the simulation approach (1) considers the equivalent model generation by bumper and paint layers to a single equivalent layer whereas simulation approach (2) considers the equivalent model generation by converting only paint layers to a single equivalent layer by keeping the bumper as a separate layer as shown in Fig. 8a, b, respectively. Detailed mathematical formulation and implementation using CST microwave studio EM simulation are described in (Dash et al. 2019). The proposed model reduces the simulation time by 88% and 57% in simulation approaches (1) and (2), respectively.

In a realistic autonomous vehicle application scenario, RADAR sensors are placed behind the car bumper because of which the sensors get affected by the bumper material as well as the high dielectric constant paint layers. In addition, the vehicle esthetic and the curvature of the bumper also affect the EM radiation from the RADAR. Moreover, the distortion in the antenna radiation pattern due to the bumper produces ambiguity in the DoA/DoD (direction of arrival/departure). There are certain earlier studies on the antenna with radome-integrated structures available in the literature. A physical optics-based tool is presented in (Schuster and Cassidian 2011) to study the effect of a spherical and ogival radome on an antenna. Similarly, an iterative physical optics-based technique is proposed in (Rim et al. 2016) to study the radiation properties at high operating frequency in the presence of an elliptical radome. However, it should be noted that the radome design considers electromagnetic transparency. On the other hand, bumpers consider the esthetic of the vehicle instead of electromagnetic effects. Therefore, the electromagnetic effect of bumper material property as well as the bumper curvature effect on the MIMO RADAR

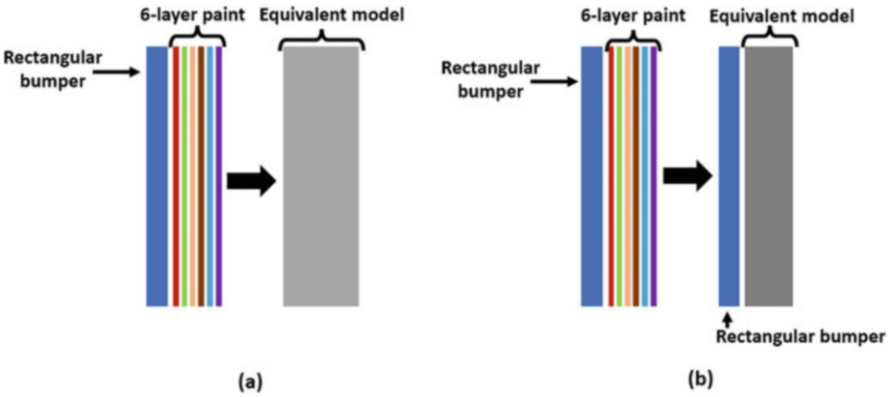

Fig. 8 Equivalent model of a rectangular bumper with multi-layered paints based on (**a**) simulation approach 1, and (**b**) simulation approach 2

antenna performance needs to be investigated since it will assist automotive industries to choose the proper bumper/paint material for robust and uncompromised functionality.

To study the RADAR antenna-bumper-integrated effect, a 2Tx-4Rx MIMO RADAR antenna configuration is designed as shown in Fig. 9 (accordingly to the design parameter provided in (Dash and Sarkar 2021)). The MIMO configuration is designed at 77 GHz automotive RADAR application frequency on a Roger 5880LZ substrate having dielectric permittivity and loss tangent 2 and 0.0021, respectively, with 0.25 mm substrate thickness. Other design parameters of the antenna are shown in Fig. 9. Similarly, the design of a simplified curved bumper configuration is shown in Fig. 10 (Dash and Sarkar 2021). The relative permittivity of the bumper is varied from 2 to 8 to study the effect of bumper dielectric property on the RADAR antenna radiation pattern. The 3D field pattern of Transmitter-1 for the integrated antenna-bumper system for the different values of bumper dielectric constant is shown in Fig. 11, which clearly shows the variation of the shape of the field pattern with respect to the change in the bumper dielectric constant. To further quantify the effect, two different analytical parameters such as (a) bidirectional loss model (BLM) (Dash et al. 2021b) and (b) antenna array ambiguity function (AAAF) (Dash and Sarkar 2021) are considered here.

(a) Bidirectional loss model (BLM): The BLM takes into account the two-way mismatch loss (ML) and dielectric loss (DL), for to and fro EM wave propagation of RADAR, as well as considers the effect of bumper shape (see Dash et al. (2021b) for a more detailed explanation).
(b) Antenna Array Ambiguity Function (AAAF): The AAAF considers the RADAR antenna pattern distortion when the RADAR is installed behind a bumper. It is evaluated using the MIMO antenna steering vector model as described in the "MIMO RADAR Working Principle" section. Mathematically, AAAF can be written as (Dash and Sarkar 2021)

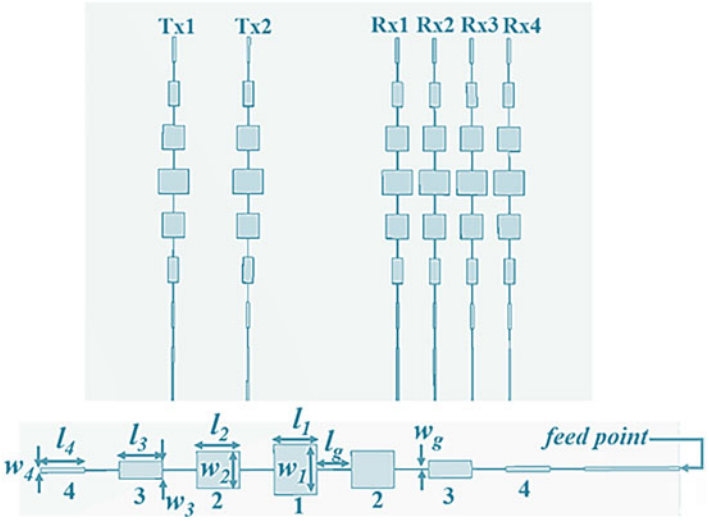

Fig. 9 Schematic of 2Tx-4Rx MIMO RADAR (individual antenna dimensions in mm: $l1 = 1.35$, $w1 = 1.6$, $l2 = 1.35$, $w2 = 1.185$, $l3 = 1.36$, $w3 = 0.553$, $l_4 = 1.39$, $w_4 = 0.185$, $l_g = 1.085$, and $w_g = 0.03$). © IEEE 2021

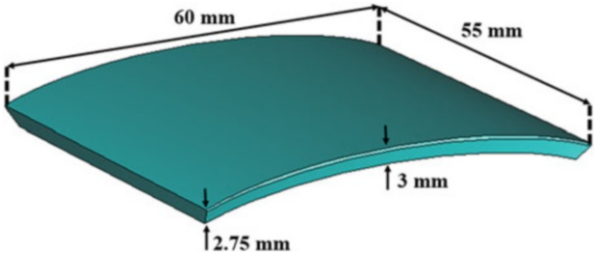

Fig. 10 Simplified curve-shaped 3D CAD model of the bumper used to integrate with the proposed MIMO RADAR as shown in Fig. 9 (Dash and Sarkar 2021). © IEEE 2021

$$\chi(\alpha_i, \alpha_j) = \frac{|\, Y^H(\alpha_i).Y(\alpha_j)\,|}{\|Y(\alpha_i)\|.\|Y(\alpha_j)\|} \tag{4}$$

where $(.)^H$ represents the Hermitian operator, $\|\,.\,\|$ represents the norm operator, $Y(\alpha)$ represents the antenna azimuth virtual array field pattern, and α represents the azimuth angle. Readers can refer (Dash and Sarkar 2021) for a more detailed explanation.

Figures 12 and 13 indicated the computed bidirectional loss (BL) and ambiguity function (AF) plot, respectively, for the integrated antenna-bumper system with the varied bumper material property. AF indicates that the bumper dielectric constants 5, 6, and 8 are creating more ambiguity in the field pattern than that of the other bumper permittivity under consideration. In addition, the bidirectional loss is

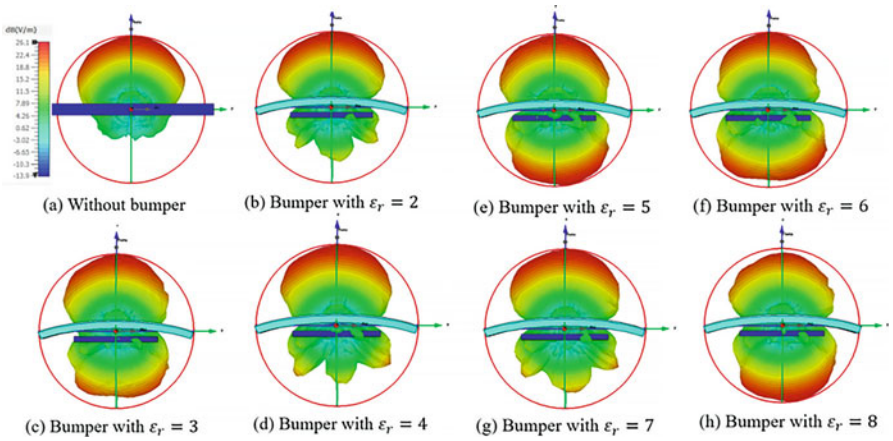

Fig. 11 The 3D E-field radiation patterns of transmitter-1 in the integrated antenna-bumper system shows pattern distortion caused by the permittivity variation of bumper. (See Fig. 10) (Dash and Sarkar 2021). (© IEEE 2021)

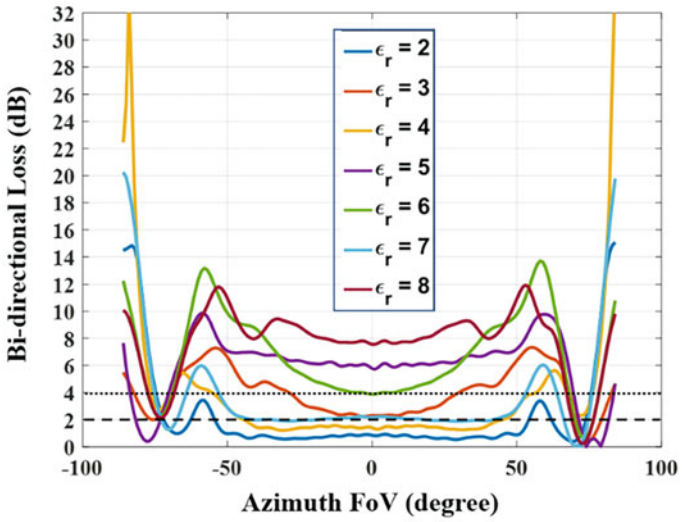

Fig. 12 Bi-directional loss plots for different material permittivity values of the bumper in the integrated antenna-bumper system (Dash and Sarkar 2021). © IEEE 2021

consistent with the ambiguity as it can be observed that the BL value is high for the same value of bumper permittivity as AF. This study provides the direction to study the antenna-bumper-integrated system which would be considered for other application scenarios where EM wave is attenuated due to the integration issue.

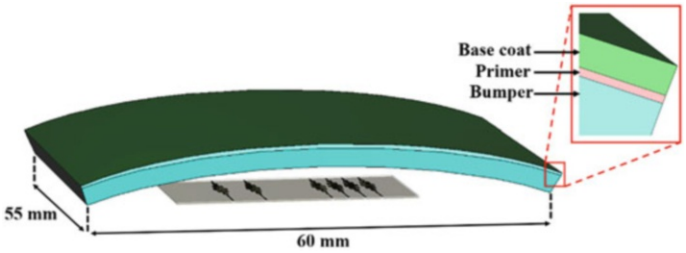

Fig. 14 Schematic of 2Tx-4Rx antenna-painted bumper-integrated system (Dash et al. 2022b). © IEEE 2022

Similar studies on the antenna-bumper integration effect, using BLM and AAAF methods, are conducted in (Dash et al. 2022b) to observe the effects when the bumper is painted. Here, to study the effect of paint on 2Tx-4Rx RADAR (as shown in Fig. 9), performance of two layers of paint material such as primer coat (ε_r =9, tan δ =0.06) and base coat (ε_r =9.99, tan δ =0.907) having thicknesses of 4 um and 15 um, respectively, are applied on the bumper (ε_r =2, tan δ =0.01) (see Fig. 14). In general, automotive industries put six-to-seven layers of paint on their vehicles with varied thicknesses (Dash et al. 2019). However, for the initial study purpose and to restrict the simulation time, the number of paint layers and their thicknesses are kept limited.

It can be seen from Fig. 15 that the bumper alone produces a loss of less than 2 dB in FoV(−40° to +40°). Gradually, the loss started fluctuating due to the addition of primer coat, and when the base coat is added the loss increases to near 4 dB within FoV though it is less in broadside. It can be seen from the AAAF plot in Fig. 16 that bumper alone has a negligible effect on RADAR FoV; however, the FoV reduces by the addition of primer coat (see Fig. 16c), and it reduces significantly due to the additional base coat layer (see Fig. 14d).

Conclusion

A comprehensive discussion on the application of MIMO RADAR in the advanced driver assistance system is discussed. The operating principle of MIMO RADAR with an explanation of the virtual array concept for 1D and 2D MIMO RADAR configurations is discussed. Further, a discussion on the state-of-the-art antenna design for the automotive RADAR application is provided based on the research literature as well as the commercially available design. Finally, the very practical issue of MIMO RADAR integration behind the multilayered vehicle bumper is explained as well as the challenges in a simulation environment, and the real environment is examined using the effective dielectric constant model and BLM and AAAF model, respectively. Such studies are potentially helpful to automotive industries to obtain more insights about integrated antenna performance and to provide better solutions with high system efficiency during real-time operation.

Abstract

The accurate prediction of radar cross-section (RCS) of various structures is crucial for controlling its visibility and hence plays a vital role in the development of stealth technologies. Several approaches like body geometry decomposition, low frequency techniques, high frequency techniques, and hybrid methods can be employed for RCS estimation based on the complexity of geometry and electrical size of the structure. Scattering entities especially electrically large ones give rise to a wide variety of electromagnetic phenomena like refraction, reflection, traveling waves, leaky waves, diffraction effects, etc. Although low frequency techniques provide accurate predictions for complex geometries, the computational complexity increases with electrical size of the structure. On the other hand, high frequency approaches, although computationally efficient for electrically large problems, give incorrect results when the problem under consideration has intricate geometrical features. Therefore, hybrid approaches incorporating both of them have been introduced to solve electromagnetic problems where neither class of formulations is sufficient by itself. This chapter presents an overview of these methods and certain case studies are also included for better clarity. Further, the popular approaches employed for reduction of RCS are also included with

Introduction

The accurate prediction of radar cross-section (RCS) of various structures is crucial for controlling its visibility and hence plays a vital role in the development of stealth technologies. The challenge is to estimate the scattering from the objects of arbitrary shape, size, and material. Moreover, the RCS estimation and measurements depend on the frequency of the incident signal, the orientation of the object w.r.t. the radar, and the polarization (Knott et al. 2004; Knott 2006). In this direction, a concise description of few of the techniques used for estimation of RCS and the popular approaches employed for reduction of the same are presented. Some case studies and results are also included for better understanding. In order to reduce the target detectability, radar absorbing materials and structures (RAM/RAS) are employed over the target surface. In current trend, frequency selective surfaces (FSS), electromagnetic bandgap (EBG) materials, artificial magnetic conductors (AMC), etc. are incorporated in the RAS to achieve wideband electromagnetic (EM) absorption. However, the researchers face challenges in these design and development in view of payload constraints, bandwidth requirements, structural strength, RF power handling capability, and environmental conditions. In particular, RCS reduction in the antennas has added constraint because any modification in the design should not degrade the antenna radiation performance in terms of its VSWR, antenna gain, and beamwidth (Singh and Singh 2021).

Basic Principles of Radar Cross-Section (RCS)

When an electromagnetic (EM) wave is incident on a target, energy is reradiated back in different directions. This reradiation is called scattering and the target itself is called scatterer. RCS is the effective area contributing to the scattering of EM waves back toward the probing radar. It can be defined as

$$\sigma = \lim_{R \to \infty} 4\Pi R^2 \frac{|E_{\text{sca}}|^2}{|E_{\text{inc}}|^2} \tag{1}$$

where

σ: radar cross-section of the target (m^2)
E_{sca}: electric field intensity of scattered wave (V/m)
E_{inc}: electric field intensity of incident wave (V/m)
R: range from the radar to the target (m)

RCS is usually expressed in dB relative to one square meter (dBsm) as given below:

$$\sigma(\text{dBsm}) = 10 \log_{10} \sigma\left(\text{m}^2\right) \tag{2}$$

The significant factors which determine the magnitude of RCS are the following:

(a) Shape of the target and roughness of the surface
(b) Material composition of the target (EM properties)
(c) Frequency and polarization of the incident EM wave
(d) Aspect angle of the target w.r.t. incident wave

As an interesting fact, RCS of a stealth aircraft like Northrop Grumman B-2 Spirit, also known as the stealth bomber, is of the order of −40 dBsm which is comparable to that of a small insect.

Estimation of RCS

Scattering entities, especially electrically large ones, give rise to a wide variety of electromagnetic phenomena like refraction, reflection, traveling waves, leaky waves, diffraction effects, etc. In addition to the complex geometrical features of the primary reflecting surface, ground planes as well as other proximal structures contribute to these effects making the problem even more intractable. Earlier, such complex scenarios have been solved using body geometry decomposition. Here, the structure is considered as a combination of different canonical shapes. Using the known solutions for these generic shapes, the overall RCS is computed by adding together (coherently or incoherently) the individual contributions. The main advantage of this technique is that the RCS of electrically large structures can be estimated without any exhaustive computations. However, it considers only first-order/specular edge scattering and does not take into account the interaction between different components.

In order to overcome the limitations of body geometry decomposition technique, two main approaches have been proposed by researchers around the globe (Mitschang and Wang 1989). They are categorized as given below:

(i) High frequency techniques
(ii) Low frequency/numerical techniques

High frequency approaches precisely account for the diffraction phenomena occurring along curved surfaces/edges using physical theory of diffraction (PTD), geometrical theory of diffraction (GTD), etc. These optics-derived techniques provide comparatively accurate scattering predictions without resorting to extensive computations. Hence, they are the preferred mode of analysis for electrically large bodies composed of relatively simple generic shapes. However, the main disadvantage of these asymptotic techniques is that the diffraction coefficients are available only for a limited set of canonic geometries like cylinders, spheres, and wedges. Further, the simplifying assumptions made during calculations lead to comparatively approximate solutions rather than accurate predictions.

On the other hand, low frequency approaches like method of moments (MoM), finite element method (FEM), finite-difference time-domain (FDTD) method, etc. provide full wave solutions to scattering problems. These techniques provide accurate predictions for intricate geometries thoroughly incorporating the interaction effects between different parts of the structure. For instance, FDTD method is a differential time-domain numerical method. Here, Maxwell's equations are expressed in terms of finite difference approximations and then the space and time domains are discretized. The electric and magnetic fields are then determined with the field calculations interleaved in both time and space. FDTD requires the problem to be meshed with fine spatial discretization, and therefore the computational complexity increases with increase in electrical size of the structure (Teixeira and Chew 2000).

FEM is another numerical method for solving scattering problems in electromagnetics (Bondeson and Rylander 2013). In FEM, a problem is analyzed in four major steps as given below:

(i) Segmentation or meshing of the structure into a finite number of elements such that each element has a homogenous dielectric associated with it
(ii) Derivation of governing equations for a typical element
(iii) Assembly of all the elements of the structure to generate the system of equations
(iv) Evaluation of the system of equations to determine the unknowns

In FEM, we have to solve a linear system of equations in order to update the fields. Consequently, for the same number of cells used for both FEM and FDTD, FEM needs more computer resources, both in terms of CPU time and memory.

Integral equation (IE) technique is another popular numerical method for the analysis of metallic and dielectric structures of arbitrary geometry (Harrington 2001). Integral eqs. (IE) are inferred from Maxwell's equations through the use of equivalence principles. They are further discretized through MoM into a linear system of equations whose solutions are the aforementioned equivalent sources. In surface integral techniques (SIE), the dielectric-to-dielectric interfaces are removed by placing equivalent electric and magnetic surface currents. The prime concern of SIE is the evaluation of Green's function, which is the electromagnetic response of a point source in a given environment. Although mathematical derivation of SIE is

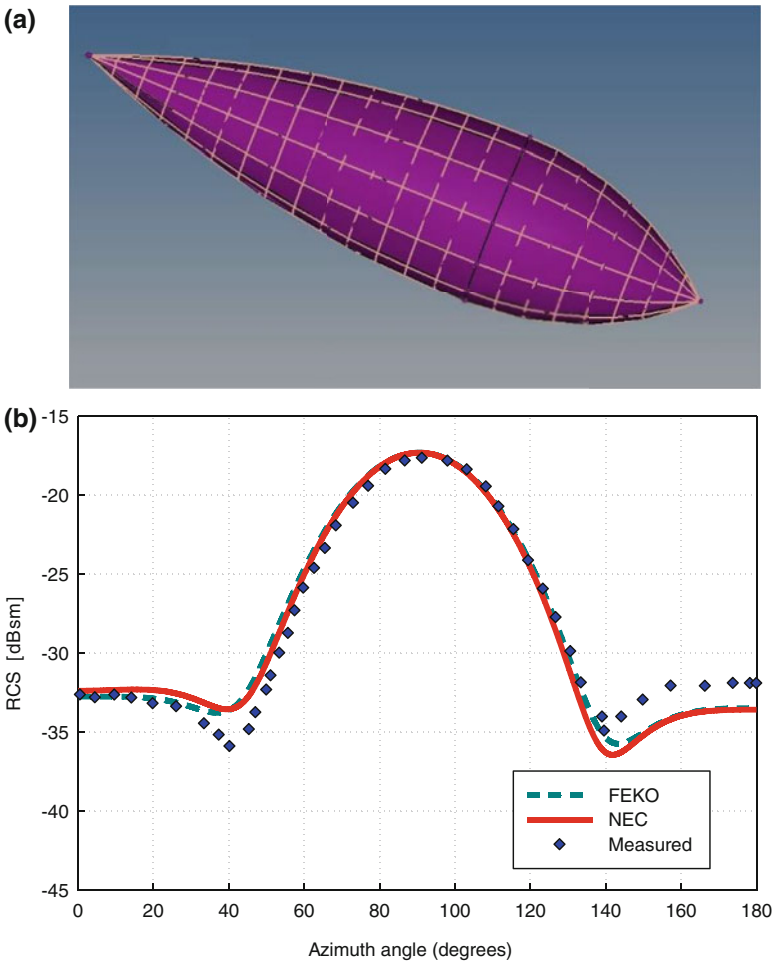

Fig. 1 Variation of monostatic RCS of metallic double ogive *w.r.t.* azimuth angle at 1.57 GHz. (**a**) Meshed model of metallic double ogive, (**b**) RCS characteristics (vertical polarization)

possible, Green's functions for arbitrary inhomogeneous medium is nontrivial and can be obtained only via numerical computation. This can be as tedious as solving the original problem.

Among all the low frequency techniques, MoM is exceptionally efficient for the scattering characterization of conducting structures. Currently, several commercial EM simulation software (like Altair FEKO) are available with MoM as the solver. Open-source codes like numerical electromagnetics code (NEC) are also widely used for the RCS analysis of metallic geometries. The monostatic RCS of a typical benchmark radar target like metallic double ogive computed using NEC and FEKO is shown in Fig. 1 (Joy et al. 2020). It is clear that the results are well matched to the measured data presented in Woo et al. (1993).

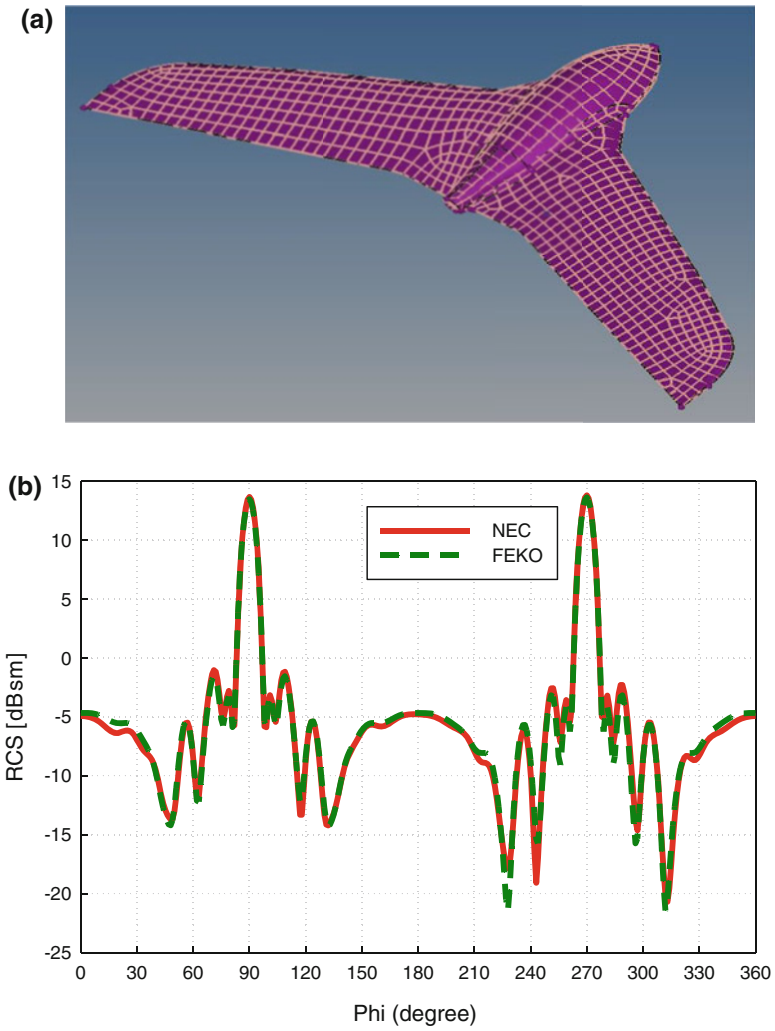

Fig. 2 Variation of monostatic RCS of metallic UAV *w.r.t.* azimuth angle at 600 MHz. (**a**) Meshed model of metallic UAV, (**b**) RCS characteristics

Further, the monostatic RCS of a complex aerospace structure like unmanned aerial vehicle (UAV) computed using NEC as well as FEKO is presented in Fig. 2. The plot clearly indicates very good agreement between both the results.

Next is the antenna RCS estimation. Here a single patch antenna is considered. Figure 3a shows the schematic of single patch antenna designed in full wave simulation software, FEKO and CST Microwave Studio, respectively. The patch element made of copper ($\sigma = 5.8 \times 10^7$ S/m) material has dimension of 6.5 mm $\times$ 9.2 mm. The antenna is fed by a microstrip feed line (length $=$ 5.75 mm, width $=$ 0.9 mm). The patch is backed by 1.588-mm-thick FR4 ($\varepsilon_r = 4.3$, tan $\delta = 0.025$)

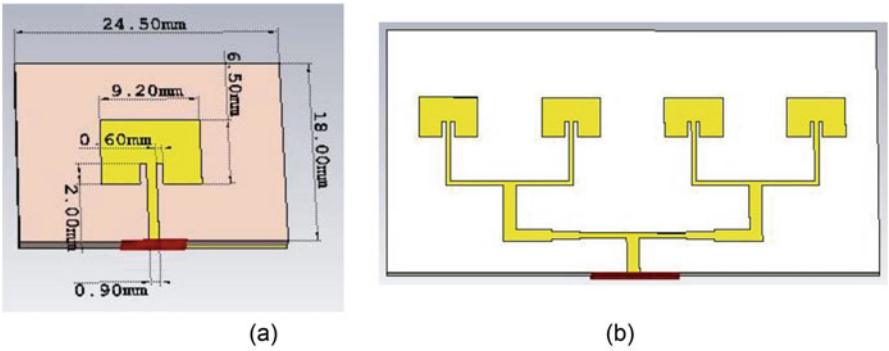

Fig. 3 Schematic showing the design of (**a**) single patch antenna, (**b**) four-element patch array with conventional PEC ground plane

substrate of dimension 18 mm × 24.5 mm. The ground plane is a copper layer with 0.018 mm thickness.

The radiation characteristics of the patch antenna have been analyzed using MoM-based FEKO and FEM-based CST. It can be noted from the return loss shown in Fig. 4a that the resonant frequency of the single patch antenna obtained through both the simulation software are approximately the same. The result obtained in CST shows that the antenna resonates at 9.93 GHz with a return loss of −18.23 dB. Using FEKO, minimum return loss (−20.79 dB) of the same patch is attained at 9.92 GHz. A slight variation in the gain of the antennas at their resonant frequencies is also evident. The maximum gain achieved is 4.85 dB (with CST), whereas it is 4.46 dB with FEKO (Fig. 4b). These discrepancies can be attributed to the different feeding techniques employed in the two cases – a wire feed in FEKO, whereas a waveguide port in CST.

The monostatic RCS of the single patch antenna is computed by impinging plane wave over the surface of the antenna. Figure 5 presents the structural RCS pattern obtained using both the full wave simulation software. The specular RCS of the antenna obtained with CST and FEKO is −25.79 dBsm and −25.59 dBsm, respectively.

A corporate-fed linear microstrip patch array with conventional metallic ground plane shown in Fig. 3b is designed using the same patch element (Fig. 3a) and FR4 substrate. The inter-element spacing between the patch elements has been kept more than 0.5λ in order to avoid mutual coupling effects. The array is placed on a FR4-based substrate of 40 mm × 77.2 mm × 1.588 mm dimensions. The bottom layer is a metallic ground plane.

The radiation and scattering characteristics of the four-element linear patch array are shown in Fig. 6. The results obtained are analyzed and compared using CST and FEKO. It can be noted that the patch array resonates at 10.56 GHz with a return loss of −46.3 dB in CST, while −31.68 dB at 10.48 GHz in FEKO (Fig. 6a). Further, it

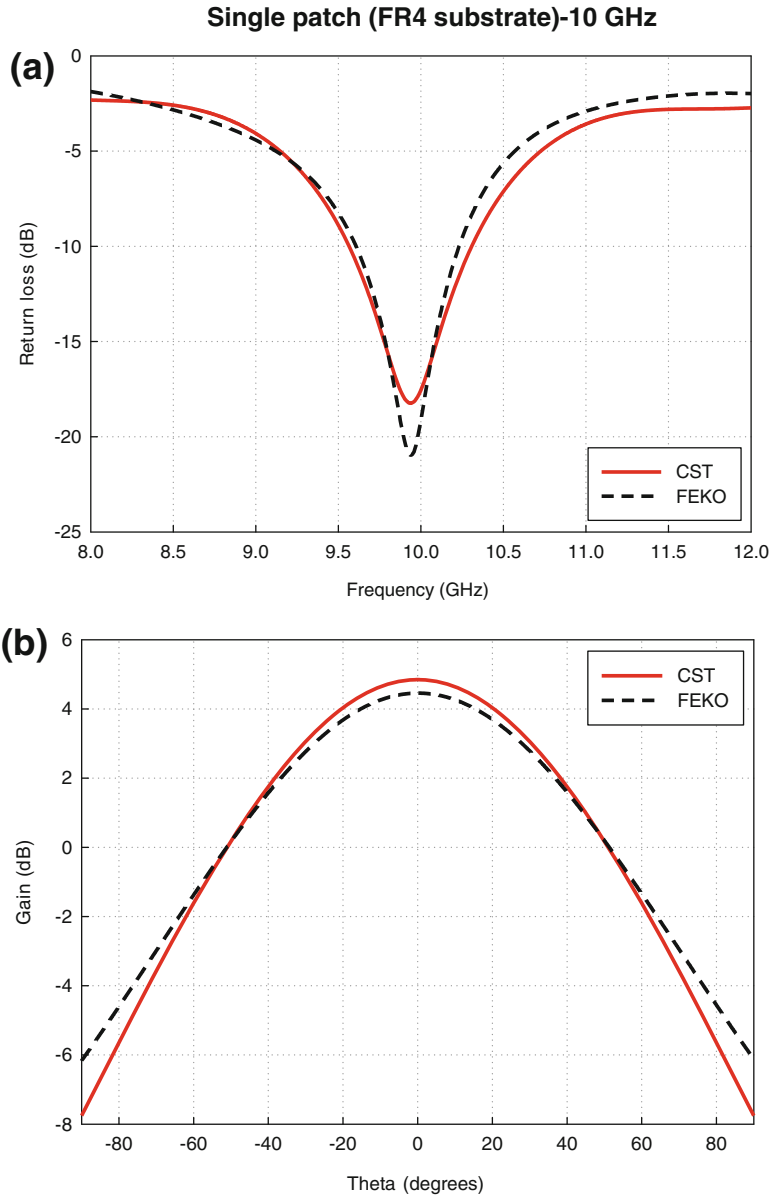

Fig. 4 Radiation characteristics of a single patch antenna with conventional ground plane. (**a**) Return loss, (**b**) gain

can be observed from Fig. 6b that there is a slight variation in the gain obtained in the two cases, i.e., 6.95 dB from CST, whereas 6.29 dB from FEKO. As already mentioned, the difference in the radiation characteristics obtained in the two cases

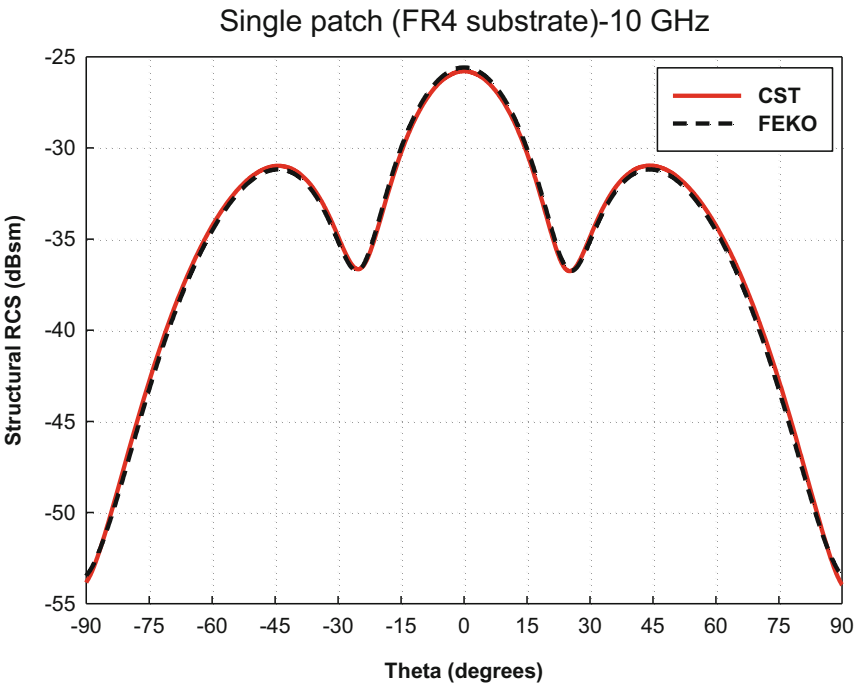

Fig. 5 Monostatic RCS of single patch antenna at 10 GHz

is due to the different feeding techniques involved in CST and FEKO. Figure 6c shows the structural RCS of the patch array for elevation angle ranging from −90° to 90° at 10 GHz. It can be noted that the structural RCS of the patch array obtained is similar using both CST and FEKO with a specular lobe of −8.83 dB at 10 GHz. The antenna RCS is estimated using plane wave source and the antenna structure only contributes to the array RCS.

However, when the antenna is radiating, i.e., switched on, then the antenna mode RCS comes into picture. This antenna mode (radiation mode) RCS is many folds higher than the structural RCS of the antenna (Singh and Jha 2015). This radiation mode is calculated by considering all the reflections and transmissions an impinging signal undergoes while traversing through the antenna and its feed network. This antenna RCS is also proportional to the antenna gain in addition to the frequency, scan angle, and antenna design parameters (Singh et al. 2020). All the impedance mismatches within the antenna and its feed network contributes to the antenna scattering. The RCS pattern of an antenna array is equivalent to the radiation pattern of the antenna array with double inter-element spacing. Essentially, the antenna RCS has twofold impact on the overall RCS of platform over which it is mounted. Thus, for stealth platforms, conformal antenna/array is employed to avoid any protruding structure giving rise to the scattering.

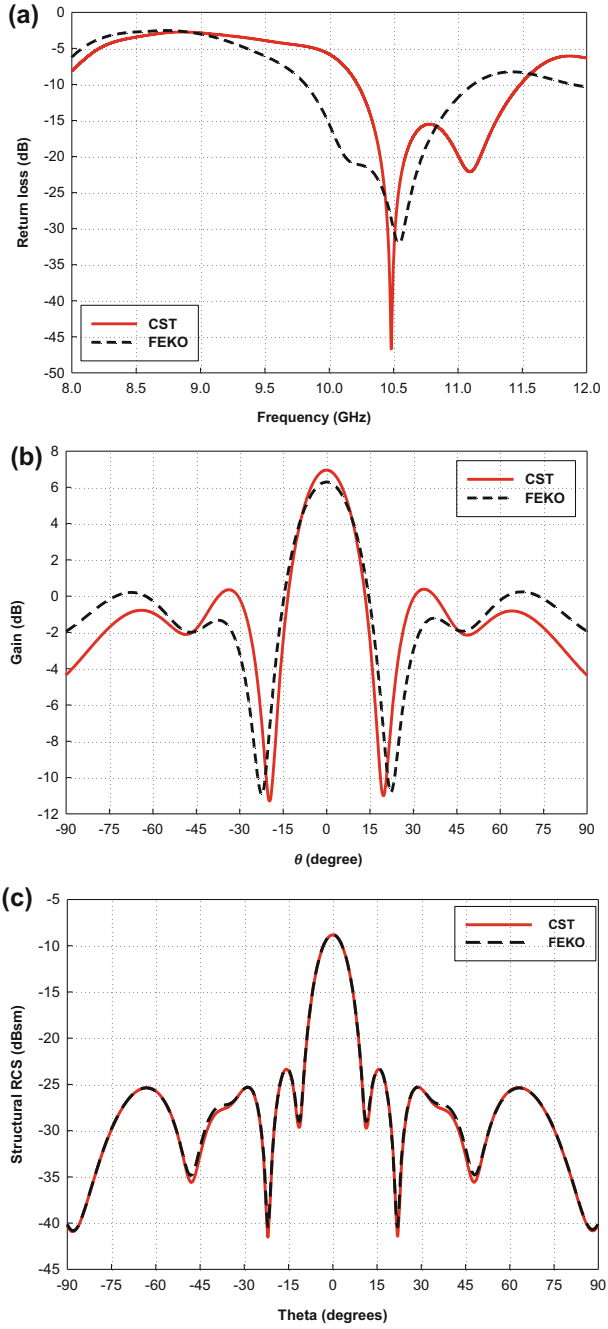

Fig. 6 Radiation and scattering characteristics of a four-element patch array with conventional ground plane. (**a**) Return loss, (**b**) gain, (**c**) antenna RCS at 10 GHz

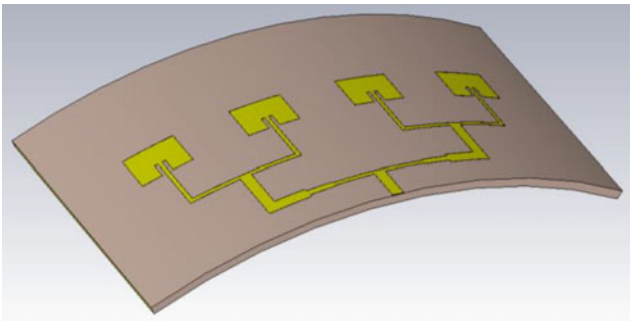

Fig. 7 Conformal patch array with conventional PEC ground plane

Thus, in order to demonstrate the RCS estimation, a patch array conformed to a cylindrical surface with radius of curvature 90 mm. Figure 7 shows the conformal patch array with conventional metallic ground plane. The patch elements are of the same dimension as mentioned for planar patch array, except for the substrate dimension being modified to 45 mm × 90 mm × 1.59 mm.

Figure 8 shows the radiation characteristics of the conformal patch array. It can be observed that the array resonates at 10.44 GHz, with a minimum return loss of 27.23 dB. The patch array has a maximum gain of 5.91 dB at the resonant frequency. Figure 9 presents the structural RCS at 10.44 GHz in the elevation plane ranging from $-90^\circ \leq \theta \leq 90^\circ$. It can be noted that the specular lobe has a null with a magnitude of −17.55 dBsm at the resonant frequency.

The variation of structural RCS of the conformal patch array for a frequency range of 8 GHz–30 GHz in azimuthal plane, $\theta = 0^\circ$ (specular RCS), is shown in Fig. 9b. The structural RCS in the specular direction for a planar and conformal four-element patch array are compared. It can be noted that a broadband reduction in specular RCS is obtained for the conformal patch array when compared to the planar patch array of the same design configuration. A maximum reduction of 12.12 dBsm is obtained in the X-band, i.e., at 11 GHz. In Ku-band maximum specular RCS reduction of 12.26 dBsm is obtained at 13GHz. In K-band a maximum reduction of 15.69 dBsm is achieved in specular RCS at 24 GHz, while in Ka-band a maximum reduction of 18.34 dBsm is obtained in specular RCS at 26 GHz. Thus, array RCS can be reduced by shaping the antenna array, i.e., conforming the antenna over the surface. In order to achieve both in-band and out-of-the-band RCS reduction in antenna array, other techniques (FSS/AMC, slotted/defected ground plane, meta-materials) are employed.

One needs to keep in mind that although low frequency approaches like MoM are suitable for a variety of scattering problems, computational intensity is a limiting factor especially in the case of electrically large structures. Here, the computation time and memory requirements increase with increase in the electrical size of the structure. Considering the inherent drawbacks of both low frequency and high frequency techniques, hybrid approaches incorporating both of them have been introduced to widen the range of EM scattering issues that can be precisely dealt

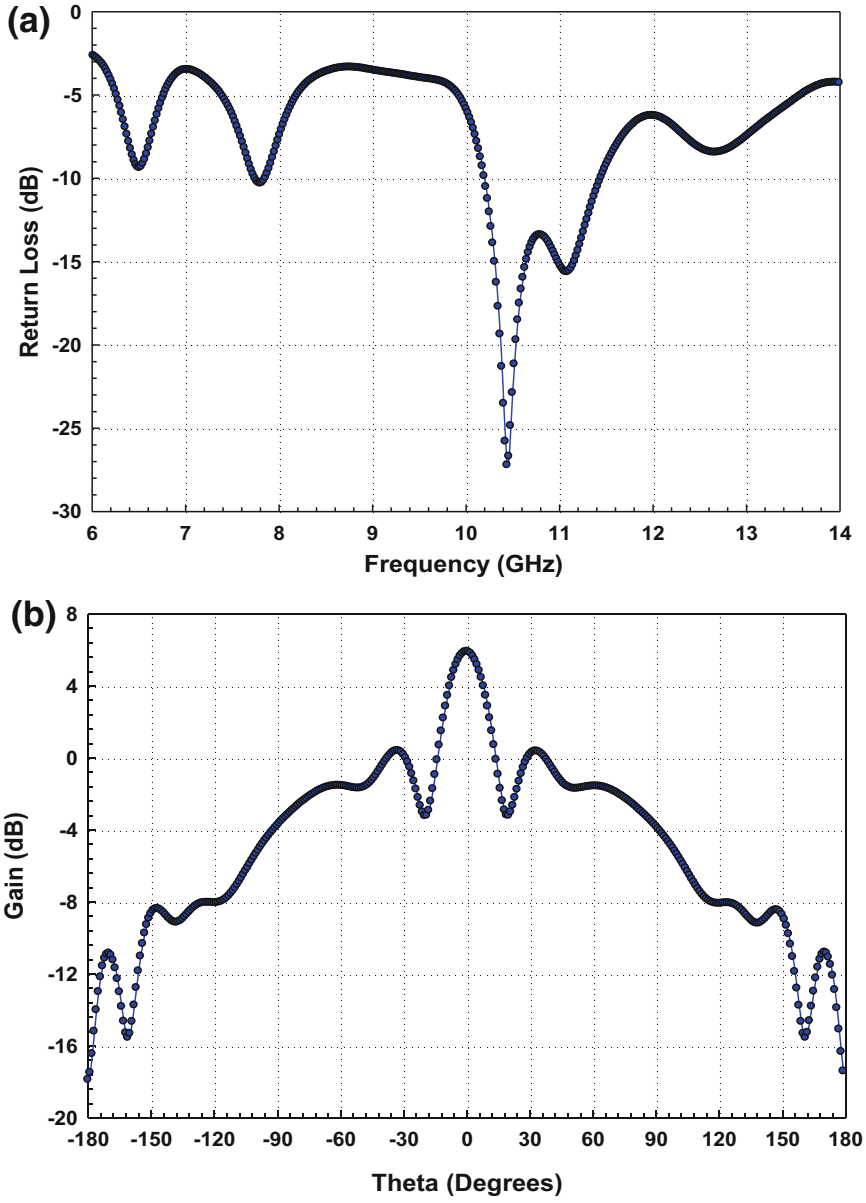

Fig. 8 Radiation characteristics of a four-element conformal patch array with PEC ground plane. (**a**) Return loss, (**b**) gain

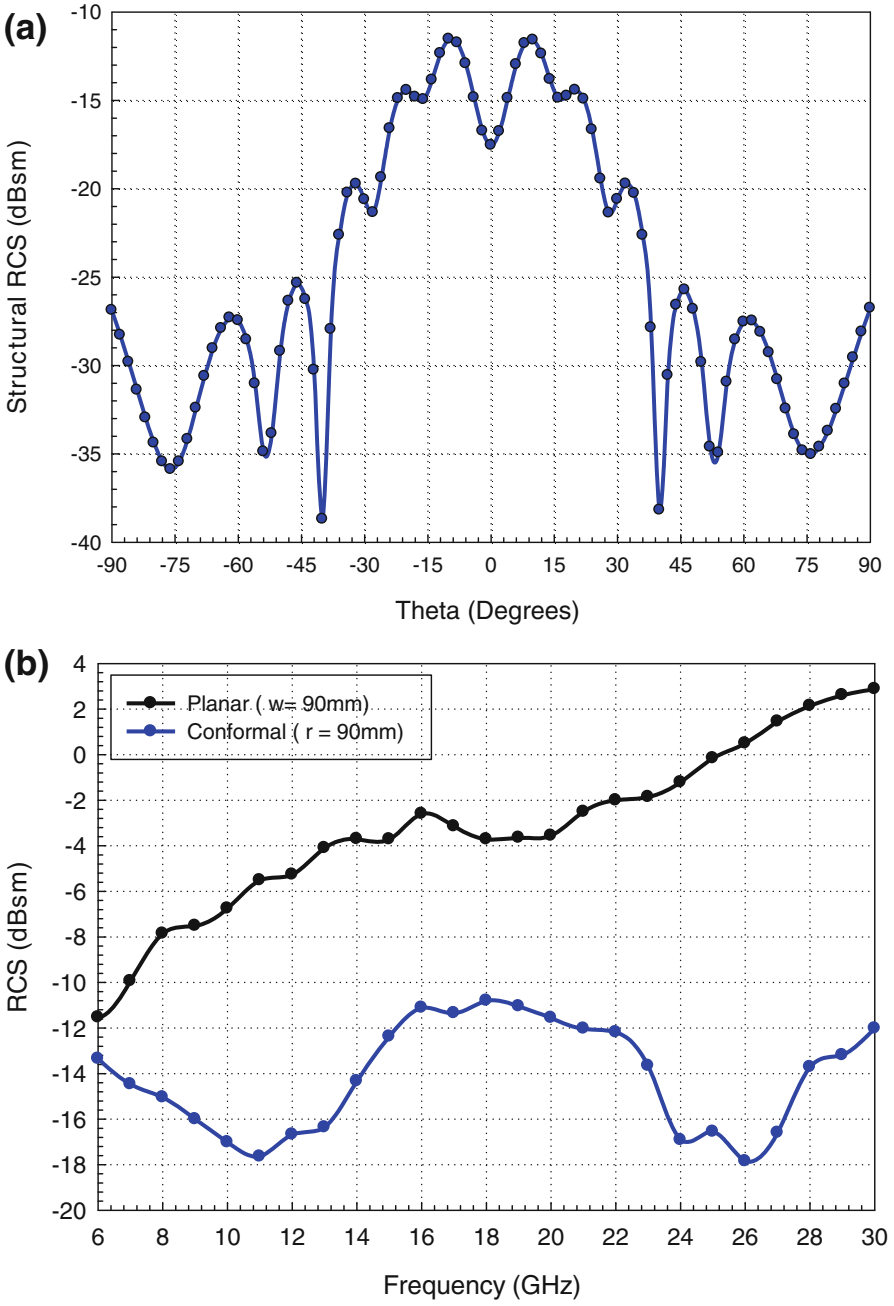

Fig. 9 Structural RCS of a four-element conformal patch array with PEC ground plane. (**a**) At frequency = 10.34 GHz, (**b**) specular RCS versus frequency

with (Bouche et al. 1993). Hybrid methods like physical optics (PO)-MoM technique are basically logical combinations of asymptotic and numerical methods for solving EM problems where neither class of formulations is sufficient by itself.

RCS Reduction

Majority of complex structures will have certain predominant hotspots which contributes significantly to the total RCS. For instance, a stealth aircraft has numerous hotspots like air intake cavity, antenna behind radome, dihedral corner reflector, leading wing edge, etc. These locations scatter majority of the electromagnetic energy incident on them, thereby increasing their visibility to probing radars. Therefore, in order to a make a structure stealthy, RCS of the major scatterers on it are to be reduced drastically.

RCS of a structure can be reduced in four ways as shown in Fig. 10. One approach used at the preliminary design stage is to modify the shape so as to deflect the incident waves in a direction different from that toward the probing radar. Another approach includes the application of radar absorbing materials (RAM) or radar absorbing structures (RAS) at pre-identified major scattering locations. The main objective here is to absorb or diffuse the incident signals so as to reduce the reflections toward rival radar systems. Passive cancellation is another technique where an additional scatterer is employed to cancel the reflections from the primary scatterer. An alternate approach called active cancellation uses active transmitters to generate modified waveforms that will destructively interfere with the original waves reflected from the structure (Cadirci 2009).

Among all these approaches, application of RAM/RAS is widely used due to the feasibility of varied range of designs catering to different locations and frequency ranges. Further, with rapid advancements in the field of material processing and fabrication technologies, the realization of RAM/RAS has become much simpler.

Methods to Minimize Reflectivity Using RAM/RAS

The primary goal while designing a RAM/RAS is to achieve superior power absorption over a wide range of frequencies for any angle of incidence and arbitrary polarization. Both reflection and transmission have to be reduced in order to enhance absorption. This section gives a theoretical background on the ways in which reflection can be reduced when an electromagnetic wave interacts with a homogenous media (Saville 2005). The reflection of an EM wave incident on a material (free

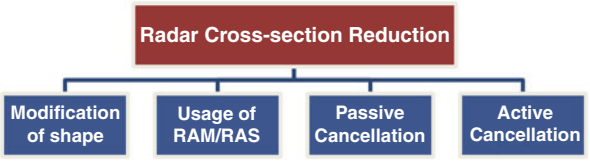

Fig. 10 Different approaches for reducing RCS of a structure

space is taken as the incident medium) can be expressed in terms of the reflection coefficient (Γ) at the interface as

$$\Gamma = \frac{Z_{\text{media}} - Z_{f_\text{space}}}{Z_{\text{media}} + Z_{f_\text{space}}} = \frac{Y_{\text{media}} - Y_{f_\text{space}}}{Y_{\text{media}} + Y_{f_\text{space}}} \tag{3}$$

where Z_{media} and Y_{media} are the impedance and admittance of the propagating medium and Z_{f_space} and Y_{f_space} are the impedance and admittance of free space, respectively. It can be observed from (3) that the reflection coefficient at the interface between two media depends on their respective impedance/admittance values. Based on (3), the following approaches can be employed for minimizing RCS:

(i) It is clear that for minimum reflection ($\Gamma = 0$), the impedance of the propagating medium must be perfectly matched to that of the incident medium, i.e., $Z_{\text{media}} = Z_{f_\text{space}}$. The intrinsic impedance of any medium is given by the ratio of the electric field intensity (E_x) to its transverse magnetic field intensity (H_y). The intrinsic impedance of free space can be expressed as

$$Z_{f_\text{space}} = \frac{E_x}{H_y} = \sqrt{\frac{\mu_o}{\varepsilon_o}} \approx 377\ \Omega \tag{4}$$

where μ_o and ε_o correspond to the permeability and permittivity of free space, respectively. Thus, in order to achieve zero reflection at the interface, the intrinsic impedance of the propagating medium should be equal to 377 Ω.

(ii) The reflection coefficient can also be expressed in terms of normalized impedance as

$$\Gamma = \frac{Z_n - 1}{Z_n + 1} \tag{5}$$

where

$$Z_n = \frac{Z_{\text{media}}}{Z_{f_\text{space}}} = \sqrt{\frac{\mu_r}{\varepsilon_r}} \tag{6}$$

where μ_r and ε_r corresponds to relative permeability and relative permittivity of the medium, respectively. When the normalized impedance is unity, i.e., $Z_n = 1$, which in turn imply μ_r being equal to ε_r, the reflection coefficient drops to zero. The relative permittivity and permeability can be expressed as $\varepsilon_r = \varepsilon_r' - j\varepsilon_r''$ and $\mu_r = \mu_r' - j\mu_r''$, respectively. The prime and double prime superscripts denote real and imaginary components, respectively. Therefore, it can be observed that the real and imaginary components of relative permittivity and relative permeability must be equal to reduce Γ to zero.

(iii) The general expression for an EM wave propagating through any medium along $+z$-direction can be written as

$$E(z, t) = E_o e^{-\alpha z} \cos(\omega t - \beta z)\widehat{a}_x \tag{7}$$

where E_o, α, and β correspond to amplitude of the electric field oriented along x-direction, attenuation constant, and phase constant, respectively. The amplitude of the EM wave gets attenuated by the factor $e^{-\alpha z}$ as it traverses through the medium. The term α can be expressed as

$$\alpha = \sqrt{\varepsilon_o \mu_o}\,\omega \sqrt[4]{a^2 + b^2} \sin\left(\frac{1}{2}\tan\left(-\frac{a}{b}\right)\right) \tag{8}$$

where

$$a = \left(\varepsilon_r' \mu_r' - \varepsilon_r'' \mu_r''\right)$$

$$b = \left(\varepsilon_r' \mu_r'' + \varepsilon_r'' \mu_r'\right)$$

For a medium with minimal thickness, α should be large for the attenuation to be high. Thus, high values of ε', ε'', μ', and μ'' are required to obtain high attenuation and henceforth minimum reflection. This approach must be applied keeping in mind the first condition, where large values of permittivity and permeability result in a large reflection coefficient. Therefore, this approach can be applied to inner layers for increasing the attenuation as the wave moves deeper.

Based on the location, frequency range of interest, and feasibility of material synthesis and application, any one of the abovementioned approaches can be used to design a RAM.

Further, artificially engineered electromagnetic entities like metamaterials, frequency selective surfaces (FSS), and metasurfaces can be used in combination with homogenous materials in order to enhance the absorption performance. Among these technologies, FSS and metasurfaces are widely used in the design of RAS as they are capable of improving the performance with reduced thickness/weight penalty. Here, superior absorption is achieved in two ways as explained below:

(i) *Impedance matching followed by absorption in lossy material:* In this case, the impedance of FSS or metasurface at the interface between free space and absorbing media is matched to that of free space, thereby reducing the reflection from first interface to zero. Once waves enter the lossy material, they get attenuated/dissipated as they propagate through it (Munk 2000).

(ii) *Cancellation of scattered waves*: Here, RCS reduction is obtained by carefully manipulating the phase difference/path difference between incident and reflected signals so that they interfere destructively. One way to accomplish this is to set the thickness of RAM/RAS equal to integral multiples of quarter

wavelength (λ/4). The category of absorbers working on this principle is called resonant absorbers.

Salisbury screen is one of the simplest forms of this type where a resistive sheet of surface resistivity equal to free space impedance (377 Ω/sq) is placed quarter wavelength away from a metallic ground plane. These layers are usually separated by a lossless dielectric spacer. At the frequency of resonance, the effective impedance of this structure becomes equal to 377 Ω resulting in matched condition. The impinging wave thus enters the dielectric material and comes out of it with a phase difference of 180° due to the reflection at the metallic ground plane. This results in destructive interference between the incident and reflected waves, thereby reducing effective RCS to zero. However, narrow bandwidth and relatively large thickness at lower frequencies are the major drawbacks of Salisbury screen.

Jaumann absorbers overcome the bandwidth constraint of Salisbury screen by stacking several layers of resistive sheets, with different surface resistivity, separated from each other by quarter wavelength at the frequency of interest. But wider bandwidth is achieved here with larger thickness. Dallenbach RAS is a different variant of resonant absorber where a homogenous lossy material of quarter wavelength thickness is placed on top of a metallic ground plane. In this case, the waves from first and second interfaces interfere destructively, thereby reducing overall reflection.

The resonant absorbers discussed so far used resistive sheets with pure resistive values. Circuit analog (CA) absorbers represent another class of resonant absorbers where the resistive sheets are configured as lossy FSS layers. This results in a complex sheet admittance, with both resistive and reactive components, which can be appropriately tailored to accomplish broader bandwidth at reduced thickness (Choi et al. 2014; Zhang et al. 2012). For the purpose of illustration, the unit cell of a three-layered CA absorber (total thickness = 6.228 mm) with square and trapezoidal pattern-based resistive layers is shown in Fig. 11. Commercially available substrates like AD255C and RO4835 have been used to configure the multilayered model (Kantikar et al. 2020). The absorber is placed on top of a metallic plane whose RCS is to be reduced. The absorption characteristics of the RAS *w.r.t.* frequency and angle of incidence for TM as well as TE polarization are presented in Figs. 12 and 13, respectively. It is clear from the plot that the power absorbed is greater than 90% for a wide range of incident angles (0° to 60°) for TM polarization. On the other hand, for TE polarization, the percentage of power absorbed is greater than 90% from 2.51 GHz to 24 GHz till 50°. The unit cell has been then used to form a 15 cm × 15 cm planar RAS as shown in Fig. 14. The monostatic RCS of the planar RAS is shown in Fig. 15 along with that corresponding to PEC plate and copper plate of identical dimensions. The plot clearly reveals that the CA absorber reduces the RCS of metallic plate by 8 dB over a broad frequency range from 2 GHz to 18 GHz.

In order to cater to conformal platforms, the planar RAS has been bent with a radius of curvature (ROC) of 280 mm (Fig. 16). The variation in monostatic RAS of the conformal RAS *w.r.t* frequency is shown in Fig. 17. It is evident that the performance of the conformal RAS model is similar to that of planar RAS without any degradation.

RCS Reduction in Antenna/Array

As mentioned already, antenna RCS is a significant parameter to be considered in a low observable platform. The antenna RCS is essentially a combination of both radiation mode and structural mode RCS. The total RCS of an antenna is given by

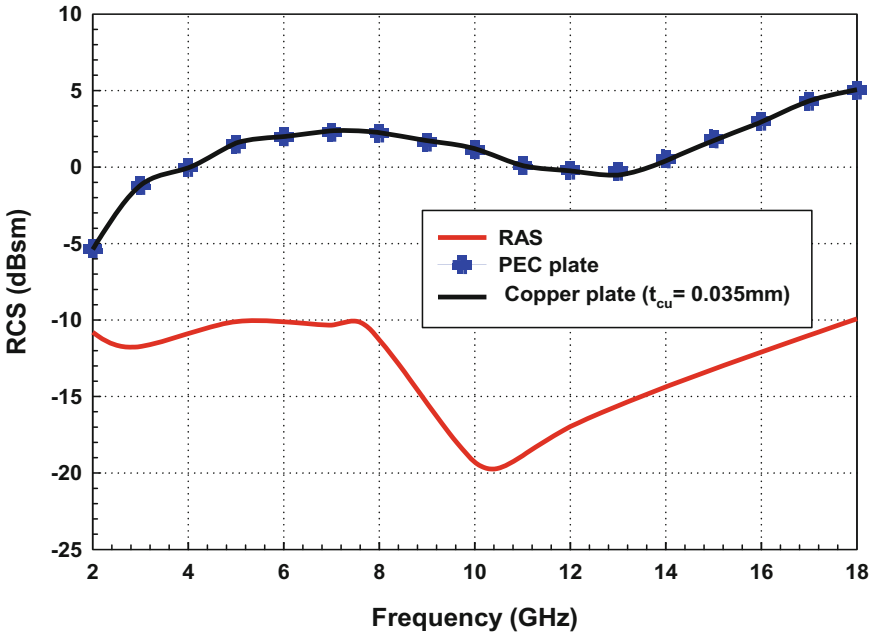

Fig. 17 Monostatic RCS characteristics of conformal CA absorber (normal incidence)

$$\sigma = |\sqrt{\sigma_{\text{struct}}} - (1 - \Gamma)\sqrt{\sigma_{\text{rad}}}e^{j\phi}|^2 \tag{9}$$

where σ_{struct} and σ_{rad} represent the structural mode and radiation mode RCS, respectively, Γ is the reflection coefficient of the antenna, and ϕ is the phase difference between σ_{struct} and σ_{rad}. One of the ways to reduce antenna RCS is to modify the ground plane of the antenna. It can be done by replacing PEC ground plane with a high-impedance surface (HIS) comprising of AMC and FSS elements. Such designs provide RCS reduction in out-of-band frequency range (Shater and Zarifi 2017). Another method is to incorporate a resistive FSS layer of single octagonal loop in the antenna design (Ramkumar et al. 2016). The implementation of embedded passive (EP) resistors without soldering facilitates RCS reduction and parasitic reactance, besides eliminating the soldering defects. Researchers have designed different combinations of AMC cells that can replace the conventional ground plane of microstrip patch array, so that the out-of-band RCS reduction can be achieved (Paquay et al. 2007; Iriarte et al. 2013). A low profile patch array with ground plane modified by hybrid FSS (Genovesi et al. 2012) shows out-of-band RCS reduction without any degradation in the radiation characteristics. An antenna array with nonuniform configuration of HIS elements can show broadband RCS reduction. However, the significant reduction in structural RCS of patch array over the desired frequency range requires extensive analysis.

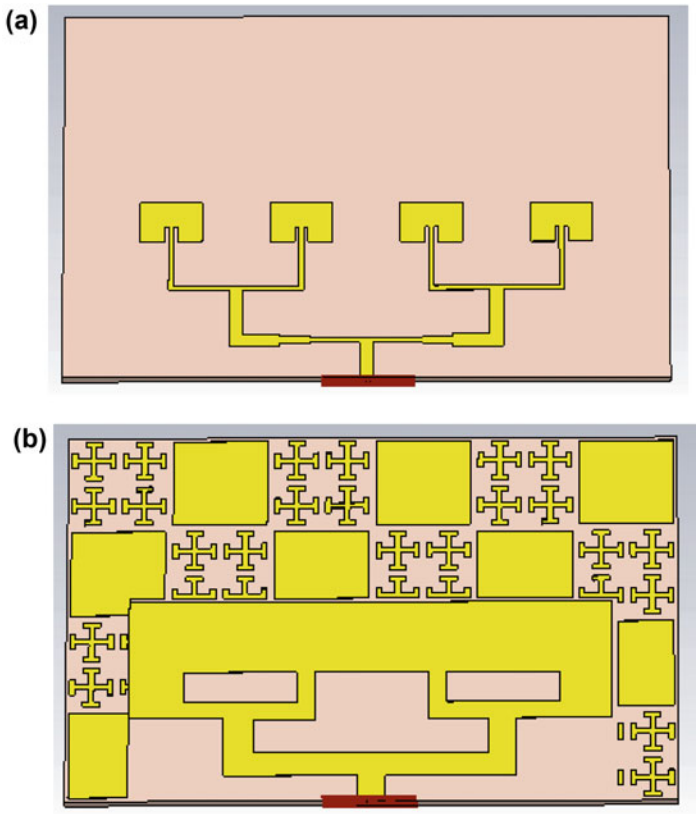

Fig. 18 A four-element linear patch array with hybrid HIS layer as ground plane at 10.5 GHz (substrate dimensions: 60 mm × 90 mm). (**a**) Top view, (**b**) bottom view.

Table 1 Radiation characteristics of a four-element patch array with hybrid HIS layer as ground plane at 10.5 GHz

Array performance	PEC ground plane	Hybrid HIS layer as ground plane
Return loss	−26.68 dB at 10.48 GHz	−22.85 dB at 10.37 GHz
VSWR	1.1	1.16
Gain	6.75 dB	7.3 dB

The main challenge is to achieve reduction in antenna RCS without any degradation in antenna radiation performance in terms of return loss, VSWR, and antenna gain.

Figure 18 shows a four-element patch array with HIS-based hybrid ground plane consisting of chessboard arrangement of patch and Jerusalem cross elements. The substrate is of 60 mm × 90 mm dimensions. It can be noted from Table 1 that the

resonant frequency of the patch array has shifted from 10.48 GHz to 10.37 GHz with a return loss of −29.24 dB, when the conventional PEC-based ground plane is replaced with HIS ground plane. The corresponding value of VSWR is 1.16. It can be observed from Fig. 19a that there is an improvement in the array gain. The gain of the patch array with HIS ground plane is obtained as 7.3 dB, in contrast to 6.75 dB with PEC-based ground plane.

Figure 19b shows the extent of structural RCS reduction over the frequency range of 6 GHz to 30 GHz. It can be noted that RCS reduction of 1.37 dBsm to 23 dBsm is achieved in the frequency range of 11 GHz to 30 GHz. Moreover, RCS reduction of 1.43 dBsm to 3.16 dBsm is obtained in the frequency range of 6 GHz to 9 GHz. A maximum RCS reduction of 23 dBsm is achieved at 25 GHz, while a reduction of 18.26 dBsm is obtained at 18 GHz. The stop-band characteristics of HIS layer are corroborated in the structural RCS plot of the patch array. The RCS reduction is not obtained at the resonant frequency of the patch array.

Figure 19c presents the variation of gain of four-element patch array with frequency. It is evident that the array gain is maximum at the resonant frequency. Moreover, the gain of the patch array with hybrid HIS layer as ground plane has increased in the frequency range of 8 GHz to 10.5 GHz, when compared to the patch array with conventional ground plane.

Conclusion

With rapid advancements in the field of stealth technologies, accurate estimation of RCS has become an inevitable component in the development of low observable structures. Different approaches used for RCS estimation such as body geometry decomposition, low frequency techniques, high frequency techniques, and hybrid methods have been briefly explained in this chapter. Special emphasis has been laid on enabling the reader to choose a suitable technique based on the electrical size of the structure. Low frequency techniques provide accurate predictions for complex geometries at the expense of increased computational cost, whereas high frequency approaches tackle relatively simple electrically large problems with less computational resources. Further, hybrid methods are logical combinations of asymptotic and numerical methods for solving EM problems where neither class of formulations is sufficient by itself. RCS of certain structures like metallic double ogive, UAV, patch antenna/array computed using commercial software, and open-source codes have been presented as well. Once RCS is estimated, the next major step is to reduce the scattering from predominant hotspots. In this regard, the popular approaches employed for reduction of RCS have also been included with special emphasis on minimizing reflectivity using radar absorbing materials (RAM), radar absorbing structure (RAS), FSS, metasurfaces, etc.

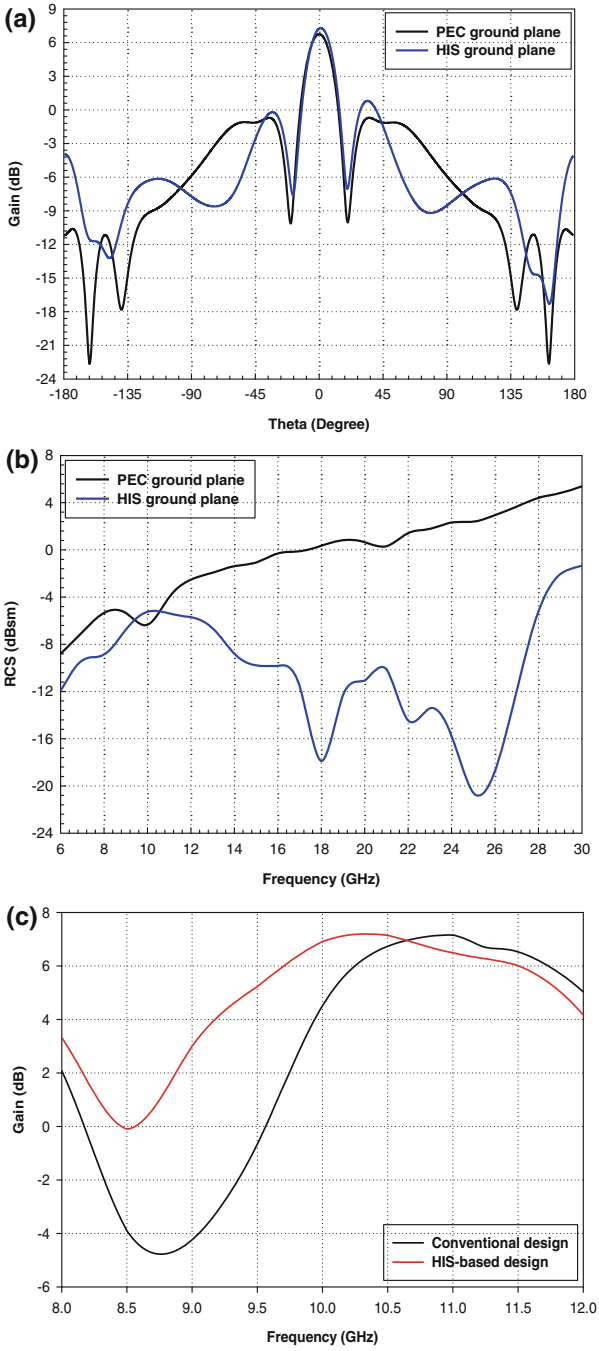

Fig. 19 Radiation and scattering characteristics of a four-element patch array with hybrid HIS layer as ground plane at 10.5 GHz. (**a**) Gain, (**d**) specular structural RCS, (**c**) variation of gain with frequency

Environmental Metrology

Environmental Metrology

62

An Introduction

Ravinder Agarwal and Susheel Mittal

Abstract

Meteorology is an important atmospheric science. It includes all aspects of the atmosphere, including atmospheric physics and chemistry. Meteorology is the short-term study of the atmosphere and its movements. Meteorology, also known as "weather," is the study of atmospheric elements that affect present or near-future circumstances. Temperature, humidity, precipitation amount and kind, wind direction and strength, atmospheric pressure, and cloud cover are just a few of the meteorological factors that characterize the atmosphere.

The "environment" refers to all natural materials that surround us, such as air, water, land, and noise, in which humans, animals, and plants coexist. Pollution wreaks havoc on the ecosystem. Our environment is poisoned in several ways. Smoke is produced by mills, factories, automobiles, burning of crop waste, and other similar sources. As a result, substantial air pollution develops, particularly in big cities and industrial areas. Pollution means contamination of this environment. The environment is polluted in many ways, smoke from the mills, factories, vehicles, crop residue burning, etc., resulting in serious air pollution especially occurring in big cities and big industrial areas.

Every day, 2 million tons of sewage and industrial and agricultural wastes are released into local water sources across the world. Human waste is the major source of water pollution; 2.5 billion people do not have access to basic sanitation facilities. Open defecation is practiced by 12% of the global population. Greenhouse gases,

dangerous chemicals, smoke, industrial pollutants, pollen, and exhaust may all combine to generate smog layers, particularly over cities and metropolitan areas, raising health and environmental concerns.

This introductory chapter provides a brief overview of the international metrology program for ensuring metrology for monitoring air indoor and outdoor quality, pollution effect on health, traceability in analytical environmental measurements, and noise pollution monitoring in urban cities with a global measurement system traceable to SI units. This book presents many policymaking innovation approaches for the development of a knowledge economy and knowledge society. Pollutants have a negative influence on not just public health but also the global climate and ecosystems. Most programs to minimize air pollution provide a "win-win" solution for both health and the environment. Lower levels of air pollution improve the population's cardiovascular and respiratory health in the long and short term. Reducing ambient and home air pollution can also reduce emissions of carbon dioxide (CO_2) and short-lived climate pollutants such as black carbon particles and methane, so helping the near- and long-term mitigation of climate change.

In general, air pollution is one of our era's biggest scourges, not only because it influences climate change but also because of its impact on public and individual health owing to increased sickness and death. Several contaminants are substantial contributors to human illness. Particulate matter (PM), particles with varying but extremely tiny diameters, enter the respiratory system by inhalation and cause respiratory and cardiovascular illnesses, reproductive and central nervous system malfunction, and cancer.

Particulate matter is made up of a mixture of solid and liquid particles such as dust, pollen, ash, soot, dirt, and smoke. Some of these particles may be visible, as evidenced by the appearance of haze, while others are too tiny to be seen with the human eye. The accurate and exact measurement of ambient particulate matter (PM) is required for a better understanding of the possible environmental and human health implications of airborne particulate matter (PM). Several methods and devices are available, ranging from filter-based sample collection for offline laboratory analysis to online instruments that detect airborne particles and provide real-time information on size distribution, particle mass concentration, and chemical data (US EPA e-CFR40; US EPA 40 CFR 2020). Depending on the scientific aims of the investigation, different measuring methodologies, sample devices, and equipment based on different principles are utilized. Continuous methods' improved time resolution has proven useful in monitoring PM concentrations and characterizing ambient PM and is becoming increasingly important in allowing policymakers to make decisions and scientists to investigate sources of particulate pollution and to probe into the dynamics and mechanisms of aerosol formation in the atmosphere. It is critical for researchers working on the subject of air quality to have a thorough awareness of the principles and limits of various PM monitoring methodologies. In this regard, this chapter gives an overview of the measuring principles of PM measurement techniques that are accessible and utilized globally. Offline and online procedures are complementary in nature, with the online methodology improving the temporal resolution of PM characterization by delivering data in 1 hour or less and

the offline technique, being nondestructive, allowing the use of the same sample for analysis by other techniques. The employment of both online and offline techniques in tandem can give a better knowledge of the particulate matter by research needs.

Knowledge of atmospheric boundary layer (ABL) characteristics that impact pollutant concentration, diffusion, and transit is required for air pollution mitigation. The ABL is one of the most essential component zones of the atmosphere since it is vital to major human endeavors such as air pollution, aviation, and communication. It is also known as the biosphere's circulatory system. SODAR is a critical ground-based remote sensor capable of detecting ABL height in real time. SODAR is a well-known and well-acknowledged meteorological technology for providing real-time and essential ABL data in real time. SODAR contributes to city planning, industrial zoning, and other air quality management approaches (Kumar et al. 2021; Saha et al. 2019). The data obtained by SODAR echograms is processed, evaluated, and compared to the Modern-Era Retrospective Analysis for Research and Applications, Version 2 (MERRA-2) model sensor, to determine its efficacy and data accuracy. Following a careful examination, it was discovered that SODAR is effective ecologically friendly equipment that can be utilized for air pollution control and air quality measurements. To accomplish this purpose, the work addresses five aspects: SODAR as a monitoring technique, SODAR system calibration and validation, SODAR application in air pollution warning system, comparison of the ABL height of SODAR and MERRA-2, and SODAR application in determining the pollution loading capacity of the region. ▶ Chapter 65, "Development of Calibrated and Validated SODAR with Reference of Air Quality Management," is divided into nine sections. In a nutshell, a new SODAR monitoring system was developed employing a novel combination of a moving-coil transducer, parabolic dish, and acoustic ACP sheet baffle. To send sounds into the turbulent zone, an acoustical parabolic antenna was deployed. The system was utilized for long-term continuous data collecting with a minimal likelihood of electronic failure. SODAR data is used to determine the region's pollution loading capacity and air pollution alarms in various atmospheric circumstances (Parag et al. 2022).

Stubble burning has been identified as a major cause of air pollution, notably in South Asia. It greatly contributes to the formation of gaseous pollutants such as carbon monoxide (CO), nitrogen oxides (NO_x), methane (CH_4), and others. India's position is more austere because of the extensive rice-wheat rotation system, which creates a considerable amount of stubble. A huge amount of waste is generated after harvesting crops like wheat and rice, most of which is burned after the valuable constituents have been removed. Some of these wastes are used as animal feeds, for making cattle sheds and rural house roofs, or as fuel for domestic cooking.

Crop residue burning (CRB) is one of the top contributors to ambient air pollution ($PM_{2.5}$) in northwestern India. Despite the magnitude of the problems associated with high particulate levels, epidemiologic data on the associated health effects of CRB focusing on rural populations is limited in India. The present study was conducted to quantify the impact of ambient air quality ($PM_{2.5}$) from CRB on the respiratory health of rural/agricultural communities in Patiala. Particle size is closely related to its ability to cause health concerns (Sachin et al. 2020; Susheel et al. 2016).

Small particles fewer than 10 micrometers in diameter are the most dangerous because they can enter your lungs and, in some cases, your bloodstream. Such particles can have an impact on both your lungs and your heart. Numerous scientific studies have linked particle pollution exposure to a wide range of problems, including premature death in people with heart or lung disease, nonfatal heart attacks, irregular heartbeat, aggravated asthma, decreased lung function, and increased respiratory symptoms, such as airway irritation, coughing, or difficulty breathing. People with heart or lung illnesses, children, and the elderly are the most vulnerable to particle pollution. Among numerous sorts of environmental imbalances, air pollution is a global health concern with substantial public health consequences. There is a relationship between air pollution and a variety of health concerns, notably among children, pregnant women, the elderly, and those with comorbid conditions.

There have been reports of the negative impact of air pollution on neurological, cardiovascular, and respiratory diseases. Maximum deterioration in FVC and PEF values was seen in one of the respiratory system experiments during each crop season. When physiological markers were compared to their baseline levels, an unrecoverable impact was detected. The rice crop residue burning season had more impact on subjects than the wheat crop residue burning season due to the release of higher concentrations of PM in the ambient environment (Bai et al. 2018). This study revealed for the first time the role of BMI in the respiratory-related sickness of human subjects during exposure to ambient air particulate matter. In the future, if necessary steps are not taken to stop these burning activities, it may cause chronic diseases like cardiopulmonary disorders, irrecoverable lung capacity or asthma, and unrecoverable disorders in human subjects in the initial age of their growth. As a result, massive awareness campaigns are required to inform farmers about the availability of economically viable alternatives.

Indoor air quality (IAQ) is the quality of air in and around a building that directly impacts human health. Over the last few decades, the worldwide scientific community, environmental research, and governmental organizations have worked to enhance building inhabitants' comfort, health, and welfare. First and foremost, why is IAQ monitoring required? Because indoor air pollution (IAP) may have a substantial and harmful influence on both occupants' health and quality of life. Given that residents spend the bulk of their time indoors, the issue of IAQ represents a compelling strategy for mitigating air pollutant exposure, particularly amid the current health crisis caused by COVID-19. Various research organizations have employed cutting-edge technology to handle IAQ testing services that precisely assess a variety of characteristics and difficulties that cause discomfort at work. As a result, the purpose of this chapter is to answer the stated need and examine the existing understanding of IAQ measurement in terms of various elements, allied science, and applications to demonstrate the strategy of translational research studies on IAQ. This chapter also covers many elements of IAQ such as measuring methodologies, characterization methods, and source apportionment, as well as their implications on human health and the environment. Thermal comfort characteristics such as ambient temperature, relative humidity (RH), and wind speed are recognized to have a vital impact on indoor air quality due to continuously changing

technology. The chapter attempts to investigate how humans may live in and near good air quality environments – overall, creating incentives to enhance IAQ in ways that benefit building occupants, employers, and owners, as well as increasing respect for IAQ in green construction initiatives (Bai et al. 2018; Dubey et al. 2021). This chapter is a comprehensive scientific publication that covers all facets of the IAQ system, including measurement techniques, characterization methods, source apportionment tools, and ways of assessing health risks. This will benefit and be highly beneficial for researchers, policymakers, and government agencies in designing new strategies and policies for improving the IAQ system.

Because of the fast expansion of industrialization, motorized transportation, and urbanization, emissions from these activities are negatively altering air quality and threatening human health, agriculture, plants, forests, animals, and property. There is an understanding of the necessity of excellent air quality and the importance of comprehensive monitoring. Monitoring of industrial emissions in developed nations, notably in the United States, Japan, and Germany, has almost entirely transitioned to the use of automatic continuous monitoring systems based on specific physicochemical or electrochemical features of the pollutants. For assessment of impacts, devices giving time-weighted average values are most desirable, and for assessment of short-term hourly variations, real-time continuous monitoring systems are more desirable. Such equipment needs very particular sensors for each pollutant; calibration methods that necessitate calibration gases of precisely specified and known composition; a dust-free, air-conditioned atmosphere; and so on. Such systems become nearly unaffordable in terms of capital costs for industrial units in developing nations, particularly medium- and small-size units. Even more difficult to address are issues such as a lack of instrument parts and calibration gases in local markets, as well as skilled personnel for the effective operation and maintenance of these complicated systems. In India, experience has shown that wherever such systems have been built, they have been inoperative nearly from the outset.

The USEPA has established straightforward ideas for measuring both source emissions and ambient air quality. Although these have become outmoded in developed nations, they are still appropriate for adaptation in underdeveloped countries. Even in this country, instruments made in the United States, Japan, Germany, and other countries frequently tend to make the instrument difficult and costly, causing problems with operation, maintenance, replacements, and so on, in addition to the much higher prices. The instruments presented here are based on simple USEPA ideas and are easy to use and maintain in the field circumstances of developing nations' warm, tropical environments. These instruments are relatively inexpensive. Furthermore, a new sort of device is necessary to measure the exposure of people who move around while working. The movement of air in the local environment is critical for understanding the buildup or dispersion of contaminants. To safeguard those with hearing impairments, immediate and LEQ noise levels must be monitored (Pokhariyal et al. 2019).

In today's environment, the reliability of measurement data creates a solid foundation for successful policymaking, resource allocation, and other major

choices for a government. Accurate and reliable measurements serve as the foundation for the country's growth and development across all sectors (Yadav et al. 2020a). Every measured data has an uncertainty connected with it, which frequently calls into question its legitimacy in the realm of metrology. Thus, metrological traceability, which connects measured findings to a specified reference via an unbroken chain of comparisons while accounting for all acknowledged uncertainties, has become critical. Although estimating uncertainty is easier for physical measurements, this concept still has to be spread in the field of chemical/biological/environmental measurements. Environmental regulation is based on qualitative and quantitative data in environmental research, and even little inaccuracies/errors can be fatal. This increases the need for traceability in environmental measurements. Analytical procedures for environmental measures include multiple processes, including sample pretreatment (extraction), sample storage, and chemical/biological analysis. However, estimating errors in environmental measurements is a difficult task due to incomplete analyte recovery, inappropriate sample handling during extraction, and incorrect sample storage. Uncertainty connected with analytical environmental measurements and the techniques that influence the quality of the data provided must still be understood and investigated in depth (Pokhariyal et al. 2019). This chapter discusses how traceability using documented standards and certified reference materials can be perceived in analytical environmental measurements, with an attempt to link the associated uncertainties at each step of the measurement of atmospheric particulate matter (PM) concentration as well as during the analytical determination of its chemical components.

Accurate assessment of an analyte level in analytical environmental measurements is extremely complex and tough to perform realistically. The missing linkages in analytical environmental measures must be addressed for this aim. There is still a need for research into the references used in environmental studies so that precise measurements may be obtained without compromise. This ensures the traceability of measurement data to references and the precise assessment of environmental pollutants.

The current chapter provides a comprehensive review of noise monitoring studies, a comparison of prediction models including physical propagation models, and applications of artificial intelligence techniques, noise mapping, and noise pollution monitoring in the mining sector conducted by various researchers. The majority of noise pollution studies are concerned with the evaluation of traffic noise, whereas some are only concerned with noise monitoring for residential, educational, industrial, and commercial areas. The study demonstrates that early models were based on mathematical prediction models, while subsequent machine learning and deep learning approaches were commonly utilized for noise-level prediction and forecasting. The chapter provides a look back at noise mapping and control. Although certain studies have been recorded in several Indian cities, the approach, strategy, and methodology of noise mapping are still in their early stages in India. However, when more studies are completed, it will provide consultants, town planners, research institutes, labs, and pollution control authorities in India with greater information and expertise in performing noise mapping studies and implementing

noise control measures. Promoting good health and a high standard of living necessitates a comprehensive strategy that focuses primarily on periodic noise monitoring and assessment of noisy locations in cities, determining compliance with ambient noise standards, and developing appropriate noise action plans in conjunction with policy issues concerning environmental noise planning and control. Furthermore, noise pollution management and abatement techniques are noted as being critical for decreasing ambient noise levels in the country's urban centers.

Moreover, our everyday lives are intrinsically linked to sound. Noise, in particular, is frequently unpleasant, degrades our living environment, and may be harmful to our health. Many efforts have been made in the past to address noise-related problems. As a consequence, the techniques for achieving precise noise measurement are the subject of this chapter. First, for noise measurement, the frequency dependence of our audible sensation and the time variation of the noise are considered, and several noise indicators are proposed. The operational principles, actual implications, and calibration techniques of acoustic measuring instruments are then covered. And after that, quantitative standards which are needed for precise noise measurement are introduced. They are achieved as the sensitivities of special condenser microphones and ensure the reliability of acoustic measuring instruments.

Despite the challenge of eliminating anthropogenic environmental contamination, a good solution might be envisioned as a close collaboration of authorities, bodies, and doctors to normalize the condition. Governments must provide adequate information, educate citizens, and involve specialists in these concerns to properly control the rise of the problem. International collaboration in research, development, administration policy, monitoring, and politics is critical at this stage for successful pollution management (Sarangi et al. 2016). Air pollution legislation must be harmonized and updated, and policymakers should propose the development of a formidable environmental and health protection mechanism. Air pollution reduction technologies must be developed and implemented in all sectors. In the future, if necessary steps are not taken to stop these burning/pollution activities, it may cause chronic diseases like cardiopulmonary disorders, irrecoverable lung capacity or asthma, and unrecoverable disorders to human subjects in the initial age of their growth.

Abstract

Sound is closely related to our daily life. Specifically, noise is frequently unpleasant, degrades our living environment, and may harm our health. So far, many efforts to deal with noise-related problems have been conducted. Therefore, this chapter focuses on the techniques for achieving precise noise measurement. First, the frequency dependence of our auditorial sensation and time variation of the noise are considered for the noise measurement, and several noise indicators have been proposed. Then, operational principles, practical use, and calibration techniques of the acoustic measuring instruments are discussed. Next, quantitative standards indispensable for precise noise measurement are introduced. They are achieved as the sensitivities of special condenser microphones and ensure the acoustic measuring instruments' reliability. Therefore, requirements for these measurement procedures and instruments are adequately provided in ISO and IEC standards. Finally, some recent advances in acoustic measurement are also introduced.

Introduction

We are exposed to sound daily in a busy area, near a construction site or transit facilities, at the workplace, and even at home. Generally, noise is an unwanted sound often regarded as uncomfortable. Long-term noise exposure may cause severe health damage, such as hearing loss, in some cases. So far, precise and reliable measurement techniques for "acoustic" noise have been studied to ensure a safe environment. These techniques underpin the acceptable noise limit and are reflected in regulations in many countries. Furthermore, quantitative noise monitoring has been achieved in various situations.

Therefore, this chapter focuses on the topics associated with noise measurement, which covers technical terms, measuring instruments, measurement techniques, and instrument calibration. Additionally, current advances in precise acoustic measurement are also introduced. This chapter refers to a few well-known textbooks on acoustics such as Tachibana and Yano 2012, Kido 1990, and Garrett 2017, especially for explaining basic quantities of sound, indicators of noise, and sound measuring principles.

Basic Physical Quantities of Sound and Related Terminology

Sound Pressure and Frequency Weighting

Sound Pressure

The vibration of sound sources such as loudspeakers and musical instruments is transmitted to the surrounding air as a sound wave producing our auditorial sensation. The sound wave causes temporal and spatial air density distribution, resulting in pressure oscillation.

The difference between the time-varying instantaneous atmospheric pressure induced by the sound wave and the static pressure at a given measurement point is known as "instantaneous sound pressure" and is defined as

$$p_{\text{inst}}(t) = P(t) - P_{\text{stat}}, \tag{1}$$

where $p_{\text{inst}}(t)$, $P(t)$, and P_{stat} are the instantaneous sound pressure, instantaneous total pressure, and static pressure, respectively. The unit of quantities in Eq. (1) is Pa, named pascal, following the International System of Units (SI). However, the instantaneous sound pressure is time-dependent and takes both positive and negative values. Therefore, for convenience, the root mean square of the instantaneous sound pressure, such as the sound pressure p, which is mainly used in acoustics, is denoted as follows:

$$p = \sqrt{\frac{1}{T}\int_0^T p_{\text{inst}}^2(t)dt}, \tag{2}$$

where t is time and T is measurement time interval.

Acoustics deals with sound pressure in a wide range. The minimum audible sound pressure is 20×10^{-6} Pa for a sinusoidal sound wave of 1 kHz, while the sound pressure of noise around 20 Pa can be endured for a short time. Therefore, it is not convenient to express the sound pressure in the unit of Pa. Alternatively, the sound pressure is transformed into a logarithm known as "sound pressure level." The unit of the sound pressure level is dB and named decibel. The sound pressure level L_p is defined as follows:

$$L_p = 10\log_{10}\left(\frac{p^2}{p_{\text{ref}}^2}\right), \tag{3}$$

where p_{ref} is the reference sound pressure of 20×10^{-6} Pa, as abovementioned. Therefore, sound pressure from 20×10^{-6} Pa to 20 Pa is converted to sound pressure level from 0 dB to 120 dB. Another reason for the logarithmic expression of the sound pressure is that human sensation is proportional to the logarithm of the stimulus.

Frequency-Weighted Sound Pressure

The sound pressure level is incompatible with our auditory perception. In acoustics, the sensory magnitude of a sound is known as "loudness." Interestingly, loudness is frequency-dependent, and an equal-loudness-level contour shows the frequency dependency of the sound pressure level, which gives the equal loudness level. Furthermore, different loudness level causes a different curve, and for each contour, the loudness level is considered as the sound pressure level at the reference frequency of 1 kHz. Moreover, ISO 226 (ISO 226 2003) provides equal-loudness-level contours for the different loudness levels.

Frequency weighting is applied to sound pressure levels to reflect our auditorial characteristics approximately. Figure 1 shows the frequency dependency of the well-known frequency weightings A, C, and Z. Particularly, frequency weightings A and C approximate the inverse characteristics of the equal-loudness-level contours of 40 dB and 100 dB, respectively. However, frequency weighting Z is 0 dB for all the frequencies and implies that the sound pressure is not frequency-weighted. These frequency weightings are formulated in Annex E of IEC 61672-1 (IEC 61672-1 2013).

Frequency weighting A is commonly applied to noise and auditory measurements in practice, while that of C or Z is employed to measure physical quantities such as sound pressure level. In the frequency domain, the A- and C-weighted sound pressure levels, $L_{p\mathrm{A}}$ and $L_{p\mathrm{C}}$, are expressed as follows:

$$L_{p\mathrm{A}}(f) = L_p(f) + A(f), \tag{4}$$

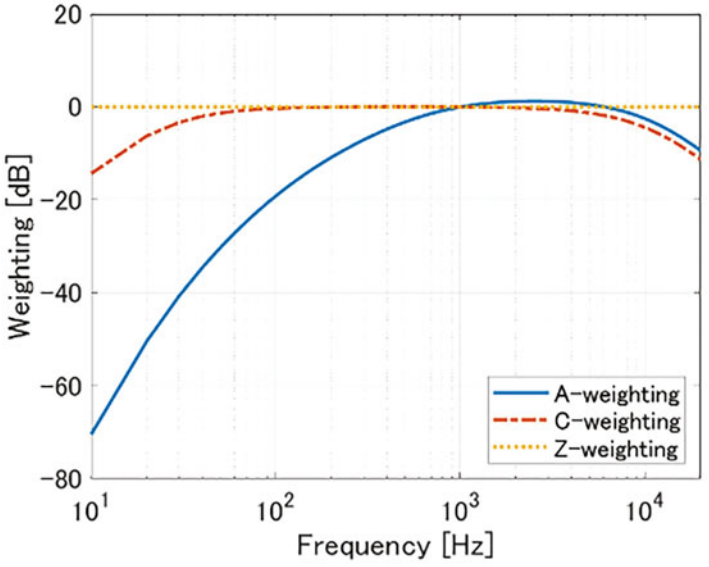

Fig. 1 Curves of frequency weightings A, C, and Z

$$L_{pC}(f) = L_p(f) + C(f), \tag{5}$$

where f is frequency, $L_p(f)$ is the sound pressure level, and $A(f)$ and $C(f)$ are the frequency weightings A and C, respectively. Figure 1 illustrates that our auditory system is more sensitive at mid frequencies than at lower and higher frequencies.

Particle Velocity

Particle velocity $\boldsymbol{u}$ is the air velocity within an infinitesimal volume caused by the propagation of sound waves. The equation of motion describes the relationship between particle velocity and sound pressure as follows:

$$\frac{\partial \boldsymbol{u}}{\partial t} = -\frac{1}{\rho}\nabla p, \tag{6}$$

where ρ is air density and ∇ is a gradient operator. Therefore, particle velocity is obtained by integrating Eq. (6) as follows:

$$\boldsymbol{u} = -\frac{1}{\rho}\int \nabla p dt. \tag{7}$$

Equations (6) and (7) deduce "instantaneous" particle velocity. Unless otherwise specified, particle velocity implies the root mean square value, similar to sound pressure. Additionally, particle velocity should not be confused with sound speed. Specifically, they are conceptually different, and sound speed in air is usually much faster than particle velocity.

Sound Intensity

The instantaneous sound intensity $\boldsymbol{I}_{inst}$ is the product of the instantaneous sound pressure p_{inst} and the instantaneous particle velocity $\boldsymbol{u}_{inst}$. This is denoted as follows:

$$\boldsymbol{I}_{inst}(t) = p_{inst}(t) \cdot \boldsymbol{u}_{inst}(t). \tag{8}$$

The sound intensity $\boldsymbol{I}$ is the time average of the instantaneous sound intensity and is expressed as the following:

$$\boldsymbol{I} = \frac{1}{T}\int_0^T I_{inst}(t)dt, \tag{9}$$

where T is the measurement time interval. As a physical quantity, sound intensity means sound power (see section "Sound Power") per unit area perpendicular to the direction of the propagating sound.

In the case of a plane progressive sound wave, the sound wave propagates unidirectionally. Accordingly, there is no phase difference between the instantaneous sound pressure and particle velocity, and the ratio is presented as follows:

$$\frac{p_{inst}(t)}{u_{inst}(t)} = \rho c, \tag{10}$$

where ρ is the density of air and c is the speed of sound in air. Therefore, the instantaneous sound intensity is described as the following:

$$I_{inst} = \frac{p_{inst}(t)^2}{\rho c}. \tag{11}$$

The sound intensity is also expressed in the logarithm and is known as the "sound intensity level." Furthermore, the unit of the sound intensity level is dB, known as a decibel. The sound intensity level L_I is defined as the following:

$$L_I = 10\log_{10}\frac{I}{I_{\text{ref}}}, \tag{12}$$

where I_{ref} is the reference sound intensity of 1.0×10^{-12} W/m^2. I_{ref} is calculated from p_{ref} of 20×10^{-6} Pa and ρc of 400 Pa·s/m for the plane progressive sound wave.

Sound Power

The sound power W is defined as sound energy emitted from a sound source per unit of time. The unit of sound power is watt, also known as joule per second. Let us consider the virtual space in Fig. 2. The sound power is formulated by using sound intensity $\boldsymbol{I}$ as follows:

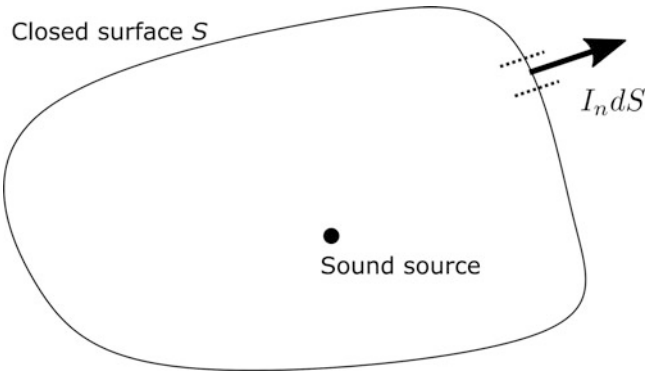

Fig. 2 Conceptual diagram of the relationship between sound power and sound intensity

$$W = \oint_S \boldsymbol{I} \cdot d\boldsymbol{S} = \oint_S \boldsymbol{I} \cdot \boldsymbol{n} dS = \oint_S I_n dS, \tag{13}$$

where S is the closed surface that surrounds the sound source, vector $\boldsymbol{n}$ is a unit normal vector, and I_n is a normal component of sound intensity.

For a plane progressive sound wave, the sound power is derived from Eqs. (9), (11), and (13) as follows:

$$W = \frac{1}{T} \oint_S \int_0^T \frac{p_{inst}(t)^2}{\rho c} dt \, dS. \tag{14}$$

Similarly, the sound power level L_W is defined as the following:

$$L_W = 10 \log_{10} \left(\frac{W}{W_{\text{ref}}} \right), \tag{15}$$

where W_{ref} is the reference sound power of 1.0×10^{-12} W and calculated in a similar approach as I_{ref} using the reference area of 1 m^2.

Sound Fields

Overview of Sound Fields

Testing and calibrating acoustic measuring instruments and noise measurement of sound sources require a special measurement environment. Therefore, this section describes the characteristics of a typical sound environment, such as pressure field, free sound field, and diffuse sound field.

Pressure Field

The pressure field is characterized by a uniform sound pressure in small, enclosed spaces. An acoustic coupler realizes the pressure field in its cavity, and the dimension of the cavity is much smaller than the wavelength of a sound wave. Therefore, the acoustic coupler is used for the calibration of microphone sensitivity under a pressure field (see section "Pressure Sensitivity Calibration by Reciprocity Method" and "Pressure Sensitivity Calibration by Laser Pistonphone Method").

Furthermore, the output voltage of earphones or headphones is measured by attaching it to the acoustic coupler, which simulates the acoustic characteristics of our auditory system.

Free Sound Field

The free sound field is also known as the "free field." Here, the sound wave travels without the influence of obstacles. Therefore, anechoic chambers have been designed to realize a free sound field.

The inner walls of the anechoic chamber, including a ceiling and floor, are frequently covered with wedged and porous sound-absorbing materials such as

glass wool. The length of the wedges determines the lower limit frequency of sound absorption. The total performance of the chamber is evaluated with the deviation from the inverse square law. This law means that the sound intensity should be inversely proportional to the square of the distance from the sound source. The procedures for qualifying the anechoic chamber are provided in Annex A of ISO 3745 (ISO 3745 2012). The space near the inner walls is practically unsuitable for the free sound field, because the sound reflection from the inner walls increases compared with the space at the center of the chamber.

The abovementioned anechoic chamber is sometimes known as a full-anechoic chamber, while a hemi-anechoic chamber has an acoustically reflective floor made of concrete, among others. The hemi-anechoic chamber is used for measuring the noise from heavy objects, such as cars and large machines, and the sound power level of sound sources.

Diffuse Sound Field

A diffuse sound field is also known as the "diffuse field." Here, sound energy density is uniform throughout the chamber, and sound energy is propagated from all directions with equal probability. Reverberation chambers have been designed to realize diffuse sound fields. The inner walls of the reverberation chamber are made of acoustically high reflective materials, such as hard stone and concrete. Additionally, the inner walls of the reverberation chamber are often placed unparalleled, allowing as many reflected sound waves to emerge from every direction as possible.

The acoustic performance of the reverberation chamber is evaluated with the reverberation time T_{60}. This parameter is defined as an interval to reduce the sound energy in a steady state by 60 dB after the sound source is suddenly stopped. The reverberation chamber is used for measuring sound absorption coefficient, acoustic transmittance of materials, and the sound power level of sound sources.

Sound Measuring Instruments and Related Equipment

Condenser Microphone

Mechanical Structure

An electroacoustic transducer, such as a microphone and loudspeaker, converts the acoustic signal into an electrical signal or vice versa. A microphone is a typical acoustic sensor and can be categorized by the conversion principle. A condenser microphone is also known as an electrostatic microphone and suitable for acoustic measurement because of a flat frequency response over a wide frequency range and sufficient short- and long-term stability.

The condenser microphone is classified into two types as follows: Type (a) requires external DC bias voltage to operate as a microphone, and it is known as the "externally polarized microphone." Figure 3a illustrates its typical structure. Specifically, a thin tensioned metal membrane and a metal backplate are placed approximately 10–30 μm apart and constitute the plates of a capacitor. The internal

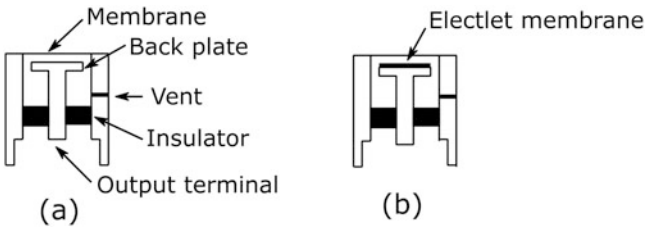

Fig. 3 Typical structure of condenser microphones: (**a**) externally polarized type (side of the housing is vented in this case) and (**b**) pre-polarized type (back plate is pre-polarized in this case)

cavity behind the back plate is exposed to atmospheric pressure through a small vent to equalize the pressure on both sides of the membrane. Furthermore, the vent passes through either the side of the microphone housing or the insulator.

Type (b) does not need DC bias voltage from an external power supply, and it is known as a "pre-polarized microphone" or "electret microphone." Figure 3b illustrates its typical structure. Morphologically, type (b) has almost the identical structure as type (a) except for pre-polarization. The microphone's membrane or back plate is partially made of ferroelectric material and stores electric charge semi-permanently. The convenient pre-polarized microphone is extensively used as a transducer of a sound level meter (see section "Sound Level Meter") and at the measurement site.

Microphone Sensitivity

The microphone sensitivity is defined as the ratio of open-circuit output voltage to sound pressure. As explained below, the sound pressure's physical meaning depends on the sound field.

Firstly, when the microphone membrane is exposed to a pressure field, as shown in Fig. 4a, the "pressure sensitivity," M_p, of the microphone is defined as follows:

$$M_p \equiv \frac{V_0}{p_p}, \tag{16}$$

where V_0 is the open-circuit output voltage of the microphone and p_p is sound pressure that is uniformly applied over the microphone membrane. The pressure sensitivity definition implies that the sound pressure p_p is "actually" acting on the membrane.

Next, let us consider the free sound field. If the measurement point is sufficiently distant from a sound source, the plane progressive sound wave is observed at that point, as shown in Fig. 4b. However, the sound field changes with the introduction of the microphone, because the sound wave is reflected and diffracted by the microphone housing, as shown in Fig. 4c. Therefore, "free-field sensitivity," M_f, of the microphone is defined to determine the sound pressure before positioning the microphone and formulated as the following:

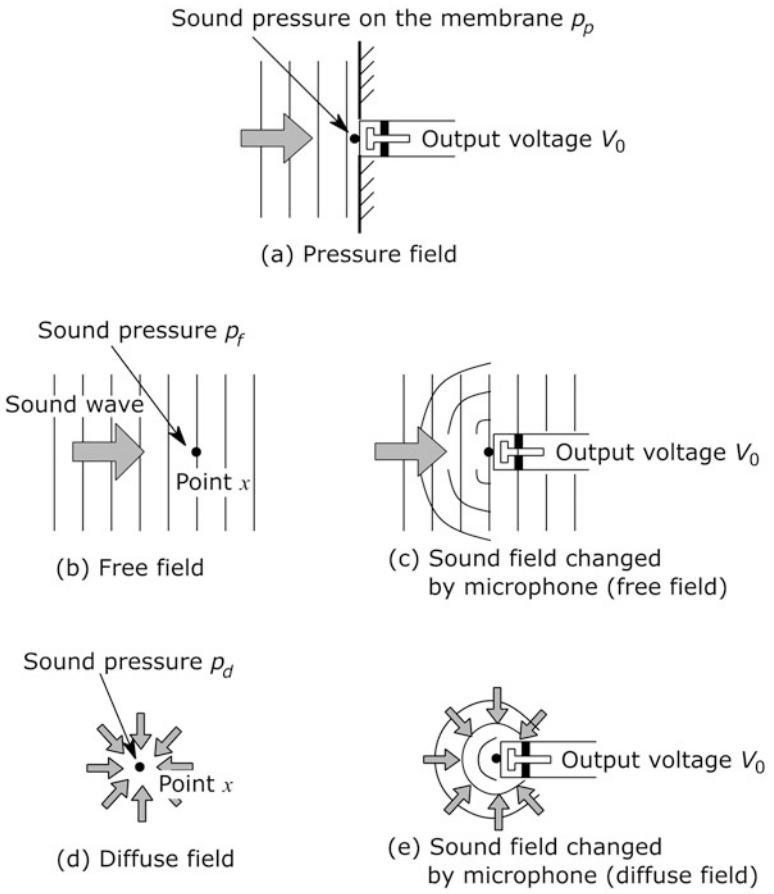

Fig. 4 Change of sound field by the introduction of a microphone

$$M_f \equiv \frac{V_0}{p_f}, \tag{17}$$

where V_0 is the open-circuit output voltage of the microphone, as shown in Fig. 4c, and p_f is sound pressure of the plane progressive sound wave that would exist at the point x without a microphone, as shown in Fig. 4b. The point x is the acoustic center (see section "Free-field Sensitivity Calibration by Reciprocity Method") of the microphone, where the microphone receives the sound pressure substantially. Free-field sensitivity depends on the sound wave's incident angle to the microphone; therefore, the incident angle should be clearly specified.

Finally, in a diffuse sound field, sound waves reach the point x from all directions with equal probability, as shown in Fig. 4d. "Diffuse-field sensitivity," M_d, of the microphone is defined in the same manner as free-field sensitivity and formulated as follows:

$$M_d \equiv \frac{V_0}{p_d}, \tag{18}$$

where V_0 is the open-circuit output voltage of the microphone, as shown in Fig. 4e, and p_d is sound pressure that would exist at the point x without a microphone, as shown in Fig. 4d.

Furthermore, random-incident sensitivity is defined as a root mean square of free-field sensitivities to sound waves coming from all the incident directions successively and with equal probability. The random-incident sensitivity has the same value as the diffuse-field sensitivity in principle and is experimentally determined instead of the diffuse-field sensitivity in practice.

The unit of the microphone sensitivity for each sound field is V/Pa and is usually expressed in logarithms. The unit of sensitivity level is dB, and the reference sensitivity is 1 V/Pa. Furthermore, microphone sensitivity slightly depends on environmental conditions, such as temperature and static pressure.

Classification of Condenser Microphones

Specifications of condenser microphones necessary for precise acoustic measurement are standardized in IEC 61094-4 (IEC 61094-4 1995), and such a microphone is known as the "working standard microphone."

Working standard microphones are categorized by grade, dimensions, and preferable sound field for use. Four characters represent the type name. The first two characters imply microphone grade. "WS" and "LS" mean "working standard microphone" and "laboratory standard microphone," respectively. A laboratory standard microphone (see section "Primary Calibration of Condenser Microphones") is a unique working standard microphone suitable for acoustic standards, and its specifications are prescribed in IEC 61094-1 (IEC 61094-1 2000).

The third character is a number from 1 to 3 accompanied by mechanical dimensions and the corresponding tolerance limits. The last character is "P," "F," or "D" and corresponds to pressure field, free field, or diffuse field, respectively. This character represents the sound field under which the microphone sensitivity is approximately flat in the broadest frequency range.

Table 1 presents typical characteristics of working and laboratory standard microphones. Figures 5 and 6 illustrate examples of these microphones.

Practically, working standard microphones that are commercially available have been classified by the housing diameter in inches. For example, the condenser microphone with a diameter of 3.175 mm is used for measuring sound pressure at frequencies up to 140 kHz; however, this is presently out of the scope in IEC 61094-4 (IEC 61094-4 1995), and there is no type name. Therefore, in this section, this type is named 1/8 inch microphone.

Furthermore, some working standard microphones are designed for special purposes, such as measuring infrasound at frequencies lower than 0.1 Hz, low sound pressure of less than 10 dB, and extremely high sound pressure of more than 180 dB.

Table 1 Typical characteristics of working and laboratory standard microphones

Type designation	WS1{P, F, D} LS1P	WS2{P, F, D} LS2aP, LS2bP	WS3{P, F, D}	1/8 inch type
Housing diameter	23.77 mm	12.7 mm	6.35 mm	3.175 mm
Frequency range	5 Hz to 10 kHz	5 Hz to 20 kHz	10 Hz to 100 kHz	10 Hz to 140 kHz
Sensitivity level	−20 dB to −30 dB	−25 dB to −40 dB	−40 dB to −60 dB	−60 dB
Self-generated noise	10 dB	20 dB	30 dB	40 dB
Maximum sound pressure level	140 dB	150 dB	160 dB	160 dB
Capacitance	50 pF	20 pF	5 pF	3 pF

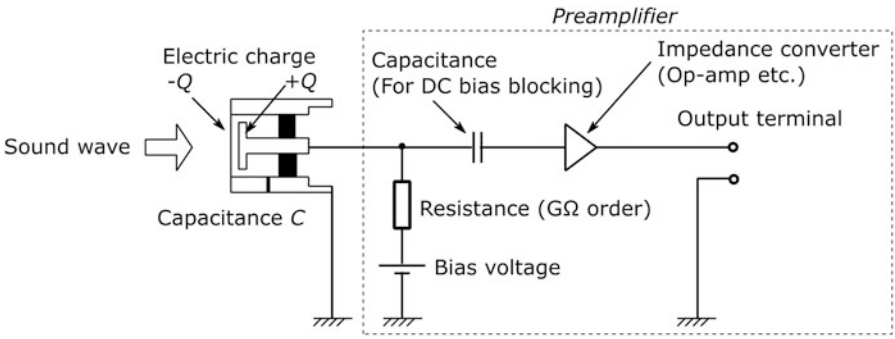

Fig. 7 Schematic diagram for obtaining electrical signal corresponding to sound pressure from an externally polarized condenser microphone

Usage of the Condenser Microphone

Figure 7 depicts the schematic for obtaining an electrical signal corresponding to sound pressure from an externally polarized condenser microphone. When sound pressure is applied to the microphone membrane, vibration of the membrane causes a capacitance change between the membrane and the back plate. Specifically, the capacitance of the condenser microphone is in the order of picofarad. This means that the microphone's output impedance is more than the order of megaohm and much larger than the input impedance of voltage measuring instruments, such as digital multimeters. Therefore, a microphone's output terminal is connected to the preamplifier as an impedance converter and then to the digital multimeter. The preamplifier gain is almost equal to 1; however, it can be obtained when necessary by applying the insert voltage technique (IEC 61094-2 2009), which applies a known electrical signal to the microphone instead of sound pressure.

Furthermore, a working standard microphone may be used without a protection grid. If necessary, a mechanical adaptor should be applied to the microphone to protect the membrane.

Sound Level Meter

A sound level meter is an instrument for measuring frequency-weighted and time-weighted sound pressure levels, which indicates the measured value on a display. The handheld type is used for on-site measurement, while the stationary type is used to monitor the noise continuously at some observation point. Figure 8 shows examples of the handheld type. Specifications for sound level meters are standardized in IEC 61672-1 (IEC 61672-1 2013). This standard provides class 1 and class 2 sound level meters. They have the same design goals, such as frequency weightings, but differ in tolerance limits and operational temperature range. Class 1 is superior to class 2.

Fig. 8 Examples of sound level meters: Rion type NL-27 (left) and Brüel & Kjær type 2250 (right)

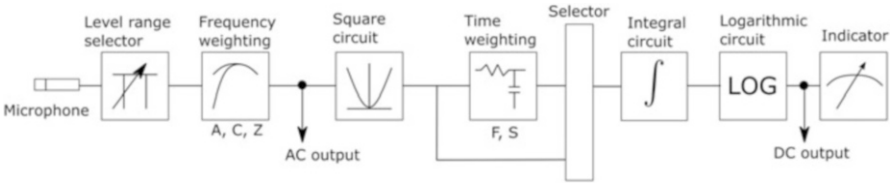

Fig. 9 Block diagram of sound level meter

Figure 9 illustrates the typical components of the sound level meter, such as microphone and preamplifier, level range selector, circuits for frequency weighting, square, time weighting, integral and conversion to logarithm, and indicator of the calculation results. Additionally, the level range is a measurement range of frequency-weighted sound pressure levels and should be selected appropriately to prevent overload and under-range. However, some advanced sound level meters do not need to change the level range because they can cover all the measurement ranges in a single level range. The formulation of the quantities measured and indicated by the sound level meter will be explained in section "Indicators of Environmental Noise Based on the Sound Pressure Level."

Time weighting is an exponential function of time with a time constant. The time constants of 125 ms and 1 s are specified in IEC 61672-1 (IEC 61672-1 2013) and are known as the "time weighting F" (fast) and "time weighting S" (slow), respectively.

The time constants are selected depending on the noise fluctuation characteristic. Time weighting F generates a time response like our auditory system, while time weighting S is used for easy reading by smoothing the fluctuating noise wave. A first-order low-pass filter realizes their time weighting circuits.

Most of the sound level meters have AC and DC output terminals, as shown in Fig. 9. DC output corresponds to the value indicated on the display of the sound level meter.

Furthermore, digital signal processing technology enabled analog circuits of sound level meters to be replaced by digital circuits, such as micro-processing unit (MPU) and digital signal processor (DSP). Some advanced sound level meters have an optional signal processing function, such as octave or FFT analysis for the noise.

Sound Calibrator

A sound calibrator is a portable sound source that produces a pressure field within its cavity when coupled to a microphone. The sound calibrator is used for checking and adjusting the sound level meter. It can also simply calibrate the pressure sensitivity of the working standard microphones. Typical sound calibrators generate a stable and sinusoidal sound pressure at 250 Hz or 1 kHz, ranging from 94 dB to 124 dB. Specifications for sound calibrators are provided in IEC 60942 (IEC 60942 2017). Figure 10 shows examples of sound calibrators.

Sound calibrators are categorized into two types by the mechanism of sound generation. The "pistonphone" creates sound pressure via the piston's vertical motion, converted from the rotating motion of a motor via a cam. Under the condition where the air in its cavity compresses and expands adiabatically, the resulting sound pressure p is given by

Fig. 10 Examples of sound calibrators: Rion NC-75 (left, loudspeaker type) and Brüel & Kjær type 4228 (right, pistonphone)

$$p = \frac{\gamma S_{SC} P_{\text{stat}} d}{V}, \tag{19}$$

where γ is the specific heat ratio of air, S_{SC} is a cross-section of the piston, P_{stat} is static pressure, d is the root mean square value of piston displacement, and V is the cavity volume formed by the pistonphone and microphone. Eq. (19) shows that the sound pressure depends on the static pressure. Therefore, when necessary, the sound pressure can be corrected to the value at the reference static pressure of 101.325 kPa. Furthermore, the cavity volume includes the microphone's acoustic characteristics. Correction values for the major microphone types are tabulated in the pistonphones' instruction manual.

Another sound calibrator type is often called "loudspeaker type" and generates sound pressure from a loudspeaker driven by a built-in oscillator. To compensate for variations in generated sound pressure by static pressure, some loudspeaker-type sound calibrators have an internal pressure sensor, and a feedback circuit automatically adjusts the sound pressure level. The more advanced type includes a feedback microphone to monitor the sound pressure level and adjust its change caused by the fluctuation of static pressure and by replacing the microphone under test.

Therefore, the loudspeaker-type sound calibrator is recommended for field use, while the pistonphone is suitable for indoor use in a well-controlled environment.

Sound Intensity Probe

A sound intensity probe is an instrument for measuring sound intensity by using two microphones that are positioned proximately. This measurement technique is known as the two-microphone method. Specifications for sound intensity instruments are provided in IEC 61043 (IEC 61043 1993). Figure 11 shows an example of the sound intensity probe.

Equation (8) shows that detecting sound intensity requires instantaneous sound pressure and particle velocity. However, direct measurement of particle velocity is difficult, and the particle velocity is approximately obtained from the difference in sound pressures observed at two proximate points. This situation is illustrated in Fig. 12.

$p_1(t)$ and $p_2(t)$ is the instantaneous sound pressure at two proximate measurement points, and Δr is the distance between these two points. The instantaneous sound pressure $p(t)$ and particle velocity $u(t)$ in the direction of sound propagation can be approximately obtained at the center point. Therefore, Eq. (6) is rewritten as follows:

$$\frac{\partial u}{\partial t} = -\frac{1}{\rho}\nabla p \approx -\frac{1}{\rho} \cdot \frac{p_1(t) - p_2(t)}{\Delta r}. \tag{20}$$

Equation (9) is similarly changed, and the sound intensity is obtained as follows:

Fig. 11 Example of sound intensity probe (Ono Sokki Co., Ltd. type MI-6410)

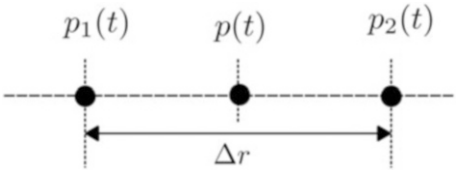

Fig. 12 Relationship between points and corresponding sound pressures

$$I(t) \approx -\frac{1}{\rho \Delta r} \overline{\frac{p_1(t)+p_2(t)}{2} \int_{-\infty}^{t} \{p_1(\tau)-p_2(\tau)\} d\tau}, \tag{21}$$

where the upper line denotes the time average.

When Eq. (21) is converted into the frequency domain, the intensity I in a frequency range from f_1 to f_2 is expressed as follows:

$$I \approx -\frac{1}{2\pi\rho\Delta r} \int_{f_1}^{f_2} \frac{\mathrm{Im}[G_{12}(f)]}{f} df, \tag{22}$$

where Im[·] denotes the imaginary part of a complex number and G_{12} is the cross-spectral density of $p_1(t)$ and $p_2(t)$. An FFT analyzer is extensively used to calculate the sound intensity based on Eq. (22).

The two-microphone method has an upper limit frequency determined by the relationship between the measurement point distance Δr and the wavelength of sound. Furthermore, the phase difference of the microphone sensitivities primarily causes the lower frequency limitation.

Reference Sound Source

A reference sound source is a stable, broadband noise source with a flat frequency response and omnidirectivity. Figure 13 shows an example of the reference sound source. The reference sound source usually generates turbulence noise from a

Fig. 13 Example of reference sound source (Brüel & Kjær type 4204)

sirocco fan. The fan rotates around a vertical axis by a motor. The fan's rotation speed depends on the voltage and frequency of the power supply and causes a similar dependency on the resulting sound power. Specifications and calibration procedures of the reference sound sources are provided in ISO 6926 (ISO 6926 2016).

The reference sound source is used as a reference for determining the sound power from a machine by using the comparison method. It is also used for measuring acoustic materials' sound absorption or insulation characteristics.

Environmental Noise Measurement Based on Sound Pressure

Overview of Environmental Noise Measurement

EU Directive defines environmental noise as "unwanted or harmful outdoor sound created by human activities, including noises emitted by means of transport, road traffic, rail traffic, air traffic, and from sites of our industrial activities" (EU 2002). ISO 1996-1 and 1996-2 (ISO 1996-1 2016 and ISO 1996-2 2017) provide indicators of environmental noise, which are determined from the sound pressure. Here, some indicators will be introduced after the classification of environmental noise. Note that the indicators' actual measurement and assessment procedures are not explained here because they should be reflected in national regulations or guidelines.

Classification of Environmental Noise by Time Fluctuation

As shown in Fig. 14, environmental noises are classified by the characteristics of time waveforms in ISO 12001 (ISO 12001 1996).

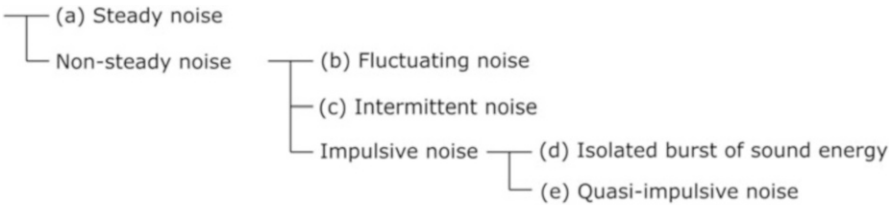

Fig. 14 Tree diagram of noises classified by time fluctuation

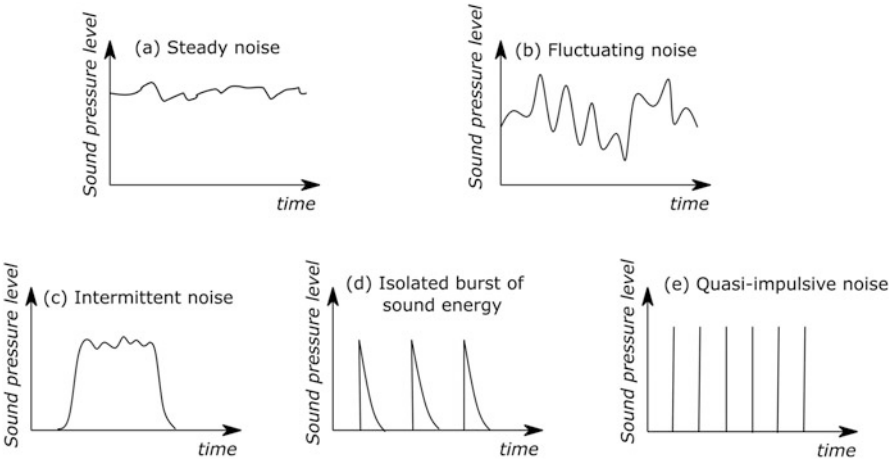

Fig. 15 Pictorial examples of noise time patterns

ISO 12001 (ISO 12001 1996) defines these noises. They are quoted below and illustrated in Fig. 15.

- Steady noise

A noise with negligibly small fluctuations of level within the period of observation (Fig. 15a).

- Nonsteady noise

A noise whose level shifts significantly during the period of observation

- Fluctuating noise

A noise whose level varies continuously and to an appreciable extent during the period of observation (Fig. 15b)

- Intermittent noise

A noise whose level abruptly drops to the level of the background noise several times during the period of observation. The time during which the level remains at a constant value different from that of the ambient is of the order of 1 s or more (Fig. 15c)

- Impulsive noise

A noise consisting of a series of bursts of sound energy, each burst having a duration of less than approximately 1 s

- Isolated burst of sound energy

A single burst of sound energy or a series of bursts with intervals larger than 0.2 s between the individual bursts (Fig. 15d)

- Quasi-impulsive noise

A series of noise bursts of comparable amplitude with intervals shorter than 0.2 s between the individual bursts (Fig. 15e).

Indicators of Environmental Noise Based on the Sound Pressure Level

Time-Weighted and Frequency-Weighted Sound Pressure Level

As introduced in section "Sound Level Meter," time-weighted and frequency-weighted sound pressure levels are the most fundamental quantity for measuring environmental noise.

ISO 1996-1 (ISO 1996-1 2016) refers to IEC 61672-1 (IEC 61672-1 2013) and mentions that time weightings F and S, and frequency weightings A and C are the standard weightings.

For example, F time-weighted and A-weighted sound pressure level $L_{\mathrm{AF}}(t)$ is defined as follows:

$$L_{\mathrm{AF}}(t) = 10\log_{10}\frac{\frac{1}{\tau_{\mathrm{F}}}\int_{-\infty}^{t} p_{\mathrm{A}}^2(\xi)\cdot \exp\left\{\frac{-(t-\xi)}{\tau_{\mathrm{F}}}\right\}d\xi}{p_0^2}, \tag{23}$$

where τ_F is the time constant for time weighting F, t is the time of observation, ξ is a dummy variable of time integration, $p_A(\xi)$ is A-weighted instantaneous sound pressure, and p_0 is the reference sound pressure of 20×10^{-6} Pa.

Maximum Time-Weighted and Frequency-Weighted Sound Pressure Level

The maximum time-weighted and frequency-weighted sound pressure level is used to evaluate single event noise with limited duration. Standard time weightings are F and S, and standard frequency weightings are A and C. For example, the symbol for the maximum F time-weighted and A-weighted sound pressure level is L_{AFmax}.

Sound Exposure Level

Sound exposure is the time integral of the square of frequency-weighted sound pressure over the interval T and gives a total sound energy of the nonsteady noise during T. If frequency weighting A is used, sound exposure level $L_{EA,T}$ is defined as

$$L_{EA,T} = 10\log_{10}\frac{\frac{1}{T_0}\int_{t_1}^{t_2} p_A^2(t)dt}{p_0^2}, \tag{24}$$

where T starts at t_1 and ends at t_2, $p_A(t)$ is A-weighted instantaneous sound pressure, T_0 is reference time of 1 s, and p_0 is the reference sound pressure of 20×10^{-6} Pa. Similar definition is applied to frequency weighting C.

The sound exposure level increases as the integration time T becomes longer. Therefore, the sound exposure level should be accompanied by a clear statement of the integral period T. Note that the sound exposure level for a single event is known as the "single event sound exposure level."

Equivalent Continuous Sound Pressure Level

The equivalent continuous sound pressure level is the time average of the square of frequency-weighted sound pressure over the time interval T and expressed in decibels. This quantity represents the energetic average of frequency-weighted sound pressure level for the nonsteady noise and is also known as the "time-averaged sound pressure level." A-weighted equivalent continuous sound pressure level $L_{Aeq,T}$ is defined as follows:

$$L_{Aeq,T} = 10\log_{10}\frac{\frac{1}{T}\int_{t_1}^{t_2} p_A^2(t)dt}{p_0^2}, \tag{25}$$

where T starts at t_1 and ends at t_2. $p_A(t)$ is A-weighted instantaneous sound pressure, and p_0 is the reference sound pressure of 20×10^{-6} Pa.

As illustrated in Fig. 16, the equivalent continuous sound pressure level of the nonsteady noise over a given period T is equal to the total sound energy of the steady

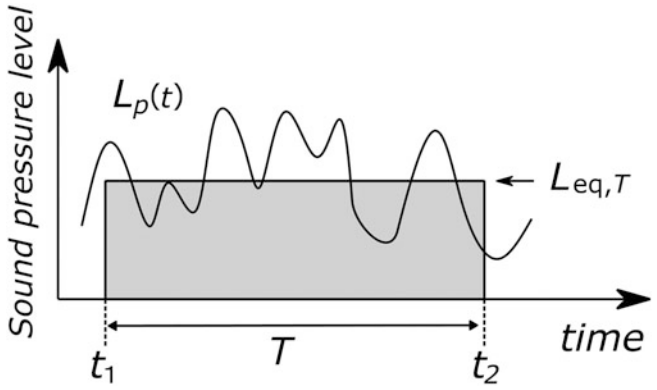

Fig. 16 Relationship between equivalent continuous sound pressure level and actual sound pressure level for nonsteady noise

sound pressure level. Consideration should be given to the measurement time interval of intermittent or impulsive noises, because this time interval may not include the whole noise event. In such a case, the start and end times of the measurement should be clearly stated.

N Percentage Exceedance Level

N percentage exceedance level represents a criterion of the sound pressure level that is exceeded for *N* % of the time interval *T*. The symbol $L_{\mathrm{AF}N,T}$ is given to F time-weighted and A-weighted sound pressure levels. The measurement procedure of $L_{\mathrm{AF}N,T}$ is as follows: Firstly, the sound pressure level is determined by the sound level meter with time interval T and sampling time ΔT. Then, the cumulative percentage distribution of the sound pressure level is obtained, as shown in Fig. 17. Finally, the sound pressure level conforming to $(100 - N)$ % of the cumulative distribution is considered as the N percentage exceedance level $L_{\mathrm{AF}N,T}$.

N percentage exceedance level is a statistic of the observed sound pressure, and the arithmetic or energetic mean obtained from a different time interval has no physical denotation.

Measurement of Noise Sources Based on the Sound Power

Overview of Sound Power Measurement

In the preceding section, several indicators of environmental noise have been introduced. They significantly contribute to monitor and assess the environmental noise. It is also important to precisely determine the sound energy emitted from the

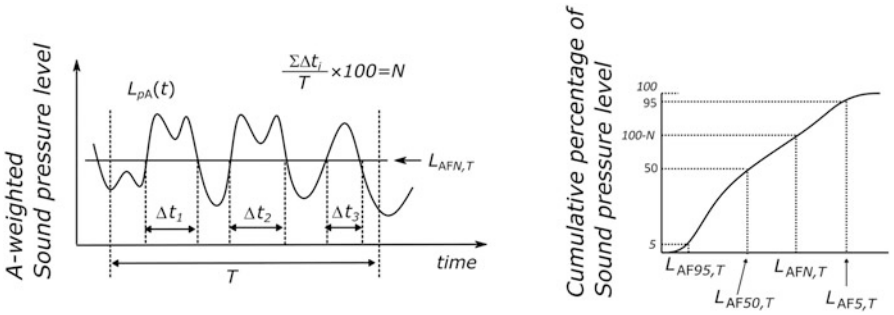

Fig. 17 Procedure to calculate *N* percentage exceedance level from acquired sound pressure level

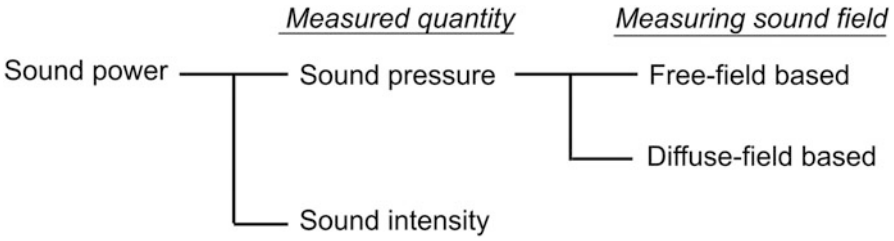

Fig. 18 Tree diagram of ISO standards for determining sound power level, categorized by measured quantity and environment

noise sources and consider their noise reduction. Sound power gives a unique value to each sound source; however, sound pressure depends on the measurement position relative to the sound source and the characteristics of the sound field. Accordingly, sound power is suitable for comparing the product noise. Furthermore, the sound power of the sound source can also be used to estimate the sound pressure at a given distance from the sound source.

Sound power is determined using Eq. (13) or (14) by taking the integral of sound intensity or sound pressure over the closed surface surrounding the sound source. Practically, the number of discretized measurement points for surface integral determines the measurement time and accuracy.

Various ISO standards have been published to obtain the sound power levels of noise sources. ISO 3740 (ISO 3740 2019) is a guidance document for the appropriate selection of the ISO standards considering the type of sound source, measurement principle, measurement environment, and required accuracy.

Here, these ISO standards will be comprehensively introduced. They are broadly classified by measured quantity and measurement environment, as shown in Fig. 18, and subdivided by the measurement method and accuracy. When applicable, the individual standards of a specific noise source should be preceded in measurement conditions.

Measurement Based on Sound Pressure in the Hemi-Free Field

Regarding the sound field for measuring sound power level, the hemi-anechoic chamber is preferable to the full-anechoic chamber for the following reasons. Firstly, the hemi-anechoic chamber has a hemispherical measurement surface; therefore, the number of measurement points is reduced by half compared with the full-anechoic chamber. Secondly, it is easy to place the sound source on a floor and at the center of the hemisphere because the hemi-anechoic chamber has a rigid floor. Finally, even heavy-weight objects can be transferred into hemi-anechoic chamber relatively easily.

Figure 19 shows the sound source placed on an acoustically reflective floor and at the center of the virtual hemisphere. The sound wave passing through the hemispherical surface is regarded as a plain progressive sound wave, because the hemisphere surface is sufficiently distant from the sound source. When the hemispherical measurement surface is divided into N segments, the sound power W in Eq. (14) is discretized as follows:

$$W = \sum_{i=1}^{N} \frac{\overline{p_i^2}}{\rho c} \Delta S_i, \tag{26}$$

where $\overline{p_i^2}$ is the time average of the square of sound pressure and ΔS_i is the area of the i-th segment, respectively. Eq. (26) is converted to logarithm as follows:

$$L_W = 10\log_{10} \sum_{i=1}^{N} \overline{L_{pi}} \cdot \Delta S_i, \tag{27}$$

where $\overline{L_{pi}}$ is the time-averaged sound pressure level. For convenience, the surface sound pressure level L_{pf} is introduced as follows:

$$L_{pf} = 10\log_{10}\left(\frac{1}{S}\right)\left[\sum_{i=1}^{N} \Delta S_i \cdot 10^{\frac{\overline{L_{pi}}}{10}}\right], \tag{28}$$

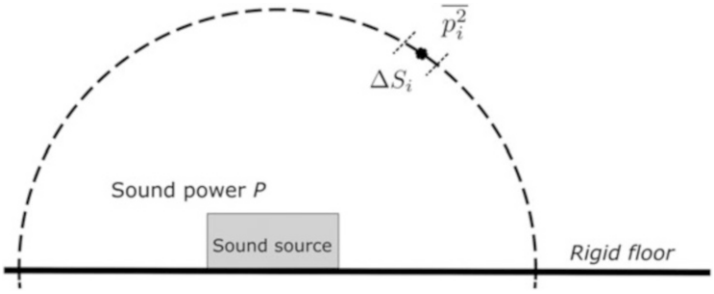

Fig. 19 Schematic diagram of sound power measurement based on sound pressure in a hemi-free field

where S is the total area of the hemispherical surface. L_{pf} is the energetic average of the time-averaged sound pressure level over the hemispherical surface. By using Eq. (28), Eq. (27) is rewritten as follows:

$$L_W = L_{pf} + 10\log_{10}\frac{S}{S_0} + C, \tag{29}$$

where S is equal to $2\pi r$ and denotes the surface area of a hemisphere with a radius r and S_0 is the reference area of 1 m^2. C is introduced to correct the temperature and pressure dependency of ρc and that of sound power of the sound source and to consider the absorption of a sound wave in the air.

There are three ISO standards for determining sound power level in a free field by using sound pressure level. They possess different accuracy, such as the "precision method" (ISO 3745 2012), "engineering method" (ISO 3744 2010), and "survey method" (ISO 3746 2010). Table 2 summarizes the differences between these ISO standards.

The accuracy depends on the degree of caution taken to determine the sound power level from Eq. (29), such as acoustic characteristics of the chamber, number of measurement points for obtaining L_{pf}, and the correction term C. The value of C is generally minute and considered only for the precision method. It is ignored in engineering and survey methods. Regarding the measurement surface, engineering and survey methods allow both hemisphere surface and parallelepiped surface.

While the precision method requires full- or hemi-anechoic chamber, engineering and survey methods allow the test chamber with higher sound absorption or outdoor. Such a practical acoustic environment will increase measurement error due to background noise and sound reflection. To compensate for this drawback, L_{pf} is replaced with L'_{pf} using the following equation for engineering and survey methods:

Table 2 Summary of ISO standards for determining sound power level from sound pressure level in free field

Standards	ISO 3744	ISO 3745	ISO 3746
Grade	Engineering	Precision	Survey
Test environment	Essentially free field over a reflecting plane	Anechoic or hemi-anechoic room	In situ over a reflecting plane
Volume of sound source	No limit; limited only by test environment	Less than 0.5% of test room volume	No limit; limited only by test environment
Number of measurement points	$\geq$9 Less than 9 is allowed in specific condition	$\geq$10	$\geq$4 Less than 4 is allowed in specific condition
Limitation for background noise	$K_1 \leq 1.3$ dB	$K_1 \leq 0.5$ dB	$K_1 \leq 3.0$ dB
Frequency range of interest	1/3 octave bands from 100 Hz to 10,000 Hz	1/3 octave bands from 100 Hz to 10,000 Hz	Octave bands from 125 Hz to 8000 Hz

$$L'_{pf} = L_{pf} - K_1 - K_2, \tag{30}$$

where K_1 and K_2 are corrections for background noise and sound reflection, respectively. Correction for background noise K_1 is obtained as follows:

$$K_1 = -10\log_{10}\left(1 - 10^{-\frac{L_{pf} - L''_{pf}}{10}}\right), \tag{31}$$

where L''_{pf} is the surface sound pressure level without the sound source operation.

Correction for sound reflection K_2 can be obtained by using the reference sound source as denoted below:

$$K_2 = L^*_W - L_{Wr}, \tag{32}$$

where L^*_W is the sound power level of the reference sound source that is obtained by engineering or survey method at the condition $K_2 = 0$ in Eq. (30). L_{Wr} is the sound power level of the reference sound source, precisely calibrated in advance.

From Eqs. (29), (30), and (32), the sound power level L_W is changed as

$$L_W = \left\{\left(L_{pf} + 10\log_{10}\frac{S}{S_0}\right) - K_1 - L^*_W\right\} + L_{Wr}. \tag{33}$$

The term in the bracket {} of Eq. (33) denotes the sound power level difference between the sound source under test and the reference sound source. Therefore, when the reference source is calibrated in advance, the sound power level of the sound source can be deduced by comparing it with the reference sound source and compensating for the sound reflection in the sound field.

Measurement Based on Sound Pressure in the Diffuse Field

As shown in Fig. 20, the sound power level can also be determined by measuring a sound pressure level in a diffuse field. In a steady state, the sound power W emitted from the sound source is equal to the sound power absorbed by the inner walls of the reverberation chamber, including the ceiling and floor, and it is formulated as follows:

$$W = \frac{c\overline{E}}{4}A, \tag{34}$$

where c is the speed of sound in air, $\overline{E}$ is the space-averaged acoustic energy density, and A is an equivalent sound absorption area of the reverberation chamber. Furthermore, $\overline{E}$ is derived as follows:

$$\overline{E} = \frac{\overline{p^2}}{\rho c^2}, \tag{35}$$

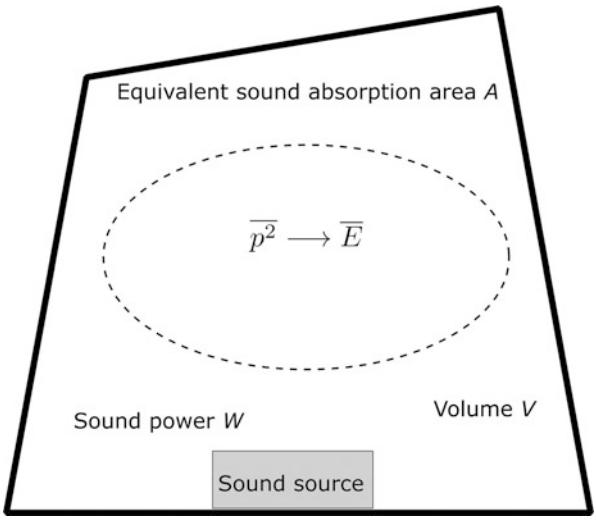

Fig. 20 Schematic diagram of sound power measurement based on sound pressure in a diffuse field

where ρ is the density of air, $\overline{p^2}$ is named "mean square sound pressure," and it means the time and space average of square sound pressure in the diffuse field. Substitution of Eq. (35) for Eq. (34) shows that

$$W = \frac{A\overline{p^2}}{4\rho c}, \tag{36}$$

where ρc is known as the "specific acoustic impedance" and is set to be 400 Pa·s/m for convenience, although it depends on temperature and static pressure.

By expressing Eq. (36) in logarithm, the sound power level L_W is expressed as follows:

$$L_W = L_p + 10\log_{10}\frac{A}{A_0} - 6, \tag{37}$$

where L_p is the mean sound pressure level in the diffuse field. A_0 is the reference of equivalent sound absorption area and is set as 1 m^2. Equivalent sound absorption area A is given by Sabine equation as follows:

$$A = \frac{55.26}{c}\left(\frac{V}{T_{rev}}\right), \tag{38}$$

where V and T_{rev} are the volume and reverberation time of the reverberation chamber, respectively.

In practice, the sound pressure is not spatially uniform in the diffuse field; therefore, the mean sound pressure level is obtained as follows:

$$\overline{L_p} = 10\log_{10}\left[\frac{1}{N}\sum_{i=1}^{N} 10^{\frac{L_{pi}}{10}}\right] - K_1, \tag{39}$$

where N is the number of measurement points, L_{pi} is the sound pressure level at the i-th measurement point, and K_1 is the correction for background noise in the diffuse field obtained in the same way as Eq. (31).

Equations (37) and (38) are the basic equations for calculating sound power levels in a diffuse field. As observed in the free-field measurement in section "Measurement Based on Sound Pressure in the Hemi-Free Field," methods for measuring sound power level using sound pressure level in the diffuse field are categorized by acoustic measurement environment and measurement accuracy. Table 3 summarizes the differences between the related ISO standards (ISO 3741 2010; ISO 3743-1 2010; ISO 3743-2 2018; ISO 3747 2010).

Actually, determining the equivalent sound absorption area A is difficult. Therefore, direct determination of the sound power level from Eqs. (37) and (38) are usually substituted with comparison measurement using the reference sound source calibrated in advance. The sound power level L_W of the sound source under test is given as follows:

$$L_W = \left(\overline{L_p} - \overline{L_{p_ref}}\right) + L_{W_{ref}}, \tag{40}$$

where $\overline{L_p}$ and $\overline{L_{p_ref}}$ are the mean square sound pressure levels of the object under test and the reference sound source, respectively, and both are obtained in the diffused field using Eq. (39). L_{Wref} is the sound power level of the reference sound source and calibrated in advance.

Table 3 Summary of ISO standards for determining sound power measurements from sound pressure level in a diffuse field

Standards	ISO 3741	ISO 3743-1	ISO 3743-2	ISO 3747
Grade	Precision	Engineering		Engineering and survey
Test environment	Reverberation test room	Hard-walled room	Special reverberation test room	Essentially reverberant field in situ
Volume of sound source	Preferably less than 2% of test room volume	Preferably less than 1% of test room volume		No limit; limited only by test environment
Limitation for background noise	$K_1 \leq 0.5$ dB	$K_1 \leq 1.3$ dB	$K_1 \leq 2.0$ dB	$K_1 \leq 1.3$ dB
Frequency range of interest	1/3 octave bands from 100 Hz to 10,000 Hz	Octave bands from 125 Hz to 8000 Hz		Octave bands from 125 Hz to 8000 Hz

Measurement Based on Sound Intensity

Equation (13) shows that sound power is principally obtained by measuring sound intensity. The acoustic environment such as a free field or diffuse field is not required for sound intensity measurement. The measurement surface of the sound intensity is divided into N segments, and Eq. (13) is discretized in the same way as section "Measurement Based on Sound Pressure in the Hemi-Free Field." The sound power level L_W is obtained as follows:

$$L_W = 10\log_{10}\frac{1}{S_0}\sum_{i=1}^{N} 10^{\frac{L_{ni}}{10}} \cdot \Delta S_i, \tag{41}$$

where S_0 is the reference area of 1 m^2. For the i-th segment, ΔS_i is its area, and L_{ni} is its sound intensity level that is normal to that segment.

Determination of the sound power level from the sound intensity level has the advantage that, in principle, the obtained sound power level is unaffected by sound sources or noises outside the measurement surface. This is because the sound intensity measurement considers only the sound waves propagating from inside to outside the measurement surface. However, measurement accuracy may deteriorate when sound-absorbing areas or objects are inside the measurement surface.

The two procedures can measure sound intensity at each segment. One is to measure the sound intensity at each discrete segment. The other is to move the sound intensity probe and scan at each segment continuously, either manually or automatically by a moving system. When a sound source has complex sound radiation characteristics, the measurement should be made at many segments. The measurement at many discrete segments will take a long time to achieve the necessary accuracy.

The scanning method considerably reduces the measurement time. However, manual scanning requires adequate operator training to achieve high measurement accuracy. In contrast, mechanical scanning does not need training, but the moving system's vibration sometimes causes a measurement accuracy problem.

Table 4 summarizes the differences between the related ISO standards (ISO 9614-1 1993; ISO 9614-2 1996; ISO 9614-3 2002) based on the measurement accuracy and method.

Table 4 Summary of ISO standards for determining sound power from the sound intensity level

Standards	ISO 9614-1	ISO 9614-2	ISO 9614-3
Grade	Precision, engineering, and survey	Engineering and survey	Precision
Test environment	No special test environment		
Volume of sound source	No restrictions		
Measurement method	Discrete points	Scanning	Scanning
Frequency range of interest	1/3 octave bands from 50 Hz to 6300 Hz		

Calibration of Acoustic Measuring Instruments and their Measurement Traceability

Traceability System of Acoustic Standards

Recently, various products and services have been required to conform to the ISO or IEC standards from the point of quality management on many occasions. For example, in acoustics, these international standards request that acoustic measuring instruments are traceable to national measurement standards to ensure their reliability.

Acoustic standards are the national measurement standards for acoustics. They have been realized as pressure sensitivities of laboratory standard microphones using more basic national measurement standards regarding voltage, length, pressure, and temperature, among others.

The National Metrology Institute (NMI) in each economy calibrates the acoustic standards. The NMI supplies the standards to calibration laboratories and manufacturers of acoustic measuring instruments, such as working standard microphones, sound level meters, and sound calibrators. They calibrate end-users acoustic measuring instruments compared with acoustic standards or other traceable acoustic measuring instruments. In some cases, the end-users instruments are calibrated by the NMI. In this way, the end-users can confirm that their instruments are traceable to the national measurement standards. Figure 21 illustrates an example of a traceability system. Other acoustic measuring instruments can also be calibrated by comparison.

Primary Calibration of Condenser Microphones

Pressure Sensitivity Calibration by Reciprocity Method

Technical requirements for the acoustic standards are as follows:

1. Acoustical characteristics are stable for a short and long time.
2. The frequency response is flat as possible over the entire frequency range.
3. The primary calibration method Is established and does not need other quantitative acoustic standards

In the audible frequencies from 20 Hz to 20 kHz, pressure sensitivities of the laboratory standard microphones satisfy the above requirements 1 and 2 and are absolutely determined using the reciprocity method. As explained in section "Classification of Condenser Microphones," laboratory standard microphones have been specifically designed for the acoustic standards (IEC 61094-1 2000). Furthermore, the reciprocity method is standardized in IEC 61094-2 (IEC 61094-2 2009).

A unique characteristic of condenser microphones is that the microphone converts an acoustic signal into an electrical signal and vice versa. The reciprocity method successfully uses this reciprocal characteristic. Firstly, two condenser

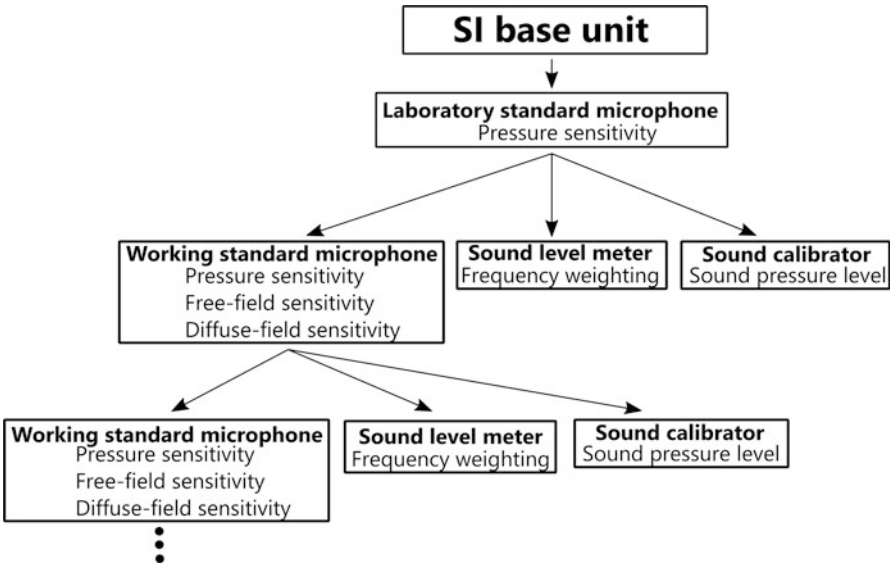

Fig. 21 Example of a traceability system for acoustic measuring instruments

microphones named x and y are placed apart in some sound field. The transmitter microphone x is supplied with the input current i_x and emits a sound wave. Next, the receiver microphone y receives the sound wave over its membrane and results in the output voltage v_y. This signal transmission is formulated as follows:

$$Z_{e,xy} \equiv \frac{v_y}{i_x} = M_x Z_{a,xy} M_y, \tag{42}$$

where $Z_{e,xy}$ is known as the "electrical transfer impedance" between microphones x and y. M_x and M_y are the sensitivities of microphones x and y, respectively. $Z_{a,xy}$ is the "acoustic transfer impedance" between microphones x and y, and it stands for acoustic coupling between the microphones. The acoustic transfer impedance is analytically derived for simple sound fields.

When pressure sensitivities of the laboratory standard microphones are determined, the microphones are acoustically coupled in an acoustic coupler through a cylindrical cavity, as shown in Fig. 22. Additionally, the acoustic coupler is usually fitted with a capillary tube to balance the static pressure inside and outside of the cavity.

When the sound pressure within the cavity is uniform and air in the cavity compresses and expands adiabatically, the acoustic transfer impedance is written as follows:

$$Z_{a,xy} = \frac{\gamma P_{\text{stat}}}{j\omega V}, \tag{43}$$

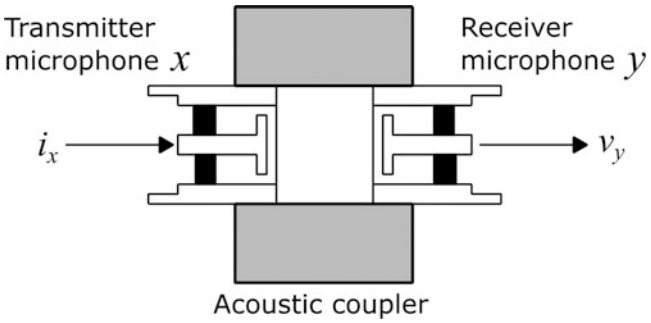

Fig. 22 Schematic diagram of microphones coupled acoustically through a cylindrical cavity

where γ is the specific heat ratio of air, P_{stat} is the static pressure, j is an imaginary unit of a complex number, ω is the angular frequency of the signal, and V is the inner volume of the acoustic coupler.

The acoustic transfer impedance should be corrected for heat conduction and viscous loss at the inner walls of the cavity and departures from uniform sound pressure distribution. Here, the corrected acoustic transfer impedance is denoted as $Z'_{a,xy}$.

Absolute determination of the pressure sensitivities requires three microphones of the same type, and they are labeled as "1," "2," and "3." Then, three pairs of transmitter and receiver microphones are sequentially made, namely (1, 2), (1, 3), and (2, 3). The following three equations are derived from Eq. (42) as follows:

$$\begin{cases} Z_{e,12}=M_1 Z'_{a,12} M_2 \\ Z_{e,13}=M_1 Z'_{a,13} M_3 \\ Z_{e,23}=M_2 Z'_{a,23} M_3 \end{cases}. \tag{44}$$

By solving Eq. (44), the pressure sensitivities of the three microphones are determined. For example, the sensitivity of microphone "3" is expressed as follows:

$$M_3^2 = \frac{Z_{e,13} \cdot Z_{e,23}}{Z_{e,12}} \cdot \frac{Z'_{a,12}}{Z'_{a,13} \cdot Z'_{a,12}}. \tag{45}$$

Precise calibration of the microphone sensitivity requires the following consideration: Firstly, as shown in Eq. (42), the electrical transfer impedance $Z_{e,xy}$ is the ratio of the output voltage of the receiver microphone to the input current of the transmitter microphone. Therefore, the insert voltage technique should be applied to the receiver microphone to precisely measure its open-circuit voltage (see section "Usage of the Condenser Microphone").

Secondly, as shown in Table 1, the capacitance of the condenser microphone is in the order of picofarad and causes a large electrical impedance. Therefore, electrical current passing through the transmitter microphone becomes smaller than the order

of microampere, and its precise measurement is difficult. When a capacitor or resistor with a known electrical impedance is connected to the transfer microphone in series, the voltage across this electrical element can be measured more efficiently and accurately. Otherwise, the electrical impedance of the transmitter microphone can be measured accurately without connecting any electrical elements.

Finally, the sensitivity of the condenser microphone slightly depends on temperature and static pressure. Therefore, the sensitivity should be corrected using its temperature and pressure coefficient if necessary.

Pressure Sensitivity Calibration by Laser Pistonphone Method

Sound waves with frequencies lower than 20 Hz are generally called infrasound. Although our sense of hearing cannot perceive the infrasound, it causes unpleasant feelings such as discomfort or oppression and makes windows or doors rattle. These sounds are generated by a large-scale blower or an air compressor installed mainly in factories. An interesting example is the occurrence of infrasound during a dam water release. Although various measures have been established to prevent infrasound generation, the number of infrasound complaints is increasing.

Therefore, precise measurement of the infrasound is required to investigate or evaluate it. Advanced sound level meters can measure the sound pressure level at frequencies down to approximately 1 Hz. However, the reciprocity method limits microphone calibration at frequencies lower than 20 Hz, because the signal-to-noise ratio deteriorates by the noise from external sound sources and internal electrical circuits.

Therefore, the laser pistonphone method (Rennie 1977) was developed and used to determine the pressure sensitivity of laboratory standard microphones. The IEC technical report covers this method (IEC TR 61094-10 2022). Figure 23 depicts the schematic of the microphone calibration system by the laser pistonphone method. A piston moves sinusoidally using a shaker and generates sound pressure in a cylindrical cavity. The piston displacement d is obtained by a laser interferometer, and the sound pressure p is given as follows:

$$p = \frac{\gamma P_{\text{stat}}}{\sqrt{2}V} S_{\text{pist}} d, \tag{46}$$

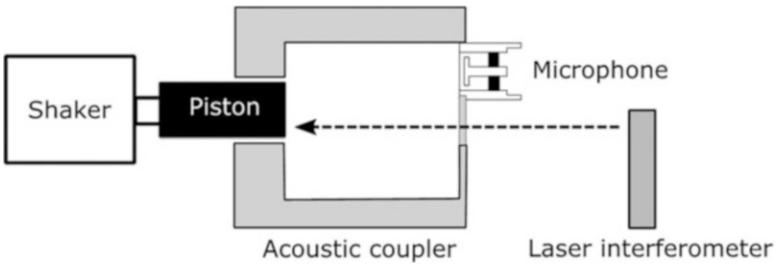

Fig. 23 Schematic diagram of laser pistonphone method

where V is the cavity volume and S_{pist} is the cross-sectional area of the piston. Piston displacement is usually determined using the interference fringe counting method and is written as follows:

$$d = \frac{n\lambda_l}{8}, \tag{47}$$

where n is the number of fringes and λ_l is the wavelength of the laser. Simultaneously measuring d and the open-circuit voltage e of the microphone under test results in the pressure sensitivity M as follows:

$$M = \frac{e}{p}. \tag{48}$$

Practically, the laser pistonphone method can generate sound pressure levels larger than 120 dB and does not have the issue of signal-to-noise ratio. The cavity's dimensions are much larger than in the reciprocity method due to the difference in measurement frequency range. A small gap between the piston and the cavity equalizes the static pressure inside and outside of the cavity.

Free-Field Sensitivity Calibration by Reciprocity Method

The reciprocity method can also determine the free-field sensitivities of the laboratory standard microphones. The calibration principle of free-field sensitivity is provided in IEC 61094-3 (IEC 61094-3 2016) and is the same as pressure sensitivity, except that the microphones are placed in a free field.

To calibrate free-field sensitivities, transmitter and receiver microphones are set in the anechoic chamber face to face and about 20–40 cm apart, as illustrated in Fig. 24.

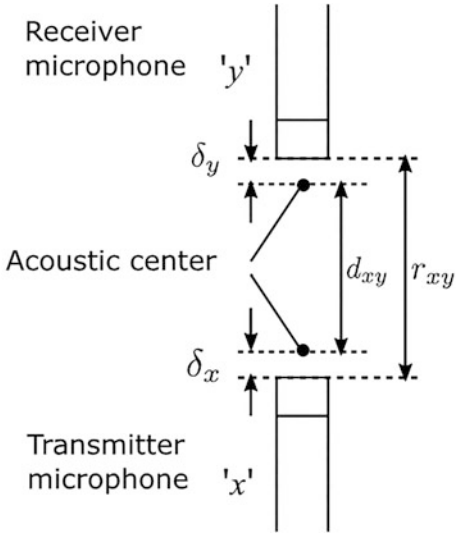

Fig. 24 Positioning of microphones mounted to rods in the free field for reciprocity calibration

In the free field, the acoustic transfer impedance, $Z_{a,xy}$, is expressed as

$$Z_{a,xy} \equiv j\frac{\rho_{xy} f}{2d_{xy}} e^{-\left(\alpha_{xy} r_{xy} + jk_{xy} d_{xy}\right)}, \tag{49}$$

where ρ_{xy} is the density of air, f is the signal frequency, α_{xy} is the air attenuation coefficient, and k_{xy} is the wave number. α_{xy} characterizes sound attenuation per unit length caused by sound travel through the air. k_{xy} is defined as $2\pi/\lambda$ using the wavelength λ of the sound wave. r_{xy} is the physical distance between the membranes of microphones x and y. d_{xy} is the virtual distance between the acoustic centers of the microphones. Theoretically, a sound source is represented by its acoustic center from which a spherical sound wave is emitted. When a reciprocal sound source is used as a sound receiver, the acoustic center of the sound receiver is defined as a point where sound pressure is effectively observed and equivalent to that of the sound source. In the case of the microphones x and y in the free field, the relationship between r_{xy} and d_{xy} is shown in Fig. 24 and formulated as follows:

$$d_{xy} = r_{xy} - \left(\delta_x + \delta_y\right), \tag{50}$$

where δ_x and δ_y are the distance between the membrane and acoustic center for microphone x and y, respectively. d_{xy} is experimentally obtained by changing r_{xy} with the least mean square method.

In practice, the reciprocity method in the free field takes much longer time than the pressure field due to the difference of signal-to-noise ratio. This is because the sound energy from the transmitter microphone is enclosed within the cavity in pressure field calibration while it spreads to all directions in free-field calibration. Therefore, the receiver microphone observes only a small portion of the sound energy. Furthermore, as shown in Eq. (49), the acoustic transfer impedance is proportional to frequency, and the signal-to-noise ratio deteriorates as frequency decreases. Consequently, performing the free-field calibration by the reciprocity is difficult when lower than 1 kHz.

Nevertheless, free-field sensitivities are frequently used by end users. The ratio of free-field sensitivity to pressure sensitivity is experimentally and analytically determined in advance and provided for the two types of laboratory standard microphones in IEC TS 61094-7 (IEC TS 61094-7 2006). Additionally, precisely determining this ratio requires pressure and free-field calibration techniques by the reciprocity method. The ratio depends on the shape and size of the microphone housing and the acoustic impedance of the microphone membrane.

So far, absolute calibration of pressure and free-field sensitivities by the reciprocity method has been performed in audible frequencies for laboratory standard microphones. Recently, noise measurement has expanded to the ultrasound range higher than 20 kHz, because high-power airborne ultrasound is used for applications such as parametric loudspeakers and haptic technology.

As explained above, the acoustic transfer impedance in the free field is proportional to the frequency. Therefore, from the signal-to-noise ratio, free-field

sensitivities of the microphones can be relatively easily obtained at airborne ultrasound range rather than audible range (Takahashi and Horiuchi 2018).

Conversely, precise calibration of pressure sensitivities by the reciprocity method becomes unrealistic at airborne ultrasound range. The dimensions of the cavity must be sufficiently small compared with the wavelength of the sound to realize uniform sound pressure distribution over the cavity. Specifically, the wavelength of the sound waves is at most 17 mm at 20 kHz and becomes smaller at higher frequencies. Therefore, preparing such a small cavity with high accuracy is difficult.

Secondary Calibration of Acoustic Measuring Instruments

Calibration of Microphone Pressure Sensitivity by Comparison Method

Calibrating the microphone sensitivity by comparison method requires two microphones: one whose sensitivity is unknown and the other calibrated in advance. They are known as the "test microphones" and "reference microphones," respectively, and their sensitivities are denoted as M_{test} and M_{ref}. Both microphones are exposed to the same sound field and the output voltage of the test microphone e_{test} and that of the reference microphone e_{ref} are measured. By assuming linearity of the microphone sensitivity and the calibration system, the ratio of the output voltages $e_{\text{test}}/e_{\text{ref}}$ is equal to that of the sensitivities $M_{\text{test}}/M_{\text{ref}}$. Therefore, the unknown sensitivity M_{test} is given as follows:

$$M_{\text{test}} = \frac{e_{\text{test}}}{e_{\text{ref}}} M_{\text{ref}}. \tag{51}$$

IEC 61094-5 (IEC 61094-5 2016) provides a comparison calibration procedure of pressure sensitivity. Both microphones are exposed to the same pressure field in an acoustic coupler simultaneously or sequentially. Additionally, the acoustic coupler has an integral sound source to produce sound pressure in the cavity. Multifrequency measurement can speed up by applying the signal, such as swept-sine or white noise, instead of the sinusoidal signal. Figure 25 shows a schematic of simultaneous and sequential calibration in an acoustic coupler using the comparison method.

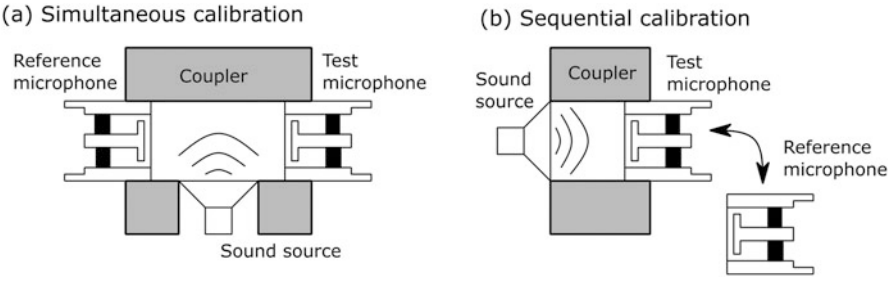

Fig. 25 Schematic diagram of pressure sensitivity calibration by comparison method

In both cases, the cavity of the acoustic coupler is designed to have sufficiently small dimensions to ensure uniform sound pressure distribution in the frequency range of interest.

Uniform sound pressure may be achieved in simultaneous calibration without needing an acoustic coupler. For example, when both microphones are mounted face to face with a separation of less than 1 mm and exposed to the sound field by an external sound source, uniform sound pressure can be applied over the membranes of the microphones at frequencies up to 20 kHz (IEC 61094-5 2016).

Furthermore, the same sound pressure should be applied to both microphones in sequential calibration. However, sound pressure may be changed in practice due to the switch of the two microphones or the fluctuating acoustic properties of a sound source. Therefore, the addition of a third microphone can monitor the change of sound pressure and correct for any changes that occur.

Calibration of Microphone Free-Field Sensitivity by Comparison Method

Calibration procedure of free-field sensitivity by comparison method is provided in IEC 61094-8 (IEC 61094-8 2012). As shown in Fig. 26, simultaneous and sequential comparisons are possible, similar to pressure sensitivity. The lower limit frequency of the free-field calibration is based on sound absorption in the sound-absorbing materials of the chamber. In a free field, microphones are positioned sufficiently far from the sound source, more than 0.5 m apart in usual cases, to realize plane progressive sound waves at the positions of microphones.

Practically, sequential calibration is preferable to simultaneous calibration. In the simultaneous calibration, it is difficult to set the two microphones at acoustically equivalent positions relative to the sound source, because the microphones and their rods for mounting interfere acoustically with each other and disturb the sound field. Sequential calibration does not have such a problem because microphones are substituted. Furthermore, in sequential calibration, the introduction of the

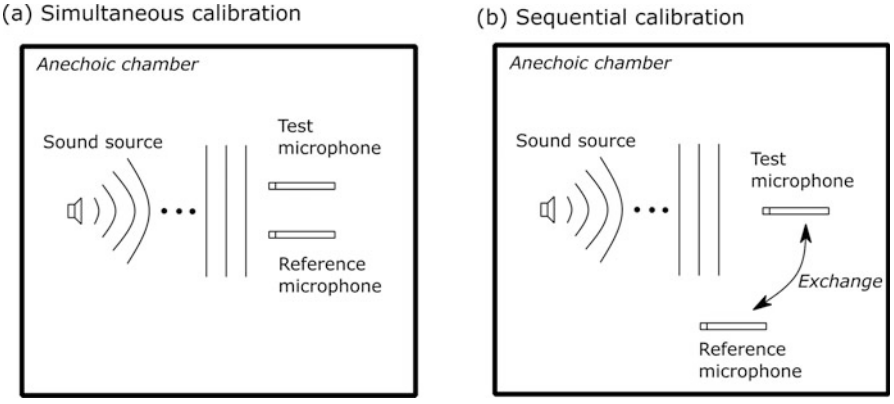

Fig. 26 Schematic diagram of free-field sensitivity calibration by the comparison method

monitoring microphone is recommended for precise measurement, because driving a loudspeaker for a long time may result in a drift of sound pressure.

Calibration of Sound Level Meter

As explained in section "Sound Level Meter," specifications for sound level meters are standardized in IEC 61672-1 (IEC 61672-1 2013). Test methods for verifying the conformity to these specifications are provided in IEC 61672-2 (IEC 61672-2 2013). A limited number of important tests are performed periodically following IEC 61672-3 (IEC 61672-3 2013). Frequency weighting is one of the essential functions of the sound level meter and is often calibrated referencing IEC 61672-2 (IEC 61672-2 2013), although this standard describes the test method to verify the conformity of the sound level meter under test. This calibration is performed for a specified frequency weighting by obtaining the difference between the sound pressure level measured with the laboratory standard microphone and the time-weighted and frequency-weighted sound pressure level indicated by the sound level meter. Therefore, this difference implies the experimental frequency weighting and is compared with the calculated design goal in the verification process.

The calibration procedure is nearly identical to the free-field sensitivity calibration of the microphone by comparison method in section "Calibration of Microphone Free-Field Sensitivity by Comparison Method," except that a device under test is changed from a working standard microphone to a sound level meter. Firstly, the sound source produces the sound wave for a given frequency, and the sound pressure level is determined at the reference point of the microphone of the sound level meter using the open-circuit voltage and free-field sensitivity of the reference microphone. This reference point of the microphone is located at the center of the membrane. Then, the sound level meter is placed instead of the reference microphone, with the microphone of the sound level meter at the same point as the reference microphone. The sound level meter's indication of time-weighted and frequency-weighted sound pressure levels is recorded visually or automatically. Sound level meters usually output the indication value from the DC output terminal or through interfaces such as RS-232C and USB. If DC output voltage is used, the quantitative relationship between the indication and the DC output voltage should be determined beforehand.

Practically, consideration is necessary for calibrating frequency weighting A at frequencies lower than 100 Hz. The design goal of the frequency weighting A is −50.5 dB at 20 Hz. However, even when the sound pressure level is set to 80 dB at the position of the sound level meter, the A-weighted sound pressure level becomes 30 dB. It is challenging to realize the stable measurement of the A-weighted sound pressure level by considering the self-generated noise of the sound level meter and the maximum sound pressure that can be produced from the sound source.

This problem can be resolved by considering the nature of frequency weighting. The following two factors cause deviation of the frequency weighting from its design goal: reflection and diffraction of the sound wave caused by the housing of the sound level meter and the influence of the internal electrical circuit of the sound level meter. Acoustical influence can be considered by applying the above

calibration procedure to frequency weighting C or Z in the free field, because the frequency weightings C and Z do not have the signal-to-noise ratio problem. A sensitivity $M_{\mathrm{SLM_}a}$ of the sound level meter is obtained as a ratio of AC output voltage $e_{\mathrm{AC_}a}$ to the sound pressure p_a, which is determined by the reference microphone. This sensitivity $M_{\mathrm{SLM_}a}$ includes the influence of sound reflection and diffraction.

On the other hand, electrical influence is obtained as follows: The microphone of the sound level meter is replaced with a dummy microphone with a capacitance similar to the real microphone. The sound level meter is set to the same frequency weighting as acoustic calibration. First, input voltage e is applied to the dummy microphone and the AC output voltage $e_{\mathrm{AC_}e}$ is recorded. $e_{\mathrm{AC_}e}$ includes only the influence of the electrical circuit of the sound level meter. The sound pressure corresponding to this AC output voltage $e_{\mathrm{AC_}e}$ is estimated as $p_{\mathrm{e}} = e_{\mathrm{AC_}e}/M_{\mathrm{SLM_}a}$ using the above sensitivity $M_{\mathrm{SLM_}a}$. Then, without changing the input voltage e, frequency weighting is changed to A, and the indication L_{AF} is recorded. Finally, the experimental A-weighing A_{exp} is obtained as follows:

$$A_{\mathrm{exp}} = L_{\mathrm{AF}} - 10\log_{10}\left(\frac{{p_{\mathrm{e}}}^2}{p_{ref}^2}\right). \tag{52}$$

The experimental frequency weighing can also be determined in the pressure field using the sound calibrator with a known sound pressure level. This method is frequently used to check the sound level meter or as a simplified testing method provided in IEC 61672-3 (IEC 61672-3 2013).

Calibration of Sound Calibrator

The sound calibrator's output sound pressure is typically calibrated according to Annexes A and B of IEC 60942 (IEC 60942 2017), which describes the pattern evaluation tests and periodic tests.

The sound pressure level of the sound calibrator is determined using the working standard microphone with a known pressure sensitivity level. When the microphone is coupled to the sound calibrator, the open-circuit voltage of the microphone is measured by the insert voltage technique (see section "Usage of the Condenser Microphone").

Furthermore, the sound pressure level can be simply calibrated with the reference sound calibrator having a known sound pressure level. Additionally, a common microphone is used to compare the output voltages for both sound calibrators. Therefore, the microphone does not have to be calibrated in this case.

Calibration of Reference Sound Source

ISO 6926 (ISO 6926 2016) standardizes two methods for calibrating the sound power level of reference sound sources as follows: One is the precision method in the hemi-anechoic chamber and refers to ISO 3745 (ISO 3745 2012). The other is also the precision method in the reverberation chamber and refers to ISO 3741 (ISO 3741

2010). Details of each precision method on sound power level measurement are explained in sections "Measurement Based on Sound Pressure in the Hemi-Free Field" and "Measurement Based on Sound Pressure in the Diffuse Field," respectively.

Recent Advances in Acoustic Measurement

New Noise Sources: Unmanned Aerial Vehicle Noise Measurement

Unmanned Aerial Vehicles (UAVs) have been widely used in many fields such as transportation, video, and agriculture. It may not be long before UAVs fly over our living space and become new noise sources. Recently, European Union has included the UAV noise in the regulation as one of the airframe specifications (Official Journal of European Union 2020).

However, current methods for evaluating the other noise sources cannot be applied to UAVs. For example, aircraft noise is evaluated by measuring the A-weighted sound pressure levels near the airport or under the predetermined flight path (ISO 20906 2009). On-site measurement of the sound pressure level is unsuitable for UAV noise, because the UAV does not necessarily move along the fixed route.

So far, various methods have been proposed for evaluating UAV noise based on sound pressure or sound power measurement. For example, outdoor measurement of the A-weighted sound pressure level is performed on the ground, which is assumed to be a hemi-free sound field (Kloet et al. 2017). However, proper measurement conditions, such as the flight altitude of the UAV and the microphone position relative to the UAV, should be discussed and provided to obtain comparable measurement results.

Alternatively, a sound power level of the UAV) gives a unique value independent of measurement conditions. However, conventional measurement methods are not intended for noise sources flying in the air. Therefore, the method specialized in measuring the sound power level of UAVs is being developed. Such a method is based on acoustic test rooms' sound power level measurement (Papa et al. 2016). However, flight operation of the UAV in a room is usually difficult because the satellite positioning system is unavailable and flight space is limited. Therefore, the hovering state is realized by fixing the UAV on a stand.

Alternative Use of Sound: Infrasound

The lower frequency limit for the infrasound complaints was around 1 Hz; however, the measurements at much lower frequency have recently been highlighted. Sounds below 1 Hz occur in natural events such as volcanic eruptions and landslides.

A well-known recent event is the 2022 Hunga Tonga–Hunga Ha'apai eruption and tsunami in the Tongan archipelago in the southern Pacific Ocean. Pressure

fluctuations, such as infrasound, caused by this eruption were observed on a global scale. As shown in this case, infrasound occasionally travels globally and long distances (Matoza et al. 2022).

To exploit this characteristic, some applications are already in operation. For example, one application is detecting or preventing natural disaster events. The basic idea of this application is to observe infrasound that occurs during the event at several points and then estimate the point where the event occurs from the time differences among the monitoring points by applying signal processing techniques.

Another application is for weather forecasts or climate change monitoring. For example, when infrasound travels long distances on a continental scale, atmospheric conditions, such as temperature and pressure, affect infrasound propagations. Therefore, observing the difference in infrasound propagation provides information on the atmospheric conditions, such as sudden stratospheric warmings. Furthermore, long-term observations on the scale of years also contribute to monitoring climate change (Pichon et al. 2019).

These applications require multiple observatories, and currently, various infrasound observation networks, from large-scale to small-scale, are in operation or under development by various organizations. The International Monitoring System (IMS), operated by the Comprehensive Nuclear-Test-Ban Treaty Organization (CTBTO), is a well-known network. This network monitors seismic, hydroacoustic, infrasonic, and radionuclidic phenomena at 321 monitoring stations and 16 laboratories built worldwide. Of these, 60 stations monitor infrasound (CTBTO 1997). The IMS network was designed and has been operated to detect nuclear explosions. The data collected by the IMS network is now used for disaster warnings and scientific studies, including climate change (CTBTO 2015).

In any infrasound observation network, the infrasound is measured by microphones, vibrometers, and microbolometers. However, the acoustic standard below 1 Hz has not been established nor have calibration methods for infrasound measuring instruments. Therefore, all infrasound observation networks are operating without calibration. Once calibration is accomplished, and the reliability of acquired data is improved, the various application performance is expected to improve. For instance, it can improve the location estimation where the natural disaster occurs. Accordingly, several national metrology institutes strive to realize the acoustic standard below 1 Hz and find calibration methods for various infrasound measuring instruments (EMPIR 2020).

Abstract

The present chapter provides an exhaustive review on the noise monitoring studies, comparison of the prediction models including physical propagation model, and applications of the artificial intelligence techniques, noise mapping, and noise pollution monitoring in mining sector carried out by various researchers. Most of the noise pollution studies deal with the assessment of traffic noise and some were focused exclusively on noise monitoring for the residential,

educational, industrial, and commercial sites noise. The study reveals that early models were based on mathematical prediction models, later machine learning and deep learning methods were generally used for prediction and forecasting of noise levels. A retrospective view on noise mapping and control is presented in the chapter. Also, the noise pollution control and abatement measures are highlighted that shall be indispensable for reducing the ambient noise levels in metropolitan cities of the country.

Noise assessment · Noise monitoring · Noise mapping · Noise prediction · Ambient noise standards

Introduction

Environmental noise pollution has become a serious concern since past decade across the globe. Noise assessment and modelling has been a subject of extensive research in larger parts of world as it poses serious risks to health and quality of life (Ising and Kruppa 2004; Stansfeld and Matheson 2003). Many studies have been conducted over last few decades on noise pollution, including noise sources (Zeng and Zhan 2005; Yang et al. 2011), noise pollution levels (Arana 2010), exposure levels (Brown and van Kamp 2009), strategic noise map (Ausejo et al. 2010; Makarewicz and Galuszka 2011), sampling strategies (Doygun and KuşatGurun 2008; Gozalo et al. 2013), and psychological and physiological effects (Morillas et al. 2005; Öhrström 2004). The European Union issued Directive 2002/49/EC (European Noise Directive 2002) relating to assessment and evaluation of noise pollution effects on community. This directive suggests the use of noise maps of the urban agglomerations in single noise parameters: L_{den} and L_{night} represented as day-evening-night and night equivalent levels over a year. The long-term noise monitoring strategy is expensive and cumbersome process. However, there are some notable example of cities which have installed extensive Noise Monitoring stations such as Lille in France (Chopard et al. 2007), Gdansk in Poland (Czyzewski et al. 2012) and Dublin in Ireland (Dublin City Council 2013).

There are three types of noise sources, i.e., Point source, linear source, and Surface source (Numan 2008). For point source, the waves propagates spherically in air. As a result, the intensity of the sound pressure level vary depending on the source to receiver distance. While, the linear source is a collection of points that travel in a straight line, separating one another at regular interval of equal distance, and surface source is a representation of two-dimensional wave emitted from the surface, such as wall window, machine room, or lab interface (Al-Taai 2021). The level of noise generated by a source are calculated using propagation models (De Coensel et al. 2005). Steele et al. (2001) thoroughly analyzed some of the significant noise prediction models. Some of the noise prediction models still in use are: Calculation of Road Traffic Noise model (CoRTN), Federal Highway Administration model (FHWA), Swiss Road Traffic Noise model (STL-86),

(MITHRA), Richtlinienfür den Lärmschutz an Strabenmodel (RLS-90), Nordic Prediction Method for Traffic Noise model (NORD-2000), French method for road traffic noise prediction model (NMPB-Routes-2008), Acoustical Society of Japan noise model (ASJ-2008), Common Noise Assessment Methods in Europe model (CNOSSOS-EU-2009), etc. The latest versions of some of these models are also available and used widely in some countries. In physical propagation model, the noise level at a receptor position is usually modelled as a function of traffic conditions (i.e., traffic speed, traffic volume, and traffic composition), absorbent ground cover percentage, distance between the source and receptor (Tiwari et al. 2022). Recently, artificial intelligence has become an emerging trend for prediction of noise data which requires past observational data. Artificial neural network (ANN) is one of the most used machine learning technique for prediction of noise levels. Cammarata et al. (1995) used neural network to predict noise levels in Italy. It is also compared with some traditional algorithms, where ANN shows better performance. Hamada et al. (2008) used regression based neural network in construction area based on BPNN to analyze the impact of noise. There are some limitations of neural network which is further addressed by using deep learning algorithm. Zhang et al. (2020) predicted environmental noise level using LSTM (long short term memory) at different interval of time. The proposed model was compared with stacked auto-encoder, random walk, and support vector machine. Navarro et al. (2020) predicted loudness level, and sound pressure level using LSTM (Long short term memory) from 1 to 60 min. The European Union has laid the foundation for creating noise maps of cities as a tool for environmental noise management and control (Štimac 2005; Kliučininkas and Šaliūnas 2006). Collecting data of the traffic flow for a specific time period, and area in the concerned city is a common strategy for conducting the street traffic flow analysis and obtaining a traffic noise forecast map (Popescu et al. 2011). The aim of the present study is to have a retrospective view on noise monitoring studies, and propagation models and prediction models. The objective of the work is summarized as:

- Ascertaining the noise scenario and methodology adopted for developing the various noise prediction models,
- Noise pollution monitoring, mapping and control studies carried out by various researchers and recommendation of harmonized noise mapping strategy in India,
- Ascertaining the significance and efficacy of the various control measures and their implications in Indian perspectives,
- Recommendations on policy measures for noise pollution control in the metropolitan cities.

Noise Monitoring Studies

Noise is typically used to refer to any annoying or intrusive sound, and noise pollution is among the general public environmental concerns. Noise monitoring strategies have a vital role in analyzing about the noise pollution scenario. Table 1

Table 1 Noise assessment studies of different cities

Author	Country	City	Error	Conclusions
Hunashal et al. (2012)	India	Kolhapur	L_{10}, L_{50}, L_{90}, NC, L_{eq}, NEI	The study indicated higher value of noise level in residential, commercial, educational, silence, industrial and recreational zones of the city.
Ravindra et al. (2016)	India	Chandigarh	L_{max}, L_{eq}	The sound pressure level exceed the permissible limit.
Yadav et al. (2021)	India	Gorakhpur	L_{eq}	The noise level was higher for all the three area considered for the study.
Masum et al. (2021)	Bangladesh	Dhaka	L_{eq}, NC, NPL	The study found that day equivalent noise level is 20–30 dB(A) higher than the night equivalent level.
Kuldeep et al. (2021)	India	Kota	L_{eq}	Noise level were measured at 10 locations of the city, and the study concludes that the noise levels were more than the limits suggested by the CPCB.
Esmeray et al. (2021)	Turkey	Safranbolu	L_{eq}	The noise level at 47 points of Safranbolu district is at medium level.
Sahu et al. (2020)	India	Burla	NC, NLP, TNI, NEI	The study indicated that the noise pollution reached to an alarming level in the city.
Balashanmugam et al. (2013)	India	Chidambaram	NLP, L_{10}, L_{50}, L_{90}, NC, L_{eq}	The noise level at 10 selected locations of Chidambaram town exceeds than the permissible limits suggested by the CPCB.
Nungate et al. (2022)	India	Imphal	L_{10}, L_{50}, L_{90}, L_{eq}	The noise level lies between 52.2–71.1 dB(A) for morning, noon, and evening hours at traffic junction of Imphal city.
Manojkumar et al. (2019)	India	Vellore	NC, NLP, TNI, L_{eq}	An assessment of noise level at 6 sites of Vellore city is done in afternoon, and evening hours and results showed that at 5 locations, noise level exceeds the permissible limit.

Note: L_{eq} – Equivalent noise level, L_{max} – Maximum equivalent noise level, L_{10}, L_{50}, L_{90} – Noise levels exceeds by 10%, 50%, 90%, *NC* Noise climate, *TNI* Traffic noise index, *NPL* Noise pollution level, *NEI* Noise exposure index

Table 2 Short-term and temporal strategies studies by various researchers

Author	Country	Year	Error	Conclusion
Utley et al. (1982)	UK	1982	Accuracy (in dB)	Sampling strategies can be a better substitute for long-term measurement for some applications.
Gaja et al. (2003)	Spain	2003	Mean, Standard Deviation, Probability [±1, ±2, ±3]	Random 9 days strategy is suggested for an error of ±1 dB.
Romeu et al. (2011)	Spain	2011	Correlation Coefficient, Skewness, R^2	15 min measurement is suggested for an error of ±2 dB(A).
Morillas and Gajardo (2014)	Spain	2014	Standard Deviation	Random 9 days strategy is recommended.
Garg et al. (2015)	India	2015	Standard Deviation, Prob. Dist.	Random 2 months strategy is suggested.
Geraghty et al. (2016)	Ireland	2016	ANOVA	Short-term noise monitoring cannot characterize long-term indicators accurately.
Tiwari et al. (2021a)	India	2021	Mean, Standard Deviation, Probability [±1, ±2, ±3]	Random 2 months strategy is suggested for all the four zones in India.

gives the detail of some studies on assessment of noise monitoring using various noise indices.

Continuous monitoring of noise level at each location of a city or country is a cumbersome and expensive process. Therefore, researchers have used short-term and temporal sampling strategies as a substitute which is described in Table 2.

Noise Prediction Models

Noise prediction models play a vital role for city planning for control and abatement of noise pollution. Therefore, a lot of mathematical/hybrid/artificial intelligence models had been developed in past years introducing sound propagation and sound specific emission empirical formulation. Thus, in order to achieve high performance, these models make use of high-speed processing computers. Therefore, it is crucial to conduct a scientific analysis and comparison of various models in order to determine their applicability generally and to identify which method is optimal for traffic noise modelling. The method of conceptually estimating the noise levels in a location of interest under a certain set of circumstances is the basic framework of noise modelling. A fixed representation of the relevant physical environment will make up the particular set of conditions for which the noise is being assessed. In reality, the physical world is typically not static but rather is characterized by continually changing circumstances. The actual sound environment

will then change in time and place as a result of these modifications in the real-world settings.

Noise Prediction Using Mathematical Models

The primary variables focused on developing a noise model are: (a) various noise sources, (b) an approximate representation of the physical variables through which noise will be transmitted from the source of the noise in the area such as built environment, terrain, and atmospheric conditions (temperature, wind, humidity), (c) path taken by sound from the noise source to the receiver position or spatial location. The mathematical noise prediction models developed due to various noise sources such as rail, industrial, road, or road traffic is given in the form of equation (Steele 2001):

$$L_{\mathrm{SPL}} = L_{\mathrm{w}} - A_{\mathrm{tot}} \tag{1}$$

where, L_{SPL} represent the sound pressure level at the receiver side, L_{w} denotes the sound power level, and $\mathrm{A_{tot}}$ represent the total attenuation factor between the source and receiver. The attenuation factor includes geometric divergence, ground absorption, diffraction dissipation, and air dissipation. Table 3 summarizes some of the Traffic noise models and their features.

Time-Series Prediction and Forecasting Approach

When a single variable is measured against time, or when time-series data are involved, time series analysis is a statistical technique that can be used to simulate real-world events. The development of intelligent models to anticipate noise levels prediction is a major area of research due to its rapid advances in computer technologies and the growing amount of traffic data. Computer systems learn to carry out tasks like pattern recognition, grouping, categorization, predictions, and other activities through the use of these models, which are closely related to artificial intelligence. Due to its great efficiency in identifying complex nonlinear features, outperforming statistical methods, and managing difficult noise level prediction forecasting problems, machine learning is becoming more popular for the task of predicting traffic flow. In this subsection, some machine learning algorithms such as Artificial neural network (ANN), Emotional Artificial neural network (EANN), Wilcoxon neural network (WNN), Extreme gradient boosting (EGB), Random forest with Artificial neural network (RF-ANN), Support vector machine (SVM) are highlighted. Deep learning approaches are now being used to improve noise levels predictions by utilizing the capabilities of artificial intelligence models. In order to learn high-level features, deep learning techniques are used, which is an advancement of machine-learning techniques, having significant amount of processing layers. In past years, it has been used as a prediction tool to predict and forecast ambient noise level, volume, and annoyance. In addition, the most recent deep

learning approach offers understanding of high-dimensional data mining. Some of the deep learning algorithms which has been used in the study were Long short term memory (LSTM), Gradient boosting model (GBM), Bi-directional gated recurrent unit (Bi- GRU), Auto-encoder-based Long short term memory (AE-LSTM) as shown in Table 4.

Noise Mapping: Strategy and Implications

Noise mapping is a method for representing estimated noise levels over a specific geographic area. The European noise directive defines noise mapping as "the representation of information on a current or estimated noise levels in terms of a noise indicator, specifying contraventions of any relevant maximum permissible in

force, the proportion of persons affected in a specific region, or the number of residences exposed to such values of a noise indicator (EC (European Commission) 2002).Numerous such studies on creating noise maps of different cities had been published in Europe and some other nations as well (Vogiatzis and Remy 2019; King et al. 2011; Escobar et al. 2012).The idea of noise mapping is a rigorous method that includes the following steps (de Kluijver and Stoter 2003):

- Identification of noise sources and collecting the noise indicators in that particular area;
- Noise level computation in a model;
- Presentation of noise level contour;
- Determination of noise impact and its effects.

Although the key phases of noise mapping are identifying hot spots, understanding the noise scenario, and determining the noise impact of various noise sources, the studies would be insufficient and ineffective without taking into account and implementing noise control measures.

Strategy and Implications

The noise maps may be created using established noise models incorporated with Geographical Interface Systems, or they may be produced using actual data taken at various locations using a specified sampling technique. Figure 1 displays the advantages of noise mapping, and Fig. 2a, b shows the framework of noise mapping. To offer an overall noise picture of the site, mapping can be done either strictly for particular noise sources, such as, railroads, road traffic, industries, aircraft, etc., or in combination with all the sources for the region under consideration (Akhtar et al. 2016). There are various considerations used in for mapping an area as follows:

- Sampling strategy
- Positioning of the microphone in accordance with the ISO 1996-2 (ISO 9613-2 1996) standard
- No of measurement points to be chosen in an area
- Control measures to be adopted

Noise Mapping Software

The noise map gives legislative authorities, local planners, researchers, and architects the baseline information they need to design and carry out new initiatives. Maps can be created either using data from noise monitoring or by using a recognized noise model. Many nations have created their own independently verified noise prediction models (Garg et al. 2021). Commonly used noise mapping software's are:

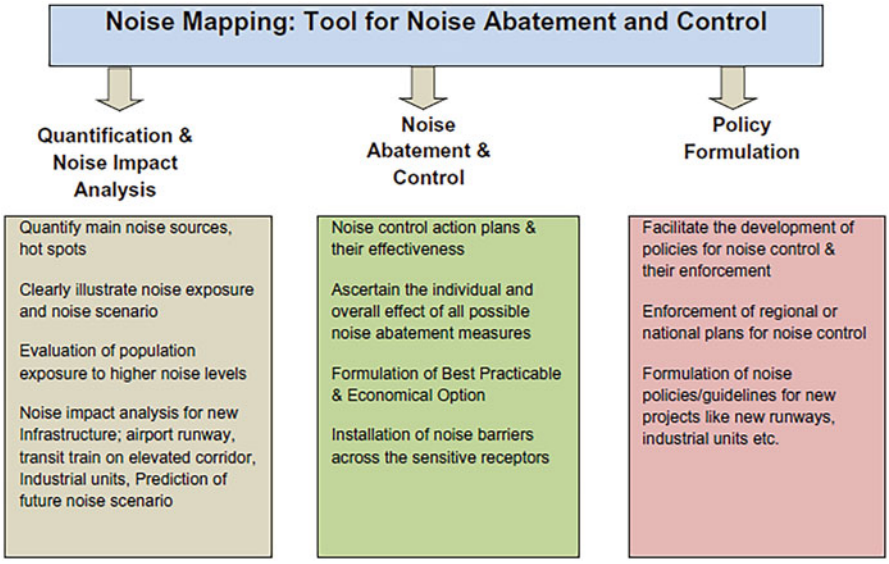

Fig. 1 Noise mapping tool. (Garg et al. 2021)

Arc GIS, Sound PLAN, Cadna A, and Predictor- LIMA. To create cross-sectional grid noise maps for various areas of the city, suitable locations should be chosen based on a clear sampling plan, in conjunction with long-term and short-term noise monitoring, and then an interpolation approach should be used. Additionally, comparing maps from various cities is made straightforward and easier by the use of a country's standardized color coding system.

Ambient Noise Standards

It is necessary to regulate and control noise producing and generating from different sources with the aim of maintaining the ambient noise levels in public areas from various sources, including generator sets, vehicular horns, industrial activity, construction activity, music systems, loud speakers, public address systems, and other mechanical devices, which have detrimental effects on human health and the psychological well-being of the people. The ambient noise standards recommended in India are tabulated in Table 5 (The Noise Pollution 2000):

- For the purpose of enforcing noise rules at various places, the State Government shall classify the areas as residential, silence, industrial, or commercial zones.
- The State Government must take action to reduce noise, including noise from moving vehicles, and must make sure that the current noise levels do not surpass given in these regulations.

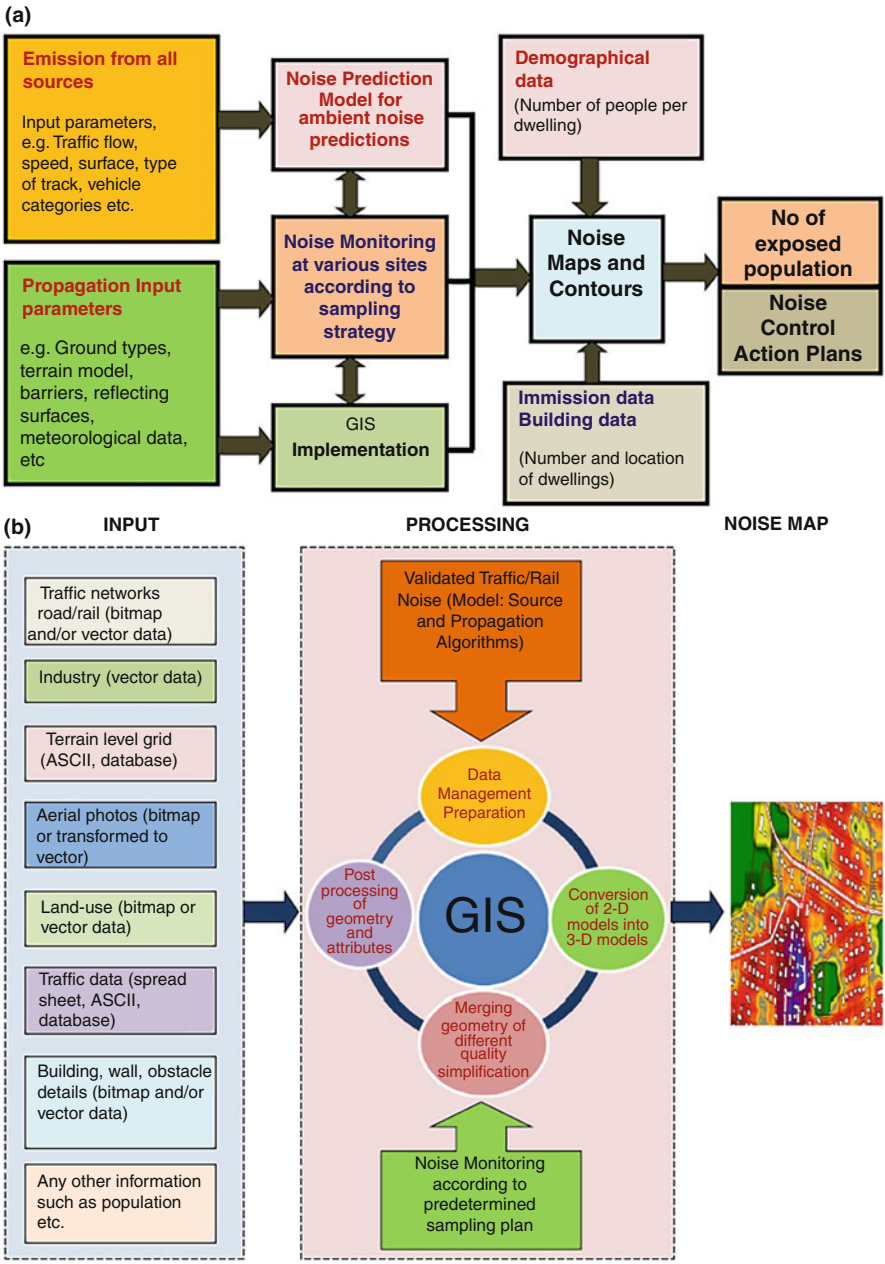

Fig. 2 Noise mapping framework. (Garg et al. 2021)

Table 5 Ambient noise standards recommended by Ministry of Environment and Forests and Climate Change

Zone code	Category of zones	L_{eq} in dB(A)	
		Day levels	Night levels
A	Residential	55	45
B	Silence	50	40
C	Industrial	75	70
D	Commercial	65	55

Garg et al. (2021); The Noise Pollution (Regulation and Control) Rules (2000)

Note:

1. Day equivalent noise levels will be measured from 06.00 a.m. to 10.00 p.m
2. Night equivalent noise levels will be measured from 10.00 p.m. to 06.00 a.m
3. L_{eq} is the equivalent sound pressure level for a certain period of time

- To avoid noise threat and to achieve the goal of maintaining the ambient noise standards, all local bodies, development authorities, and other concerned departments must include all aspects of noise pollution as an attribute of quality of life when planning developmental exercise or conducting out activities related to town and country planning.
- For the purposes of these rules, a silence area may be established in the vicinity of educational institutions, hospitals, and courts that is in range of at least 100 m.

Noise Impact Assessment

Noise impact assessment is concerned with the impact of a particular project or a new establishment on the ambient noise levels of an area or locality with respect to the noise standards recommended by the authorities. It is very helpful in the planning phase of many residential, silence zone or industrial areas in order to adopt appropriate protection for reducing the noise pollution and its impact on health and quality of life. The types of control methods involved can be: Avoidance; Reduction and Compensation. Avoidance can also be achieved by controlling or limiting the hours of operation; limiting the number of events; or limiting the number of different sources operating. Reduction involves the various measures like use of barriers, enclosures etc. Compensation may include measures like using the double glazing's in windows of the dwellings to protect from the outside traffic noise (Guidelines for Environmental Noise Impact Assessment 2014). The noise impact assessment should be exercised at the planning stage by the relevant authorities and all the control measures should be taken prior the new establishments or project so as to minimize the impact on community. Figure 3 summarizes the methodology of Noise Impact Assessment and Mitigation with some modifications to that proposed in report (Guidelines for Environmental Noise Impact Assessment 2014; Garg 2021).

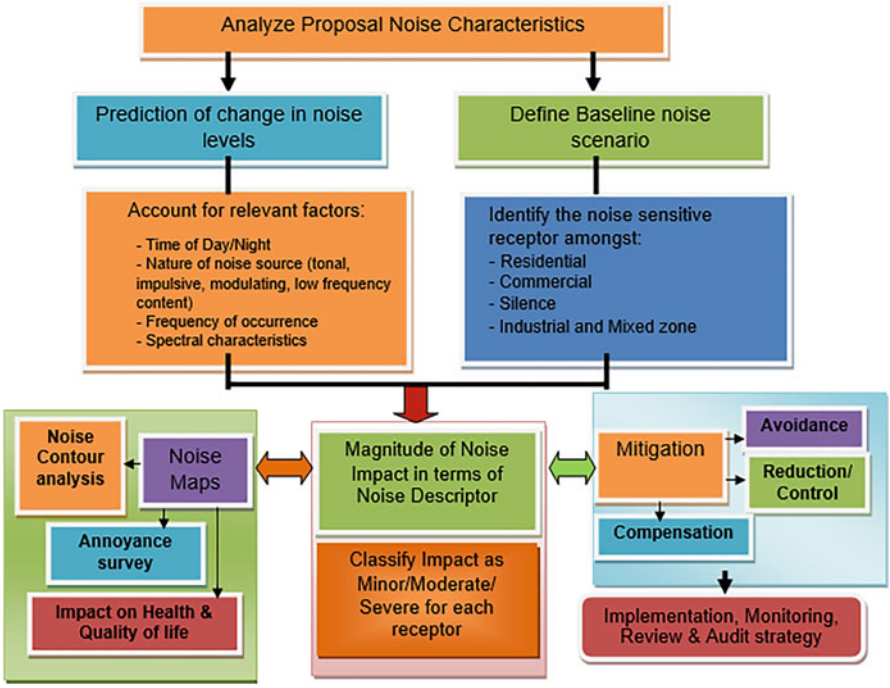

Fig. 3 Summary of Noise Impact Assessment and Mitigation. (Guidelines for Environmental Noise Impact Assessment 2014; Garg 2021)

Noise Pollution in Mining Sector and Construction Activities

Due to the introduction of modern and heavy machineries (such as bulldozers, continuous miners, mine trucks, and drilling machines) using advanced technology, natural mineral productivity has been massively increased over time to fulfil the exponentially growing needs from all over the world. Increased use of these types of machinery has resulted in increased road transportation and a significant increase in noise levels (Tripathy 2008). Mostly all mining activities generate noise from a variety of stationary, mobile, and impulsive sources, making it an inherent part of the mining area. It is described as sound having no pleasing musical quality or sound that is undesirable. Noise is a typical environmental concern in opencast mines, as it is generated by heavy earthmoving equipment. As the mining activity proceeds, the equipment and environmental circumstances alter. The overall mining noise generated from the mining equipment varies in quality and level depending on their placement. Most mining equipment's in opencast mines emit noise levels in the range of 90–115 dB(A), which can cause noise-induced hearing loss and other non-auditory health problems in miners over time (Tripathy and Patnaik 1994; Vardhan et al. 2003). Fig. 4 shows the mining operation in open cast mines.

Fig. 4 Mining operations

The mining operation includes:

- Blasting
- Drilling
- Excavation
- Loading and Transportation

Noise Assessment in Mines

Noise assessment in opencast or closed mines is done to determine:

1. Noise pollution condition inside and in nearby areas of mines.
2. The sound pressure level generated by heavy machineries used for various mining operations.
3. Octave band analysis of various equipment and noise induced hearing loss of workers working in mines.

Utley et al. (1980) described about the assessment, measurement, and prediction of noise levels generated in coal mines. The study also discussed about the control measures required for reduction noise pressure levels. Singh et al. (2004) considered various environmental pollution issues at mining locations due to use of heavy

machineries. Further, the study also analyzed about impact of noise on the residents and workers. Ghose et al. (1990) briefly discussed about the measurement, mapping and analysis of noise pollution in mines. Bhattacharya et al. (1994) measured noise levels generated from drill machine and crusher in Meghatuburu mines. The equivalent noise level was 101–106 dB(A), while maximum noise level was in between 106–110 dB(A). Pal et al. (1994) measured noise level in underground mines at a distance of 5, 15, 25 m from the noise source.

Noise Prediction in Mining Area

The effect of ambient noise levels in opencast mines is influenced by the sound power level of the noise generators, the current geo-mining environment, and the meteorological characteristics. The noise levels must be examined as a combined effect of the aforementioned variables. As the mining operation advances, the environment and equipment conditions are constantly changing. The common mining noise coming from the mines differs in quality and volume depending on where they are located. As a result, for environmental noise prediction models, the sound pressure level (SPL) at every receiver site must equal the sum of all the noise sources. It is generally known that it is important to precisely forecast the noise level produced by opencast mines. Some of the widely used noise prediction algorithms in Europe were Conservation of Clean Air and Water in Europe (CONCAWE), German Draft Standard VDI-2714 Outdoor Sound Propagation, and Environmental Noise Model (ENM) (Manning 1981; Tonin 1985; Nanda et al. 2009). The International Standard Organization (ISO) standard addresses various aspects in this regard (Cho et al. 2004; Nanda et al. 2012).

Noise Control

According to a US research study quantifying the traffic noise costs, $21 annually per housing unit per decibel increase is estimated (Perkins 1998). Therefore, it is unavoidable that every nation would have a robust noise control strategy with the basic goal of preventing and minimizing the detrimental impacts of noise on human wellbeing. As a result, it implies that regions with amplified ambient noise levels beyond the legal limits require noise action measures. In order to restrict exposure to environmental noise and consequently ameliorate its impacts, such as sleep disruption and discomfort, the European directives on environmental noise require that authorities to implement, establish, and carry out action plans against urban noise. Acoustic planning, which refers to reducing future noise by deliberate actions including traffic and land-use planning, noise reduction at the source, and sound insulation techniques, (Murphy and King 2010). Understanding the noise scenario, prioritizing control measures, and involving stakeholders and the public all contribute to the structure and prioritization of noise control measures in noise action plans. A traffic relocation strategy that involves building a bypass highway, for example, could be a helpful mitigation strategy (Lokhande et al. 2017). In regions with high

ambient noise levels, the potential decrease can be achieved by constructing noise barriers. The other appropriate strategic plans mentioned by Torija et al. (2012) include source control, which entails setting restrictive speed limits, reducing travel demand, prohibiting heavy vehicles in residential and sensitive areas, and testing vehicles' periodic noise emissions; mobility management, which encourages the use of public transportation systems urban planning, and reduces traffic jams; which entails land-use management and planning, such as pedestrianism, zoning, and other techniques. A harmonized noise policy at regional and national level for a sustainable environment and the integration of noise control planning into urban planning activities are essential. However, at the local and regional levels, the cost-effectiveness and applicability of the policy actions may vary.

A synergistic, uniform, and coordinated strategy to noise pollution control across the nation would be provided by the adoption of a harmonized national policy at both the regional and national levels. Figure 5 represents the cost-effectiveness score and analysis of different control techniques. Additionally, there should be coordination between various initiatives and plans, such as the air pollution control program and Swatch Bharat mission, with the cooperation of all related personnel. The Working Group on Health and Socio-Economic Aspects found that the current benefit of noise control in Europe be valued at 25 Euros per household/dB/year (Working Group on Health and Socioeconomic Aspects 2003). Clearly, this measurement can be interpreted from an Indian perspective as well as a coordinated strategy with a harmonized national policy for sustainable urban mobility strategy and noise pollution regulations at both national and regional levels; noise mapping of metropolitan areas and implementation of potential new initiatives would be indispensable in reducing the adverse health effects of noise exposure and prevalence of diseases linked to environmental noise in India.

Practical Implications and Recommendations

Whereas the idea behind noise mapping seems to be very intuitive and practical, there are still a number of open questions regarding noise mapping, public information disclosure, population exposure assessment, and noise strategic planning, which can sometimes make it challenging for urban planners and pollution control entities to adopt a standardised approach. Prior conducting the noise mapping of a city, it is essential to make decisions on the assessment of day and night noise levels in different seasons, sampling technique, impact of metrological parameter. Noise mapping procedure should be standardized, resulting in the lowest possible level of uncertainty in the noise forecasts. This would be achieved through the use of a validated noise model, an acceptable interpolation technique, and a harmonized representation with reference to color coding. The implementation of the same modelling technique and software that has been established from an Indian perspective would essentially constitute a unified strategy for full standardization of the noise mapping process. Additionally, the following recommendations are made (Garg et al. 2021):

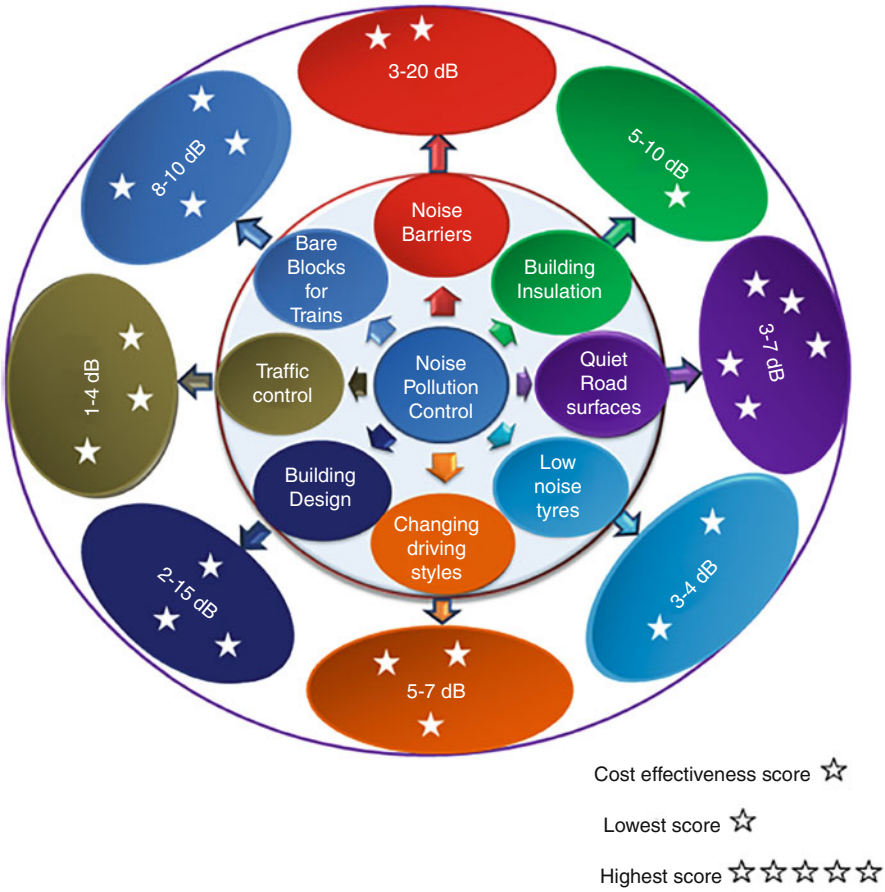

Fig. 5 Cost-effectiveness score and analysis of different control techniques. (Garg et al. 2021)

- A hybrid strategy that use interpolation algorithms and prediction models to anticipate the ambient noise levels at specific spots and the usage of noise monitoring stations for noise assessment at numerous locations may be used.
- Prior to conducting noise mapping studies, an optimal strategy has to be decided about the locations for noise measurements and accuracy. Increasing the grid size increases the map accuracy depicting the ambient noise levels, but at a higher expenses.
- The number of points to be sampled for the city's mapping may be determined based on a variety of factors, including the location of sensitive receptors and noise-generating sources, the division of the area into hot spots that are suitable for sampling, areas of high relevance, grid-based sampling, and the division of the area based on factors like traffic flow, road size, residential zones, and highway roads.

- For locations wherein noise assessment is not done, the predictive algorithms can cover the gap. However, reducing the uncertainty in noise forecasts would benefit from the model and software prior calibration.
- Short-term noise monitoring strategies (Tiwari et al. 2021a) can be utilized for efficient utilization of Noise Monitoring Terminals for nose monitoring of larger sites of the metropolitan cities.
- Noise Control measures utilizing the Multi Criteria Decision-Making (MCDM) techniques (Garg 2021) shall be indispensable for noise pollution control at the noisy hot spots. Also, policy measures and cooperation of all stakeholders, and awareness among the community shall be very helpful for reducing the ambient noise levels in cities.
- The noise barrier must physically fit in the available space, must completely break the line-of-sight between the noise source and the receptors. Noise barriers should be tall enough to provide noise reduction for the upper-most stories of nearby sensitive receptors. A barrier must achieve a Sound Transmission Class, STC (or weighted sound reduction index, R_w) of 30 or greater in accordance with ASTM Test Method E90 or ISO 717 in order to ensure adequate sound transmission loss characteristics and effective mitigation. Also, the source side of the barrier can be lined with acoustical absorptive materials in order to avoid reflections with building facades (Thalheimer 2000).

Conclusions

This chapter presents a detailed discussion of noise monitoring studies, noise prediction models, and noise mapping in different countries. It is evident that the artificial intelligence technique offers more reliable and accurate prediction capabilities as compared to the conventional mathematical models. The technique, strategy and methodology of noise mapping is at primitive stage sin India although some studies had been now reported in some cities of India. However, as an when more and more studies shall be conducted, it will give consultants, town planners, research institutions, laboratories, and pollution control bodies in India more knowledge and experience for conducting noise mapping studies and implementing the noise control measures. Promoting good health and a high standard of living requires a comprehensive strategy that focuses primarily on periodic noise monitoring and assessment of the noisy locations in cities, ascertaining their compliance with the ambient noise standards, and developing appropriate noise action plans in combination with policy issues on environmental noise planning and control.

Acknowledgments Authors also express their gratitude toward Director, CSIR-National Physical Laboratory, India, for his constant encouragement and support. Authors also express their sincere thanks to Dr. Sanjay Yadav, Head, Physico-Mechanical Standards and Professor Ravinder Aggarwal, Professor, Thapar University, Patiala for their constant encouragement and support for this chapter. The views and opinions expressed in this chapter are those of author's own and do not

necessarily reflect the official policy or position of any agency of the Government of India. The content of the papers is solely to present a retrospective and prospective view of noise levels and may not be used or considered for disputes redressal in legal framework.

Abstract

Air pollution control necessitates knowledge of Atmospheric Boundary Layer (ABL) parameters that influence pollutant concentration, diffusion, and transit. The ABL is one of the most important constituent zones of the atmosphere, as it plays a critical role in major areas of human endeavor such as air pollution, aviation, and communication. It can also be thought of as the biosphere's circulatory system. SOnic Detection And Ranging (SODAR) is an important ground-based remote sensor competent to detect ABL height in real time. It is utilized in air quality management as a diagnostic tool for monitoring air quality in a variety of hazardous circumstances that are directly related to human health issues. The present work focuses on the methods derived for probing the ABL using SODAR for effective air shed management. The data generated through SODAR echograms is processed, interpreted and compared with MERRA-2 Model sensor so as to determine its effectiveness and precision of data. After critical analysis it was observed that SODAR is an effectual environmentally friendly instrument that can be used for air pollution abatement and air quality measures.

Keywords

SODAR · Atmospheric boundary layer · Air pollution · Ventilation coefficient

Introduction

Ground-based SOnic Detection And Ranging (SODAR) is an active acoustic remote sensing device that is used to probe the Atmospheric Boundary Layer (ABL) structures and to determine the ABL height influenced by the convection and turbulence in the atmosphere. The SODAR system generates real-time and spatial echograms, as well as a visual representation of ABL dynamics. SODAR as a ground-based sensor provides appropriate vertical and temporal coverage with high resolution data that can be used for vivid applications like to study the thermal structure of the atmosphere, wind shear structure, as well as three-dimensional wind information in the lower part of the atmosphere (Crescenti 1997). SODAR echograms are used to infer ABL height influenced by meteorological conditions prevailing at the loci. This ABL height is detrimental for examining the pollution load of a place through ventilation coefficient, a factor determined by ABL height and wind speed. SODAR is acoustical instrument and works by sending and receiving directed acoustical signals. The two most critical needs in any SODAR system are a transmission system to illuminate the highly directed signal in the turbulent area and a sensitive reception signal to identify an air-scattered signal from the air. The present work describes the development and improvement of Monostatic SODAR and the adavancement underwent during the ongoing years. The calibration of the instrument has been putted it on the front with high accuracy and precision. The work also emphasizes the role of SODAR in air quality management.

Atmospheric Boundary Layer

The Atmospheric Boundary Layer (ABL) is the lowest part of the troposphere where the direct effect of surface heating and cooling has been seen (Stull 1988; Emeis 2010). All biological and human activities take place in this layer (Bradley 2007). The ABL extends to a height of convective mixing of buoyant parcels of air or the base of an elevated inversion layer during daytime unstable conditions, and the level of surface-based inversions determines the height of the ABL during nighttime stable conditions. Furthermore, turbulence is a necessary component of ABL (Stull 1988). It facilitates the movement of water vapor, heat, momentum, pollutants, and other tracer elements from one location to another. Wind speed normally increases with height in the ABL, while pressure decreases regularly with height, temperature decreases less regularly, and humidity decreases very irregularly (Stull 1988; Singal 2006). The derived parameter refractivity usually decreases exponentially, but sharp gradients can occur depending on weather conditions. ABL height is a critical parameter for understanding the ABL structure's characteristics such as turbulence, atmospheric stability, and diurnal pattern related to convection. The ABL structure varies from day to night and with synoptic and mesoscale weather conditions. The development and growth of ABL height is primarily influenced by various controlling factors such as surface turbulence flux, surface temperature, soil moisture entertainment of warm and dry air from the free atmosphere, and so on. Surface turbulent fluxes are related to the formation and development of ABL and are important feedback parameters in the coupled system.

The ABL is in convective equilibrium with the Sun-warmed Earth's surface (Emeis et al. 2008). The Sun is the primary energy source for the Earth's atmospheric system. The precise amount of this energy is determined by the time of year, the time of day, latitude, topography, and weather conditions. The nature of the soil and the type of surface determine the amount of energy reflected, absorbed, or transmitted from the Earth's surface (Stull 1988). The absorbed energy is converted to heat energy either directly or indirectly through evaporation or conversion to mechanical, electrical, or chemical energy. The direct heating of the surface of the Earth sets up convective motions in the atmosphere while the indirect heat energy gets stored in the Earth for long periods in the form of chemical energy (say as fossil fuels) before being converted back into heat energy.

Need for ABL Studies

Air quality management and environmental protection are global issues that require joint attention and action at the international, individual, national, and even grassroots levels of domestic human activities. The troposphere, particularly the bottom 2×10^3 m, plays an important role in important human endeavors such as communication, aviation, and air pollution (Seibert et al. 2000). These situations necessitate complete information on wind velocity, humidity, and thermal structure at a location in order to monitor potentially hazardous situations. As a result, it is critical to have a

thorough understanding of its microscale details as well as their distribution in real time and space.

Monitoring Techniques for ABL

Various monitoring techniques have been developed over time to monitor atmospheric parameters such as temperature, pressure, humidity, wind speed and direction, and their distribution in space, providing information about atmospheric structures and various dynamical processes active at a local scale (Stull 1988; Emeis et al. 2008). Table 1 (Seibert et al. 2000) depicts the schematic arrangement for using the various techniques to obtain information about a specific atmospheric volume. All the techniques have their relevance to monitoring any parameter.

These techniques are broadly classified as in situ techniques and remote sensing techniques based on their mode of operation. In situ techniques necessitate carrying measuring sensors or instruments aloft to the height range of interest. In situ techniques such as the radiosonde and microwave refractometer have the advantage of providing detailed height and space profiles, but they are not continuous, which is required for some applications (Singal 2006).

Different types of remote sensing techniques have been developed in recent years using acoustic and optical and radio waves are, SOnic Detection And Ranging (SODAR), Light Detection And Ranging (LiDAR), and RAdio Detection And Ranging (RADAR), respectively (Seibert et al. 2000). Radio And Sounding System (RASS) has also been developed using radio and acoustic wave technology.

Table 1 Different techniques for measurement of ABL or atmospheric volume

Microwave RADAR is similar to LiDAR or Laser RADAR. LiDAR may be used to derive air density profiles above 30 km and map aerosol distribution using intensity back scatter observations. For quantitative probing, resonant, Raman, and fluorescent scattering are being studied, with a focus on pollution monitoring. RADAR probing measurements of reflectivity and doppler shift also include attenuation measures of total water content in storms, as well as polarization effects indicating particle shape, Strom structure, rain water and snow distributions, and cloud, storm, convective cloud, and wind shear dimensions and heights, among other things (Stull 1988). The temperature of the Earth's surface, cloud tops, and other objects is measured using infrared and optical techniques, and vertical profiles of temperature, water vapor, and ozone are inferred using an inversion technique. Microwave radiometer probing is a passive technique that is confined in space and time to a line of sight to the sun. Acoustic techniques (Mono static, Mini, Doppler SODAR) have been used to detect and analyze volcanoes, earthquakes, ocean gravity waves, tornadoes, jet streams, and aurora, among other phenomena (Singal 2006). The following atmospheric information can be obtained using SODAR techniques: first, profiles of mean speed and direction, second, profiles of the three-dimensional spectrum of kinetic turbulence, i.e. intensity of mechanical turbulence as a function of height, wave number, and direction, third, profiles of the three-dimensional spectrum of temperature inhomogeneity, fourth, location and measurement of the intensity of temperature inversion, and finally, information about the intensity of temperature inversion. This chapter concentrated solely on acoustics waves and SODAR.

SODAR As a Monitoring Technique

Thomas (1968) recognized the potential of acoustic sounding for remote detection of thermal inversion layers in the atmosphere. He used an 18-meter-diameter parabolic dish with a transducer at its focus to work at a frequency of 190 Hz. Under low ground noise conditions, echoes from 600 m altitude were received. The received echoes were attributed to a temperature inversion, random atmospheric inhomogeneities, cloud layer boundaries, and temporary wind shear conditions. However, the echosounder/SODAR technique for remote sensing was used to study the index of refraction fluctuations within the atmosphere (McAllister 1968, 1971; McAllister et al. 1969). McAllister (1968) developed an array of loudspeakers and parabolic dish with a horn-loaded transducer mounted at its focus to be used as an acoustic antenna. The frequency used was *950 Hz* and therefore the echoes from an altitude of *1000 m* were detected. The increase in detection range compared to Thomas (1968) could be ascribed to McAllister (1971)'s use of a higher frequency, which increased the signal-to-noise ratio. The introduction of a facsimile recorder, which provided a 3-D display in terms of height, time, and intensity, improved the richness of the observations of atmospheric structure acquired by McAllister et al. (1969). The event of basic physical concepts of the influence of turbulent inhomogeneities on sound wave propagation and scattering within the atmosphere was surveyed by

Kallistratova (1963). However, the most theoretical and experimental results were obtained and summarized, the analysis of fundamental problems, requiring an answer for practical applications of sound waves within the atmospheric research, was given.

Little (1969) examined the possibility and limits of an acoustic RADAR and addressed several acoustic approaches for distant probing of the atmosphere. Fukushima et al. (1974) used a concrete paraboloid dish having an aperture of *16 m* and this antenna was used as the acoustic sounder for studying the lower atmosphere. The interrogating waves had a frequency of *850 Hz* within the sort of pulses of 60×10^{-3} *s* duration repeated every *3.6* or *12 s* depending upon the detection range. They had recorded the meteorological structures of the lower troposphere and realized their usefulness within the effective monitoring of the troposphere. Hall (1972) described an acoustic SOnic Navigation And Ranging (SONAR) for detecting the temperature and velocity structure of the Earth's physical phenomena. The specifics of the SODAR development and experiment work were documented by several experts (Brown and Hall 1978; Beyrich 1997; Ito 1998; Sgouros et al. 2011). Several studies (Stull 1988; Emeis 2010; Bradley 2007; Melas 1993; Antoniou et al. 2003; Kallistratova et al. 2018) provided outlines of the theory of SODAR research.

SODAR operates on the principle of active echo sounding, which employs acoustic waves to probe the lower atmosphere. The propagation of these waves through the medium is affected by meteorological factors such as temperature, relative humidity, and wind. These parameters exhibit their degree of variability through fluctuations in the refractive index of the medium, causing acoustic waves to be refractive, scattering, and attenuated as a result. Sound wave phase and amplitude fluctuations have been evaluated in terms of spatial and temporal fluctuations in atmospheric temperature, wind velocity, and humidity in a manner similar to that of electromagnetic waves. Table 2 shows that acoustic waves are considerably more sensitive to atmospheric fluctuations than are electromagnetic waves and further that wind and temperature fluctuations dominate for sound waves (Rossing 2014; Müller and Möser 2012; Lo and Lee 2013). The strong interaction of acoustic waves with fluctuations in temperature and wind velocity compared to electromagnetic and optical waves makes it possible to monitor the presence and behavior of various atmospheric structures more effectively using sound waves.

SODAR is one of the most effective remote sensing techniques for providing continuous real-time data on air quality, meteorological variables like mixing height/

Table 2 The sensitivity of remote-sensing equipment to atmospheric parameters

Parameter	Magnitude changes of the parameter	Corresponding change in refractive index		
		Acoustic	Radio	Optical
Temperature	1° K	1700	1	1
Humidity	1 mb	140	4	0.04
Wind	1 m s^{-1}	3000	2×10^{-6}	2×10^{-6}

inversion height, ABL stability, and wind profile (Stull 1988; Emeis 2010). It is well known on a global scale and has been shown to be cost-effective. It is internationally recognized and recommended by the Environmental Protection Agency (EPA) for air quality dispersion modeling in Environment Impact Assessment (EIA). All over the world, this technique is used in a variety of practical and ABL research applications. Thermal convection, inversion, elevated inversion, advection, subsiding air mass, sudden gust, waves, and other phenomena can be easily identified using SODAR data. SODAR data is useful for tracking the evolution of coastal boundary layer occurrences (Sea/Land breeze) (Kallistratova et al. 2018). Information has been used to evaluate and comprehend the real-time signal performance of communication links. In bright sunlight, the air warms significantly faster than air close to the Earth's surface. It becomes lighter and rises as a result of this. Thermal plumes have been observed on SODAR as a result of this vertical movement (dense inverted cones). SODAR is one of the most effective ABL approaches in real time and up to 3000 m in space (Seibert et al. 2000).

Mechanism of SODAR and Generation of Echogram

Small-scale refractive index fluctuations occur continually in any volume of atmospheric air, according to the literature (Stull 1988; Emeis 2010; Bradley 2007). These differences serve as tracers for the scattering of the acoustic beam. The variations are caused by turbulence inside an area of refractive index gradient associated to either temperature inversion or convective activity. Turbulent temperature changes half the length of the acoustic wavelength scattered the energy. When the wavelength was shortest, the dispersion was greatest. Without turbulence, temperature inversions were unlikely to have large enough temperature gradients to create substantial echoes. To induce scattering, sufficient turbulence fluctuations were necessary, as well as air stratification different than neutral (Stull 1988; Bradley 2007; Emeis 2010).

The mechanism of generation of turbulence due to temperature lapse rate other than dry adiabatic was discussed (Tatarskii 1961; Monin 1962; Antoniou et al. 2003; Emeis 2021). Tatarski (1961) obtained an expression for scattering cross-section $d\sigma$ as

$$d\sigma(\theta) = 2\pi k^4 v \left[\frac{1}{C^2} E_v(k) \cos^2\frac{\theta}{2} + \frac{1}{4T^2} \emptyset_T(k)\right] d\Omega \tag{1}$$

Kallistratova et al. (2018) and Monin (1962) used a different approach to effects of wind speed and temperature to obtain the expression for $d\sigma$

$$d\sigma(\theta) = 2\pi k^4 v \cos^2\theta \left[\frac{1}{C^2} E_v(k) \cos^2\frac{\theta}{2} + \frac{1}{4T^2} \emptyset_T(k)\right] d\Omega \tag{2}$$

This expression didn't consider the Doppler frequency shifts and scattering due to humidity fluctuations. However, such effects were normally quite small for sound

waves. Furthermore, in the development of the expression for scattering cross-section, they assumed that the field of fluctuations within the scattering volume didn't vary significantly during the passage of sound waves. The refractive effects on the scattering volume, scattering angle, and Doppler bordering of frequency were investigated in detail (Parry and Sanders 1972; Georges and Clifford 1974; Fortuna and Kozaczka 2014). They found that these effects were small for sounding up to a height of *1000 m*. The amplitude of the dispersed signal was proportional to the degree of turbulence, and the acoustic wave scattering occurred in all directions.

The estimation of received acoustic power in the case of a SODAR depends on the amount of atmospheric attenuation along its path in addition to various other parameters. In the case of hemispherical spreading of sound, the intensity I at a distance R from the source was expressed as

$$I = \frac{P}{2\pi R^2} e^{-\alpha R} \tag{3}$$

Harris (1963, 1966) published detailed results for sound absorption in the air as a function of humidity and temperature. However, this work was of significance for sea-level investigations and was somewhat limited for use in the free atmosphere because it didn't include the less well-defined effects and results from scattering and refraction in the free atmosphere.

After the development of the SODAR system, receiving power was determined to be a finite value. The receiving power was dependent on the number of parameters. These parameters were used to develop the system and affect the measuring of the ABL component.

$$\text{Receiving Power}, P_r = P_t \cdot \sigma \cdot \frac{c\tau}{2} \frac{A.L}{R^2} \tag{4}$$

$$C_T^2 = \frac{\sigma_{180} T^2}{4 \times 10^{-3} k^{-1/3}} \tag{5}$$

where σ = scattering cross-section; c = speed of sound; τ = pulse width; R = range; A = antenna area; L = factor containing the equipment efficiencies, antenna gain, and the atmospheric absorption; P_t = the transmitting power; C_T = temperature structure constant; k = angular wavenumber; T = temperature.

Backscattering was only caused by temperature inhomogeneities, according to the monostatic SODAR power Eq. (4) and temperature structure Eq. (5). These backscattered sound signals were examined by the monostatic SODAR system. As a result, dish curvature, antenna gain, and atmospheric absorption were critical to transmitting and receiving the acoustic wave. Wind and humidity fluctuations cause temperature fluctuations, which affect the temperature structure parameter. The received signal was processed to derive information on amplitude about the degree of prevalent turbulence, while the frequency contained information about the current wind speed.

Calibration and Validation of SODAR System

SODAR is an important piece of equipment that measures ABL height in near real time this has been employed as a diagnostic tool in the management of air quality for environmental monitoring in various hazardous conditions such as communication, aviation, wind energy sourcing evolution, meso-meteorology, and as a contemporary technique to other techniques. To achieve these aspirations and predictions, the most specialized ground-based distant sensing of the mean wind, temperature, and humidity within the troposphere is used to monitor and predict the weather. SODAR has been the preferred choice for a long time due to its combined capability to provide data on the dynamics of ABL thermal structures, the ability to disperse the environment, and real-time wind profile measurements in a variety of applications. SODAR is an active sensor that allows us to measure absolute values of the temperature structure parameter of turbulence (C_{2T}), a very useful parameter for studying the behavior of the optical refractive index in the atmosphere, among many other practical applications (Danilov et al. 1992). However, the primary interest of researchers has been in data validation to make sure the standard of knowledge and gain confidence before its direct use as an alternative to standard data availability from existing conventional direct measurement technologies like an instrumented tower, radiosonde, etc.

For the efficacy of the system, careful calibration of SODAR components is prerequisite. Evaluation methods for precision measurement and inter-verification interval measurement for measurement devices based on the concept of measurement uncertainty are required in order to determine the timing of the next scheduled or unscheduled verification of the correspondence of metrological characteristics to their standardized values (Vasilevskyi 2014). A number of possible sources of errors while measuring the absolute turbulence parameter-derived ABL Height are highlighted and are categorized into three categories, which includes geometrical error (errors in tilt angle, scattering angle), bias in ABL Height, wind estimation (uncertainties in calibration against which the calibration is done), and noise interferences (loss of transmitted and received signals). A few of these errors are indeed "operational problems," in the context that they can cause a change in calibration based on the location, conditions, or SODAR operating parameters (Bradley et al. 2005). Coefficients for converting electrical power to acoustic power and vice versa are commonly used to measure absolute values of structure parameters. Despite the development of several approaches for such calibration, most modern commercial SODARs and many research SODARs lack absolute calibration. Fukushima et al. (1974) used a corner reflector for outdoor calibration of the SODAR. Coulter and Kallistratova (2004) described a straightforward method for calibrating a parabolic-type transmitter receiver using a standard-size anechoic chamber and a theoretical antenna directivity pattern. Several works used calibration by comparing echo signal intensity to C_{2T} values measured at a nearby mast (Coulter and Kallistratova 2004).

Marshall et al. (1972) conducted a theoretical examination of horizontal and vertical wind profiles using SODAR, while Beran et al. (1974) and McAllister (1971) conducted practical evaluations. Little (1969), Beran et al. (1973), and Wesely (1976) investigated the viability of employing SODAR data to compute

the vertical humidity profile. The ABL was precisely measured using a SODAR, a parameter used by Greenfield et al. (1974) in the theoretical computation of temperature profiles inside the lower atmosphere under changing climatic conditions. Mahoney et al. (1973) conducted an experiment at Haswell including the use of 3-axis SODAR placed *240 m* apart at the corners of a triangle within which is a *150 m* instrumented tower capable of delivering information about temperature and wind at a rapid rate to correlate the information collected by the SODAR with meteorological factors. Although some of the SODAR data was understood in terms of the recorded turbulent heat flux and momentum, it was determined that the system required to be evolved into an independent quantitative instrument to unravel a large number of details seen. To ascertain the validity of SODAR records, dissimilar researchers had compared the SODAR observations with vertical temperature profiles obtained from radiosonde techniques, captive balloons, LiDAR, and RADAR (Lokoshchenko 2002; Neff et al. 2008; Richardson et al. 2013; Dang et al. 2019; Emeis 2021; Kumar et al. 2021a). They showed that echoes on the SODAR echograms correspond to regions of enhanced temperature discontinuities. Earlier the measurement of SODAR calibration parameters required either a tethered balloon, a high mast, or a very large anechoic chamber for getting precise results. However, a straightforward approach for assessing calibration parameters was described in 1992, using a standard size anechoic chamber and a theoretical antenna directivity pattern (Danilov et al. 1992).

Work at Council of Scientific and Industrial Research-National Physical Laboratory (CSIR-NPL), New Delhi began in 1972, with a preliminary experiment on SODARs. In 1973, after fabricating suitable directional acoustic antennas, a colocated SODAR was established, which was later converted to monostatic operation in 1974. The first calibration of SODAR was initiated in 1976 when another SODAR was set up at the Ayanagar Observatory of the India Meteorological Department in Delhi. The second SODAR was calibrated with the radiosonde data. However, during the calibration field measurement of SODAR antenna, stable windless weather condition along with the high mast or tethered balloon was required, which was found to be an inappropriate method for calibration as it lacked the precision due to the undefined variation in radiation patterns. If structure parameters are to be computed, accurate estimation of SODAR antenna parameters, back-scattering cross-section, and knowledge of acoustic absorption in atmospheric air are required. Thereafter, to delimit the limitations in calibration deployment of anechoic chamber for the acoustical calibration of SODAR transducer and horn with a theoretical estimate of Sant (area of SODAR antenna) was calculated (Danilov et al. 1992).

A method using a theoretical antenna directivity pattern, together with measurements of transduction characteristics of the acoustic transducer, was used for SODAR Antenna calibration (Danilov et al. 1992; Bradley et al. 2005). Theoretically (Eq. (6)) and experimentally determined directivities of the acoustic transducer, one from Russian Academy of Science, Moscow (LATAN-1) and other from CSIR-NPL, New Delhi have been compared (Danilov et al. 1992). The thermal structural values obtained for Sodar Latan-I observed in August 1990 at Mount Mayadank

(2600 m above sea level, Uzbekistan, West Parnero Alay) were calculated by means of the aforementioned approach and compared to those measured simultaneously using microthermal probes for calibration. The deviation between SODAR and in situ data was relatively small when compared to the large range of uncertainty in C2T values (around four times higher at given altitudes and eventually up to five times greater whenever the height dependence within boundary layer is taken into account) (Danilov et al. 1994). The height of ABL during the inversion period was computed using the bulk-Richardson-number approach, diagnostic equations for the equilibrium ABL height, and a relaxation-type prognostic equation, and was explained in terms of their physical foundation and applicability of experimental data (Stull 1988; Richardson et al. 2013). They concluded that the critical bulk Richardson number (R_{iBC}) of the ABL throughout the inversion period was not constant. They also stated that the Richardson number-based computation methodologies should only be used for rough ABL calculations. The output efficiency, input efficiency, and directivity distribution of the LATAN-1 and CSIR-NPL SODAR transducer-horn assemblies were measured in the anechoic chambers of the respective laboratories at operating frequencies of *2.0 KHz* and *2.2 KHz,* respectively. The theoretical directivity distribution behavior was also computed, and the two directivity distribution behaviors were displayed. The two theoretical and experimental curves match adequately within 20% of their values inside the angles at which the paraboloids of the two SODARs are observed from their respective foci, as can be seen in Fig. 1. With a view to illustrating the values of correction, the measured and corrected data were represented for the CSIR-NPL SODAR transducer in Table 3 (Danilov et al. 1992).

$$D_h(\theta_h) = \frac{1 + \cos(\theta_h)}{kR_h \sin(\theta_h)} J_1(kR_h \sin(\theta_h)) \tag{6}$$

where J_1 is the Bessel function, and R_h is horn aperture

Danilov et al. (1992) were computing the directivity behavior; for the SODAR LATAN-1, an exponential horn was used with $R_h = 0.085$ m, which at a working frequency of 2 kHz gives $kR_h = 3.14$**.** The horn used for the CSIR-NPL SODAR is also exponential and has $R_h = 0.075\ m$, which at a working frequency of *2.2 kHz* gives $kR_h = 3.04$. The angles at which the apertures of the reflecting paraboloids are seen from their respective foci are 61° for LATAN-1 and 67.5° for the CSIR-NPL SODAR.

It may be noted that the output efficiencies and the parameters, kR_h and b, for the two SODARS are more or less the same. It may also be noted that the numerical coefficient in Eq. (7):

$$K = 25\pi b^4 (kR)^2 (kR_b)^{-4} \tag{7}$$

is constant for a given device. For LATAN-I it has been computed and found to be $K = 10.7$.

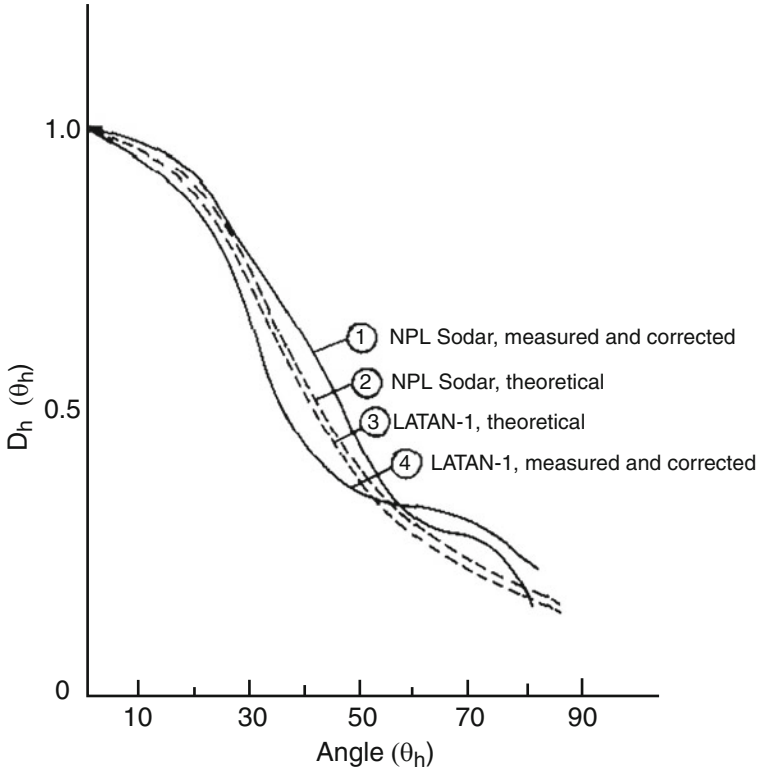

Fig. 1 The comparison of the theoretical and the real directivity diagrams of loudspeaker units with horns (Danilov et al. 1992)

Table 3 Measured and corrected data *for* directivity determination of the NPL SODAR source

Measured angle θ_m	0°	10°	20°	30°	40°	50°	60°	70°
Distance d from horn aperture to microphone (m)	0.80	0.80	0.81	0.83	0.86	0.88	0.92	0.95
Distance variation correction 20log(d/0.8)	0	0	0.1	0.32	0.65	0.87	1.30	1.65
Real angle θ_h	0°	12.5°	25°	37°	48°	60°	70°	78°
Measured level, dB	0	−0.3	−1.8	−4.0	−6.5	−10.5	−12.5	−16.0

The acoustic dish was created to investigate the lower atmosphere. For the acoustic antenna, a fiber parabolic dish with an aperture diameter of *1.2 m* and a dish depth of *0.22 m* was built. A commercial driver unit (60 watts RMS/90 watts maximum) was mounted on a tripod platform at the focus of the dish, *0.60 m* from its apex, with a fiber exponential horn. Figure 2 depicts the entire dish, horn, and driver unit. Figure 3 shows the directional response of this antenna arrangement at frequencies of *1000, 2000,* and *2500 Hz.* At *1000 Hz, 2000 Hz,* and *2500 Hz,* the 90°

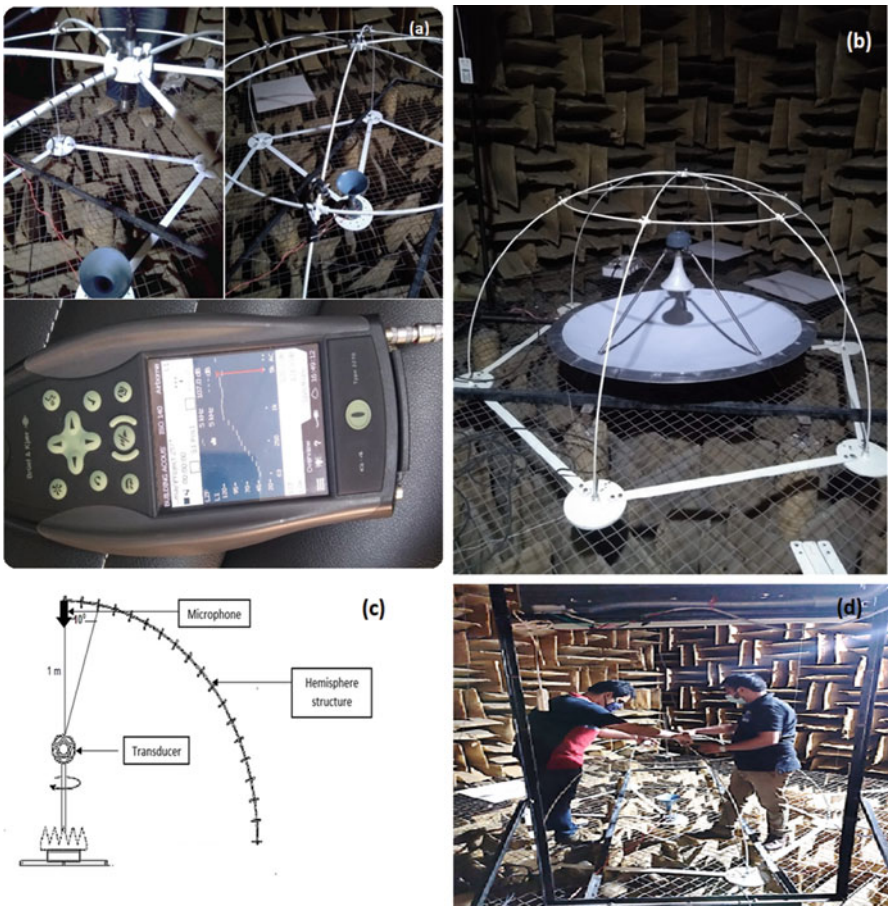

Fig. 2 Transducer testing in anechoic chamber

side lobe suppression is roughly *15 dB, 20 dB,* and *25 dB*, respectively. At *1000 Hz,* the primary lobe had a width of $\pm 12°$. Without the dish, the maximum impulse output was 110 dB for a 60 W input, and with the dish, it climbed to 136 dB at 1000 Hz utilizing a typical sound source. Under free field conditions, the system's receiving sensitivity was *12.5 mv/μbar*. The characteristics of a parabolic dish in a receiving transducer with a B&K pre-polarized free-field 1/2 microphone type 4189, set at its focus, with open-circuit sensitivity of 26.9 dB (1 V/Pa) and 0.2 dB uncertainty (95% confidence level). The boost in the received signal due to the paraboloid reflecting surface was found to be on the order of *25 dB*. (approximate). If the sounding source moved by an angle of $\pm 20°$ on either side of the axial line of the paraboloid surface, the received signal was reduced by *10 dB*, with *25 dB* side-lobe rejections at *90°*. To calculate the antenna transducer's receiving and

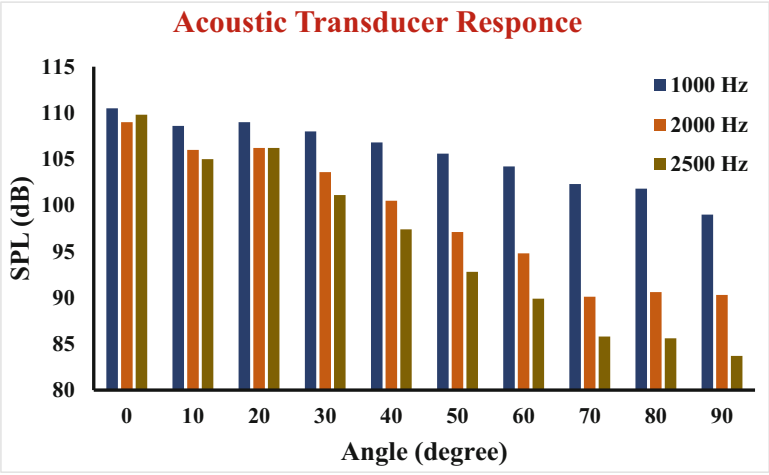

Fig. 3 Transducer response in transmitting mode

transmitting power efficiency, calculations were done (Bradley 2007). Receiving and transmitting efficiencies were calculated to be *21.3*% and *29*%, respectively.

SODAR Application in Air-Pollution Warning System

The use of concentration monitoring networks in air pollution investigations has some physical, technological, and economic restrictions. Air pollution dispersion models are commonly utilized for diagnostic purposes, forecasts, simulation studies, and climatological assessments as a result of this feature. Models are extremely important in air pollution control systems, where anticipated concentration levels are required to assess potential hazards, forecast violations of Air Quality Standards, and activate countermeasures.

The dispersion models are analytical expressions that describe the pollutant's concentration field as a function of emission, source characteristics, and meteorological conditions in their most generic form. The atmospheric stability category, mixing layer depth, and wind vector as a function of height are the meteorological data utilized in dispersion models, which are not dependent on their detailed structure. These data may be required in many formats depending on the purpose; for example, measurable data for diagnosis, projected values for air pollution forecasting, and values characteristic for a specific time period for climatological investigations. SODAR can provide useful information in all of these situations. SODAR recordings can be used to read real-time features of stability, inversion layers, and higher winds. The ability to connect Doppler SODAR to a modeling computer directly is particularly useful in this application. A series of regular SODAR observations is required for longer climatological investigations. The forecast is the most difficult scenario; it necessitates unique ways.

Furthermore, the SODAR technology has proven to be a useful diagnostic tool for line-of-sight communication lines and remedial actions. SODAR data provides detailed information on the dynamics of a variety of atmospheric events that influence communication quality in both analogue and digital systems. The stable conditions explored by the acoustic sounder are usually linked with severe fading decreasing the quality of reception in line-of-sight links. SODAR is the most practical instrument for diagnosing communication issues caused by extreme fading induced by reflected or refracted components from the ground and higher layers.

The SODAR system provides continuous data of ABL height (during convection and inversion condition) and its situations in air pollution, communication, and aviation. In this part, we show how SODAR data can be put to good use in a variety of different weather condition for air pollution.

Method of Determining ABL Height Using SODAR Echogram

The SODAR is a low-cost remote sensing system that employs sound waves. It enables round-the-clock monitoring. This is a straightforward operating principle. A SODAR sends out sound pulses at different levels of the atmosphere and receives back dispersed pulses in temperature inhomogeneities. SODAR echograms provide images of reduced climate turbulence as well as contaminant distribution responsibilities. The echogram's vertical profile of the acoustic refractive index divides atmospheric conditions into two categories: convective period and non-convective (stable) period (output of SODAR). Bradley (2007), Beyrich (1997), and Singal et al. (1997) have compiled methods and algorithms for calculating the ABL height using SODAR data. Being based on sonic principles, the range of SODARs is limited to a few hundred meters extending a maximum up to $3000\ m$ based on the power and frequency of the emitted pulse. The data must be divided into two categories by the observer: inversion time and convection time. Fog-layer, rising-layer, multilayer, and other ABL structure classifications exist, and each classification necessitates a distinct technique to ABL height estimate.

Aside from the convection period, the ABL height was directly extracted from the echogram using visualization. Because SODAR can record both thermal and shear echoes as a gauge of turbulence in the lower atmosphere, it can be used to estimate ABL height both during the day and at night. The most active ABL height can be seen during the day in the form of thermal plumes. The only factor that determines whether or not this is an accurate representation of the ABL height is SODAR sensitivity. A suitable empirical relationship, on the other hand, can always be used to approximate the theoretical limit stated by the Holzworth model. They were covered by a low-level elevated shear echo layer (Emeis 2010; Bradley 2007; Singal and Aggarwal 1979). So, the actual ABL height can be determined by using an empirical formula (Singal and Aggarwal 1979).

$$y = 4.24x + 95 \tag{8}$$

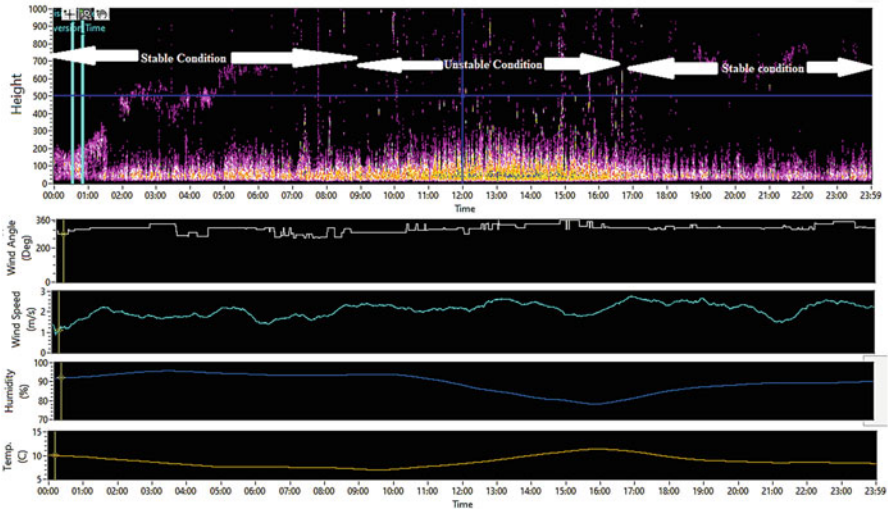

Fig. 4 Stability conditions observation at Delhi

where y is the calculated ABL height and x is the observed thermal plumes height in the echogram. This formula was determined by comparing SODAR data with Radiosonde data.

Thermally stable echo returns are visible at night. The ABL height of the atmosphere can be estimated by measuring the top of the acoustic echo. An advantage of this technique over more convectional direct measurement is that it records the presence and height of inversion layers in real time.

On the echogram, Fig. 4 depicts the stable and unstable situations for the atmosphere. These conditions were the result of many meteorological occurrences causing thermal inhomogeneities in the lower atmosphere.

As the sun sets, thermal plume activity decreases, and SODAR data shows that the characteristics of the echoes change. The structure depicts how nocturnal inversions occur on the ground surface as the air cools in contact with the cooler ground. Wind speed, cloud cover, and surface characteristics all have an effect on the thickness and lapse rate of the cooled layer, i.e., the depth and strength of the inversion layer. To demonstrate how the echo layer represents mechanically induced turbulent mixing and atmospheric stability, consider the following: an acoustical echo's base represents the depth of a mixed layer, its thickness represents a stable zone, and the echo layer's peak represents an inversion peak. SODAR recordings show a horizontally stratified layer or layers throughout the night. As soon as the sun comes up, the thermal plume activity begins to take over and replace the horizontally stratified structure. The diurnal pattern of the nocturnal inversion and the turbulent mixing depth can be determined from a typical SODAR night record. An echo layer that starts at the ground suggests that the stability begins at the surface and that the mixing height based on lapse rate is zero.

During the day, fog rises and persists near the surface at a height of 500 m, resulting in a significant increase in air pollution. The best time to observe these

phenomena is on a cloudy day following a night of intense radiation cooling. Aviation is also jeopardized as a result of vision deterioration. Such situations do occur on occasion as a result of inversion advection during a cold wave in Delhi. In reality, the current studies' primary goal is to try to determine the significance of SODAR records in providing micrometeorological information relevant for monitoring air pollution situations over a 3–5-year period.

SODAR Measurement at Delhi Region

India's Capital Region, i.e., Delhi (*28.70° N, 77.10° E*) in the homogeneous urban area is placed near the bank of the river Yamuna at *715 feet* above sea level (Kumar et al. 2021b). It is unique in that it serves as a gateway between the Thar desert to the southwest, the Aravalli range to the northeast, and the Himalayas to the north. The climate of Delhi is determined mostly by its remote inland location and the presence of continental air, as shown in Fig. 5. The climate of Delhi is known for its extreme dryness, as well as its hot summers and frigid winters. This is influenced by easterly or southerly air and is responsible for seasonal changes in temperature, humidity, cloudiness, and precipitation. Delhi's climate is influenced by the wind. The wind is moderate for most of the year. In June it is strongest and in November it is the lightest. During the summer months, hot and dust-laden winds can lead to storms and storms. During the period from September to May, the prevailing wind direction to the northwest is dominated by the easterly monsoon component. In summer, the temperature increases gradually to *46° C*, and in winter, to *2° C* (Kumar et al. 2021c).

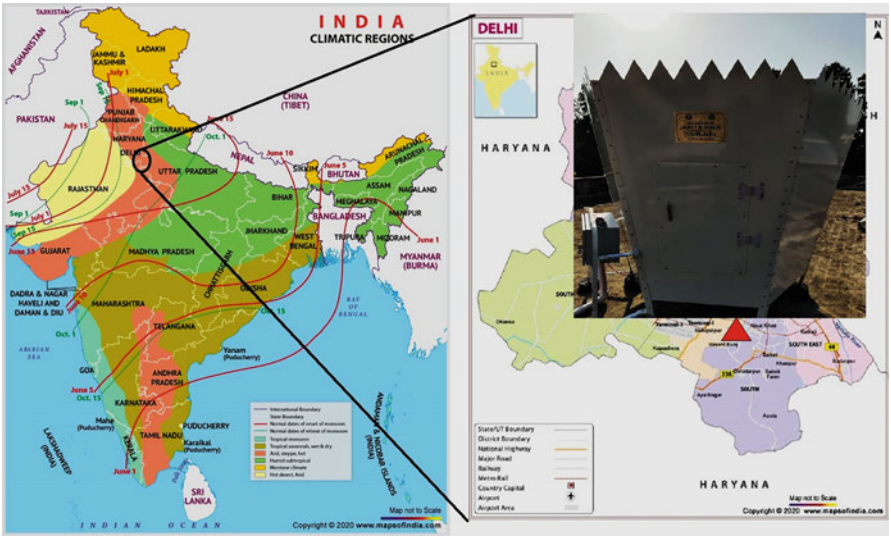

Fig. 5 Monsoon map of India and installed SODAR system at Delhi. (Courtesy: www.mapindia.com)

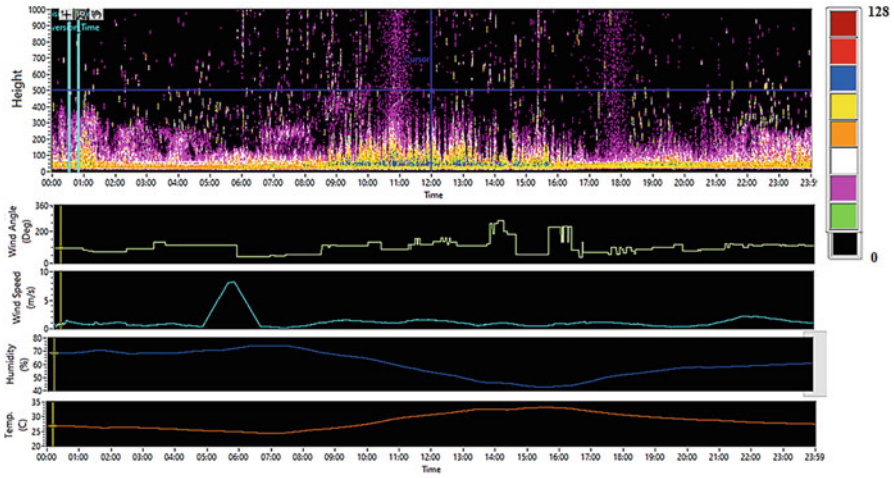

Fig. 6 SODAR echogram observation at Delhi

Monostatic SODAR has operated in Delhi for a few months, during the day and at night, under different atmospheric conditions. It is seen that stable and unstable conditions can be easily determined and classified on the echograms, together with various types of perturbations and Kelvin-Helmholtz blows. The echograms have studied details with the application of software resolution. These structures are caused by various meteorological phenomena and are the appearance of thermal inhomogeneities within the low atmosphere. The diurnal variation and varied architectures of the ABL with variations in wind direction, wind speed, relative humidity, and temperature are shown in Fig. 6. SODAR echogram for the 17^{h} *October 2019*, from *0000 to 2359 IST*. The principal regime is a "classical" 24-h pattern with two transition phases of around *0700–1000 IST* and *1600–1800 IST*, alternating between stable (inversion in the evening and night, *1900–0900 IST*) and unstable (convection in the daytime, *0900–1700 IST*) stratification. Local circulation is unclear in this case; the wind pattern is described as a land breeze with a direction of *150–250 degrees*. Temperature and relative humidity diurnal patterns are typical of fair-weather circumstances. Wind speed increases monotonously with elevation in the inversion layer reaching an extreme at the top of the inversion layer. Due to the disintegration of the stratified echo layer, the wind speed and direction change between *0430 and 0630 IST*. The ABL varied constantly throughout the day, as evidenced by these structures.

Comparison of the ABL Height of SODAR and MERRA-2

Data from 1980 are available in the Modern-Era Retrospective Analysis for Research and Applications, Version 2 (MERRA-2). Because of advancements in the assimilation technology that enable assimilation of recent hyperspectral radiance

and microwave observations, as well as GPS-Radio Occultation datasets, it was introduced to replace the original MERRA dataset (Gelaro et al. 2017; Bosilovich et al. 2015; Rienecker et al. 2011). MERRA-2 includes improvements to both the GEOS model and the GSI assimilation system. The spatial resolution is similar to MERRA (approximately 50 km in the latitudinal direction). Along with the meteorological assimilation improvements, MERRA-2 makes substantial progress toward GMAO's goal of an Earth System reanalysis (Bosilovich et al. 2015). The MERRA-2 reanalysis is the first long-term global reanalysis to incorporate space-based aerosol measurements and depict their interactions with other physical processes in the climate system (Rienecker et al. 2011). The ice sheets over Greenland and Antarctica are represented in MERRA-2.

Figure 7 shows that during the analysis, the MERRA-2-derived ABL height is monthly 0.5 × 0.625 (MERRA-2 model M2TMNXFLX v5.12.4) over January 2019 to December 2019, shape India, region 77.12E, 28.64 N. SODAR-derived ABL heights are compared to MERRA-2-derived ABL heights in the following. Scatter plots of both ABL heights SODAR and MERRA-2 for the Delhi region are shown in Fig. 8. There have been a significant number of MERRA-2 derived ABL heights that

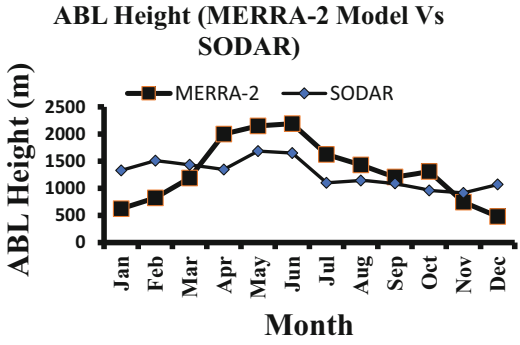

Fig. 7 Monthly variation of ABL height of Delhi

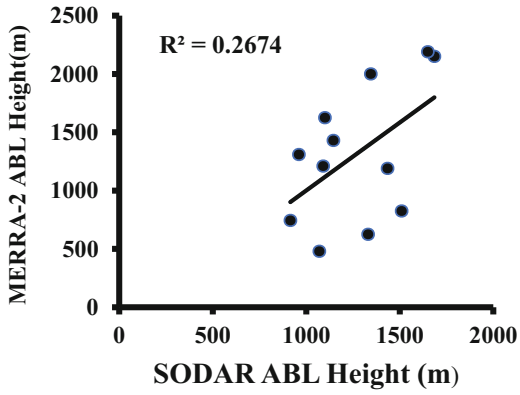

Fig. 8 Scatter plot between SODAR and MERRA-2 dataset

is larger than those derived from SODAR. The average deviation is approximately 450 m, and it tends to increase with increasing ABL heights.

SODAR Application in Determining the Pollution Loading Capacity of the Region

Because of its ability to provide continuous data about the thermal boundary layer and its variability in space and time, the SODAR system is used in dangerous situations such as air pollution, communication, and aviation. In this section, we will discuss how SODAR data can be used in pollution control.

Simmons et al. (1971) and Beran and Hall (1974) discovered that the concentration of pollutants in any location grows as the square root of the distance along the trajectory when the emission intensity is uniform. Also, the concentration rises parabolically with distance over the source area, and it falls off rapidly at first, then slowly as the air moves further away from the source. Upwind mixing and lateral diffusion can only reduce, not remove, pollutant levels no matter how far downwind they are. Solar heating and winds to an extent help to remove pollution but by far the most affective process to remove pollutants from the atmospheric air is the falling of rain. The rain removes the particles and gases present in the cloud drops and in the polluted air. The vertical change of temperature (low-level stability, inversion, topography and buoyancy, etc.) and the direction and strength of the wind are the primary determinants of pollutant concentration in the atmosphere (Kumar et al. 2017a; Saha et al. 2019). The rate at which contaminants spread upward is controlled by vertical temperature changes, and clear air from above mixes downward into the polluted air. The quantity of mixing and rate at which pollution spreads horizontally as it is carried downstream is determined by wind speed, while the wind field variance controls the atmosphere's stability. Aside from these two fundamental parameters, air quality in any given urban region is affected by local and surrounding terrain, landscape features, climatology, location and type of pollution source, political borders and legislation, demography, total effluent, types of effluent, time distribution of emission, and synoptic weather pattern, among other factors.

The ventilation coefficient is the product of the ABL (mixing height) measured by SODAR and the average wind speed; it is an atmospheric condition that indicates air quality and pollution potential, i.e., the ability of the atmosphere to dilute and disperse pollutants across a certain area (Kumar et al. 2015; Sujatha et al. 2016; Kumar et al. 2021d, 2017b). The higher the ventilation coefficient, the more effectively the atmosphere can dispose of contaminants, and therefore the air quality improves. Lower ventilation coefficients, on the other hand, result in poor pollutant dispersal, stagnation, and poor air quality, potentially resulting in pollution-related dangers. The ABL and the average wind speed across the mixing layer are directly connected to the ventilation coefficient. The ventilation coefficient varies in response to changes in the ABL and average wind speed. High pollution potential is indicated by a ventilation coefficient of less than 6000 m2s-1 during the afternoon hours, or by

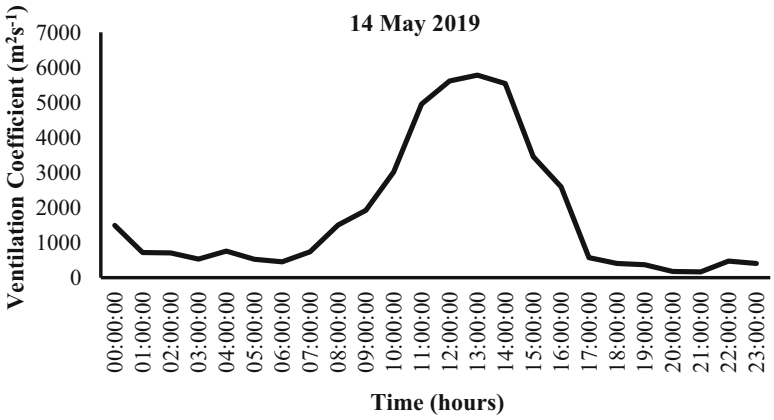

Fig. 9 Temporal variation of ventilation coefficient

an ABL height of less than 500 m during the morning hours. Using SODAR data, the ventilation coefficient over Delhi was calculated (Fig. 9), revealing severe pollution loading.

In varied atmospheric conditions, Fig. 10 depicted the decision algorithm's scheme for air pollution warnings. The synoptic analysis and actual ABL observations by SODAR were utilized to calculate various types of data and verify the stability of actual pollution conditions.

Conclusion

SODAR is a well-known and widely used meteorological tool that provides continuous real-time and critical ABL data. SODAR contributes to city planning, industrial zoning, and other air quality control methods. Data is essential for assessing environmental impact assessments and determining a city's carrying capacity for pollutants. For site-specific dispersions, SODAR has proven to be extremely useful in controlling air pollutants at a low cost. SODAR and other approaches were now being developed as part of these efforts. Every year, new advancements in devices and applications were reported, demonstrating technical versatility. More commercial enterprises have improved SODAR models with a new R&D concept and application potential.

Future Scope

A combination antenna baffle made of high-acoustics material and high-density foam may provide better atmospheric noise cancellation for low-strength backscatter signals from critical atmospheric structure information in the spatial domain. For better ABL structure identification and atmospheric noise reduction, a hardware-

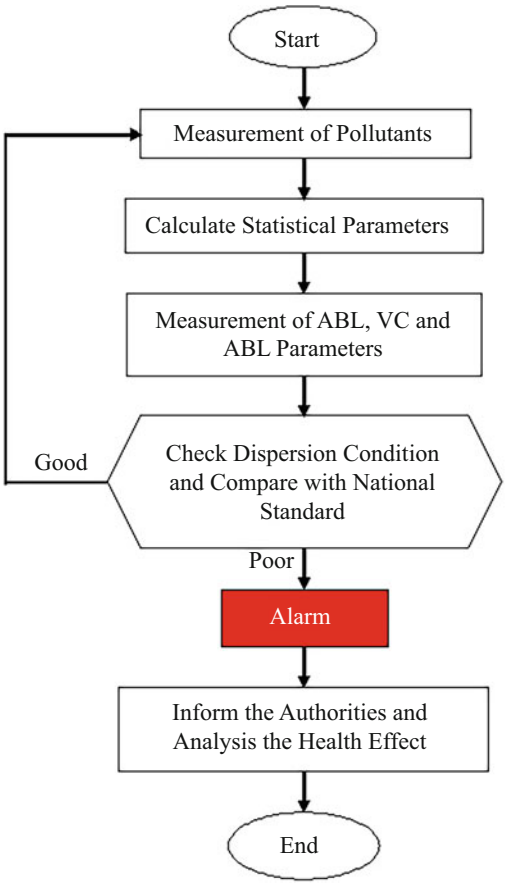

Fig. 10 Scheme of the decision algorithm for air pollution in different condition

based machine learning system composed of an electronic representation of the pre-amplifier output in real-time mode can be designed. The acoustic antenna structure can be created using 3D printing and lightweight fiber material.

Abstract

Air quality in indoor environments is defined as the eminence of air in and nearby the house that directly affects human health. In the last few decades, the international scientific forum, environmental research, and political institutions have strived upon the improvement of the comfort, health, and well-being of building occupants. First and foremost, why is monitoring of IAQ necessary? This is due to indoor air pollution (IAP) which can have a serious and negative impact on both health and quality of life of inhabitants. In view of majority of time spend indoors by occupants, the subject of IAQ beholds a compelling approach for

mitigation of air pollutant exposure specifically during current health crisis owing to COVID-19. Various research groups have used the latest equipment to manage the IAQ testing services that precisely test a range of parameters and concerned issues causing discomfort at the workplace. Thus, the aim of this chapter is to address the necessity and review the current knowledge of IAQ measurement in terms of different aspects, allied science, and its applications in order to show the strategy of translational research studies on IAQ. In addition, the different aspects of IAQ such as measurement techniques, characterization methods, source apportionment, and their effects on environment and human health are also parts of this chapter. Due to the rapidly changing technology, thermal ease parameters such as temperature, relative humidity (RH), and wind speed are known to play an important role in indoor air quality. This chapter is an attempt to discover how persons can live in surroundings of the environment with a good air quality and comfortable lifestyle.

Keywords

IAQ · Measurement techniques · Characterization · Application and science

Introduction

Indoor air quality (IAQ) is basically defined as the circumstances within the house which usually comprise air quality admittance to views, daylight, lovely sound situations, resident activities, and thermal relief. IAQ is also demarcated by the illustration of air pollutant concentrations (gaseous compounds and particles such as non-biological and bioaerosols) and thermal circumstances which could be harmful and influence the fitness, coziness, and enactment of a building's inhabitants (Satsangi et al. 2014; USEPA 2020). IAQ definitions can be different and depends on perceptions of the human user, indoor air space, and source contribution profile to indoor air pollution (Bluyssen 2009).

IAP is considered within the five top risks to public health (USEPA 2020). The disclosure leads to health hazards including respiratory and cardiovascular syndromes and their carcinogenic effects (lung cancer and childhood leukemia) (Franklin 2007; Lin et al. 2013). The World Health Organization (WHO) recognizes an array of pollutants like particulates (PM), carbon dioxide (CO_2), nitrogen dioxide (NO_2), carbon monoxide (CO), radon (Rn), formaldehyde, polycyclic aromatic hydrocarbons (PAHs), and volatile organic compounds (VOCs) (benzene, naphthalene, trichloroethylene, and tetrachloroethylene) for assessing IAQ (WHO 2010). Around 4 lakh impulsive demises due to air pollution were reported in 2019 by the European Union (European Environment Agency 2019). Therefore, it is serious to afford declarative and conceptual consciousness about the survival of air pollutants and their sources, formation methods, limit values, and health effects along with their measurement methods and principles (Rohra et al. 2018, 2020; Pipal et al. 2021).

The IAP led to greater than four million premature deaths in offspring and adults as per the WHO report in 2012. It is also responsible for 1.5 million deaths and 2.7% of the worldwide burden of illness (WHO 2010). IAP is one of the nine utmost substantial global burdens of disease risk (Forouzanfar et al. 2015). In this connection, the climate variation, environmental ruin, quick growth in urban areas, and epidemics are the global challenges. In order to overcome these global issues, the review and modification are highly required in the current understanding/outdated methods of evaluating man-made effects on the environment, multidisciplinary tactics of integrated valuations, and sustainable environment development methods.

The Sustainable Development Goals (SDGs) and targets were sated by the United Nations which aims to close risky deficiency and generate a strong and workable world by the year 2030 (UN SDGs 2015). Air pollution is precisely stated in the diverse SDGs which are as follows: Goal 3 emphasizes on moral health and well-being, Goal 7 marks entree to fresh and reasonable energy, Goal 11 pays attention to maintainable cities and societies, and Goal 13 focuses on challenges for climate change. Apart from these goals, necessary action and strategies (like converting to cleaner energy, green economy, smart cities, cooking and transport solutions) should be taken for improvement of IAQ.

Consequently, these steps are to abstract what has been educated and relate it to the individual atmosphere which comprises the plans for keeping good IAQ. This has expanded significant importance in scientific community and public awareness during the COVID-19 pandemic period. IAQ has been debasing due to excessive emissions of air pollutants and directly results the extent of COVID-19. The $PM_{2.5}$ magnifies COVID-19 infectivity which permitting to the epidemiological study led in Italy (Borro et al. 2020). It was shown that growth (10–25 $\mu g/m^3$) in $PM_{2.5}$ concentration is responsible for increasing the infection rate at three times and enhance (twice) the mortality case. An epidemiological assessment was conducted by Cole et al. (2020) to find the association between air quality and COVID-19 losses in 355 municipalities of the Netherlands by a deleterious binomial regression model with chemical transport modeling (Cole et al. 2020).

Therefore, regular ventilation, proper cleaning, and other precautions in indoor environments are crucial to decrease the probable viral burden in the air which diminish the likelihood of infection with the COVID-19. In addition, the concentration of air pollutants (PM and VOCs) could be reduced which are responsible for various harmful symptoms (disorders, headaches, and dizziness). Metal oxide semiconductor (MOS) sensors used for direct measurement of VOCs and CO_2 measurement are also a sign for IAQ monitoring system (Höfner and Andreas 2021). The good air quality in classrooms and schools is also important to make ideal situations for learning and other scientific activities. In addition to avoid the high emission of air pollutants every day, regular ventilation system is the most actual mode to approve good IAQ. Thus, the environmental awareness and its consequences along with make approval for ventilation trials which are the basic requirement for maintaining a good IAQ. Moreover, agreeing to recent ideas of environmental knowledge and attitude in terms of different aspects and environmental behavior is a very important part. It has been displayed that the modest teaching of

environmental familiarity about the pollutants and principles of sensor technology is a basic requirement, and this type of information alone is not adequate to create a variation in environmental performance (Szagun et al. 1994; Milton et al. 1995). Thus, measurements, characterization, and source apportionment of IAQ are necessary in order to examine the entire aspects of IAQ system with respect to current science and its applications. However, IAQ is hard to measure and evaluate for several causes, prominent among them are:

(i) The absence of fixed metrics, standards, and consent on auspicious IAQ.
(ii) The diversity and difficulty of air pollutants which are found in indoor environments can distress public health and their comfort at very low levels.
(iii) The scarce understanding of relations among indoor pollutant levels, separate exposure, and combined air pollutants and its health effects (acute and chronic).
(iv) The variety of health issues which are related to IAP exposure also can affect humans in various ways.
(v) The probe of whether the pollutants being measured are the ones that really matter.
(vi) The lack of awareness of potential problems and remedies.

Moreover, climate variables such as temperature, rainfall, water vapor, WD, WS, and cloud properties affect air quality in direct and indirect ways. For instance, the higher temperature in outdoor environment leads to amplified O_3 level and subsequent reactions which generate air pollutants in indoor environment. Increased temperature and precipitation in indoor environment could increase chemical off gassing degrees from indoor resources and threat for flooding and water damage, respectively. The regional climate change is also responsible for affecting the flood arrays, droughts, wildfires, vegetation, and allied indoor exposures (mold, dust, bacteria, ignition products, chemical contaminants, pesticides, and pollen).

The different indoor air pollutants and their concentration level and sources along with health effects are shown in Table 1.

IAQ and Potential Pollutants

The research of IAQ includes concentration measurement of PM and primary (Rn, O_3, NOx, SO_2, CO, diatomic carbon, and VOCs) and secondary gaseous pollutants. Several studies have reported higher particle number concentration in ultrafine (<0.1 μm) than coarse range in urban indoor environment (Thomas and Morawska 2002; Gramotnev and Ristovski 2004). In indoor environments, the usage of chemical products has been increased brutally in the last decade. This can generate numerous hazardous chemicals in indoor under room temperature that are associated with several health issues. VOCs exposure is associated with different indications like respiratory symptoms, headache, vertigo, fatigue, nausea, and nose, eye, and throat annoyances (Yang et al. 2001; Gorai et al. 2014), whereas adverse effects of NO_2 toxicity are associated with fever, sneezing, coughing, diaphoresis, chest pain,

Table 1 Summary of different IAPs and its characteristics, sources, and health effects

Pollutants	Sources	Health effects	Levels	Steps to reduce exposure
Radon (Rn)	Rn sources are Earth crust, rocks beneath home, water, building construction materials	No immediate symptoms. Lung cancer deaths (7–30 k/year). Smokers are at greater risk for lung cancer	Average Rn level is 1.3 (pCi/L) and ~ 0.4 pCi/L in indoor and outdoor, respectively. It is based on a national residential survey done in 1991	Testing your home for Rn, fix your home if Rn level is >4 pCi/L and this Rn level still pose a risk
Environmental tobacco smoke (ETS)	Cigarette pipe and cigar smoking	Eye, nose, and throat annoyance, headaches, lung cancer, and heart disease. In addition, increased risk of lower respiratory tract infections and asthma	PM levels are lower as compared to outdoor concentration in indoors without smokers or other strong particle sources, while PM levels may higher many times in homes than outdoor smokers	Stop smoking inside the buildings. Rise ventilation and open windows and use exhaust fans in the smoking areas
Biologicals	Drizzly/humid walls, ceilings, carpets, and furniture strictly maintained humidifiers, dehumidifiers, and air conditioners	Eye, nose, and throat irritation, shortness of breath, and other infectious diseases	Indoor levels of pollen and fungi are lower than outdoor levels. The dust mites are higher in indoor as compared to outdoor levels	Fix and use fans vented to outside in kitchens and bathrooms. Daily clean cool mist and ultrasonic humidifiers, and refill with clean water. Clean and dry or remove water damaged carpets. Use dehumidifiers to preserve humidity (30–50%)
CO	Unvented kerosene and gas space heaters dripping and furnaces leaking	At low-level concentrations, fatigue and chest pain in healthy people and people with	Normal level (0.5–5 ppm) in homes without gas stoves while 5–15 ppm in near to well-	Keeping gas usages accurately adjusted. Acquiring a vented space

(continued)

Table 1 (continued)

Pollutants	Sources	Health effects	Levels	Steps to reduce exposure
	chimneys, gas water heaters, wood stoves and fireplaces gas stoves and automobile exhaust	heart disease, respectively. At higher concentrations: headaches, dizziness, and nausea	adjusted gas stoves. Poorly accustomed stoves may be 30 ppm	heater. Using good fuel in kerosene space heaters. Fitting and using an exhaust fan vented to outdoors over gas stoves. Properly sized woodstoves. Make sure that doors on all woodstoves fit tightly. Having a good inspect, clean and tune up central heating system
Nitrogen dioxide (NO_2)	Kerosene heaters, unvented gas stoves and heaters, ETS	Eye, nose, and throat annoyance could cause reduced lung function and amplified respiratory contagions in children	Average level in homes without burning usages is half of outdoors. With gas stoves, kerosene heaters, unvented gas space heaters, indoor levels than surpass outdoor	See steps under carbon monoxide
Organic gases	Household products (paints, strippers, and other solvents), wood protectors, aerosol sprays, cleansers, antiseptics and air fresheners, stored fuels, and automotive goods	Eye, nose, and throat anger, headaches, nausea, kidney and central nervous system diseases Several organics can cause cancer in animals; few are supposed to cause cancer in humans	The levels of organics found two to five times greater in indoors than outdoors. During certain activities (paint stripping), the levels increased to 1000 times of background (outdoor)	Household products should be used as per the maker's instructions. Confirm and provide amply of fresh air while using goods Keep out children and pets Never mixed household care products
Respirable particles	Firesides, woodstoves, and kerosene heaters	Eye, nose, and gorge frustration,	Particle levels in homes without smoking or	Vent furnaces to outdoors; keep other doors open

(continued)

Table 1 (continued)

Pollutants	Sources	Health effects	Levels	Steps to reduce exposure
		respiratory infections, and bronchitis lung cancer	other robust sources are similar or lower than outdoor levels	when using unvented space heaters. Select well-sized woodstoves; clean and tune up central heating system. Repair leaks quickly. Frequently change filters on central heating, cooling systems, and air cleaners
Formaldehyde	Wood products (hardwood, plywood wall paneling, and fiber board) and furnitures. Drapes and glues	Irascibility for the eye, nose, and throat, wheezing. Coughing, skin rash; allergic reactions cause cancer and other effects due to organic gases	Average concentrations in older homes are below 0.1 ppm. Homes with significant amounts of new wood products are greater than old homes	Use external rank pressed wood products. Use air conditioning and dehumidifiers to reserve adequate temperature and decrease humidity levels Increase ventilation to diminish formaldehyde sources
Lead (Pb)	Pb-based paints, polluted soil, dust, and drinking water	Pb affects all body systems. High levels of Pb (80 ug/dl) in blood can cause convulsions, coma, and death, while low levels can cause adverse health consequences on the nervous system, kidney, and blood cells. Pb in blood (10 ug/dl) can harm mental system and physical growth		Children playing areas should be kept clean and dust-free Do not disturbed Pb-based paint; do not sand or burn off paint. Do not bring Pb dust into the home Eat Ca- and Fe-rich balanced diet

headache, throat frustrations, and pulmonary edema (Hesterberg et al. 2009). Numerous studies expose that an adequate CO_2 level in indoor environments has been associated with fatigue and headaches and it leads to vomiting, dizziness, and nausea (Yu et al. 2009). IAP could be a reason for number of chemical reactions in the environment which generates secondary air pollutants. It was reported by various studies that secondary air pollutants are much dangerous as compared to primary pollutants (Wainman et al. 2000; Rohr et al. 2003). Indoor secondary pollutants (ISP) like O_3, NO_2, and SO_3 are commonly detected which cause major anxiety and injurious influences on human health. The measurement and prediction of ISP are more challenging due to their chemical complexities (Yu et al. 2009). Moreover, volatile, nonvolatile, and non-biological mediators cause a destructive effect on people living inside the environments. Biological creatures (pollen, fungi, bacteria, and insects), mycotoxins, and contagious chemicals also play a vital role in deteriorating the indoor air quality (Nolte et al. 2001).

Investigation of Indoor Air Quality: A Scientific Approach for Better Environment

IAQ is an important cause for comfort of public health and quality of air inside the home which is resolute via huge issues and, subsequently, diverse occupations that are intricate in allocating with solution of indoor air difficulties. The eminence of indoor environment has converted a rising problems and fear due to a range of undefined indicators (annoyance/aridity of mucous membranes, burning eyes, headache/fatigue) in the last eras. These symptoms was reported on the basis of survey and complained by occupants who are living in several indoor environments (Habil et al. 2013; Satsangi et al. 2014).

Moreover, these symptoms might be related to raise air pollutant concentrations in homes which were committed to evaluating climate situations and chemical components in the indoor environments. Therefore, the purpose of indoor air monitoring is to define the state of surroundings, evaluate the fears, analyze the influence of several discharge sources, and offer monitoring data for policymakers to make a conclusion. In addition, monitoring and characterization may contain relevant measurements for corporal atmosphere with the buildings' technical systems, measurement contact, studies of the occurrence of aggravation reactions, or signed reports due to IAP.

IAQ is affected by air exchange rate, RH, temperature, ventilation, air movement, etc. (Graudenz et al. 2005), as the buildings presently constructed are airtight and built by the use of sophisticated isolation ingredients which can aid to diminish the damage of energy. Nevertheless, the modern building envelope and the air conditioning systems cause a drop in motion of new air. Additionally, the chemical goods and man-made resources used in indoor atmospheres have contributed to diverse VOCs (Wang et al. 2004). The studies infer that people are still not innocuous from risks related with IAP.

Investigations of IAQ provide evaluation of air quality in community and profitable houses. The procedure for investigating IAQ is from gathering information to formation and testing of hypothesis. The following factors are known to influence IAQ:

- A building's inhabitants
- A heating, ventilation, and air condition (HVAC) system in buildings
- Probable contaminant ways
- Potential sources of impurity

Therefore, the investigation of IAQ requires several steps which are as follows:

Planning

- Gathering background information for building systems
- Interviewing precious people, understanding the grievances and indications, and checking for designs as to where and when it arises
- Setting purposes
- Approaching determination

Data Assembling

Air pollutant (CO_2, CO, PM, VOCs, chemicals, and bioaerosols) measurements and collection of other environmental conditions like temperature, relative RH, and ventilation rate in the building.

Analyzing the Data

Measurements to eradicate assured areas or alleged difficulties as well as irregularities that directly relate to zones which require further attention.

Reporting of Probable Outcomes

Entire results showing a need for helpful action which wants be conveyed.

Contribution Support

Preparing an IAQ executive strategy (conducting routine measurements and setting policies) for maintaining a good air quality.

Although many restrictions and snags arise in the calculation of indoor quality in different environments, still there is a robust necessity to bear scientific studies for monitoring of IAQ. Obtaining analytical data could be used for statistical analysis for getting complete aspects of indoor air quality in domestic zones. Figure 1 shows various aspects which are affecting the complexity of IAQ measure and estimation system.

The strategies for collection of scientific data and its analysis are very intricate tasks for the researchers due to the complexity in indoor environments. The objectives and interest of the study play an important role in examining the IAQ. Thus, the entire aspect of IAQ such as levels of different air pollutants, chemical and physical characteristics, sources, and their probable effects on human health along with

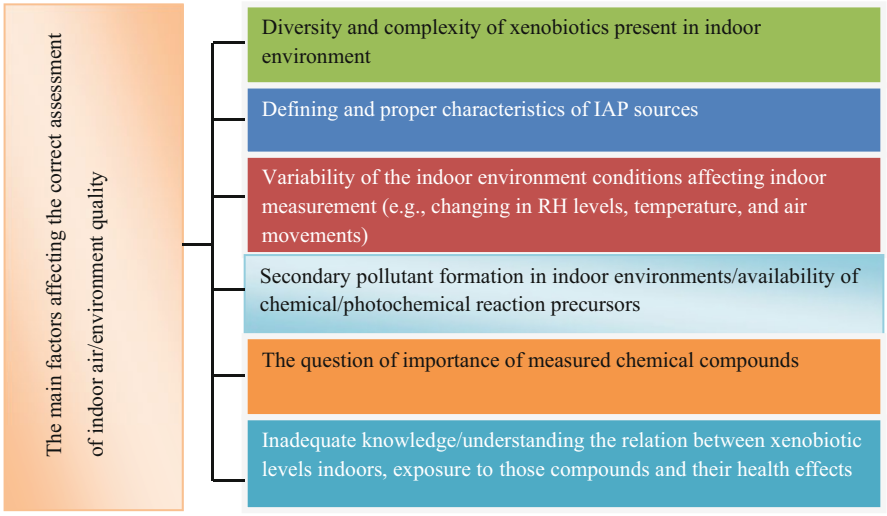

Fig. 1 Key features that disturb the effort to measure and guess the IAQ (Steinemann et al. 2017)

meteorological parameters should be considered as necessary task to obtaining the acceptable and comfort air quality (Pipal et al. 2021, Jan et al. 2017; Satsangi et al. 2014). In this regard, various researchers have been reported their finding in different microenvironments (schools, offices, and other environments) in terms of chemical composition (metals and ions) and morphological aspects (size, shape, and mixing states). A few of the studies mentioned here have reported different scientific techniques for data collection and statistical tools for data analysis and interpretation. Satsangi et al. (2014) have characterized fine ($PM_{2.5}$) and inhalable (PM_{10}) particles at urban and rural locations in terms of metal concentrations and their bioavailability, health risk assessment, and in silico study with nucleosomal protein. This study could deliver the standard data for health-associated contaminants of the urban and rural indoor environment. It is also useful for air pollution abatement programs and can encourage advanced studies on relative metal dispersal, source influence, and enrichment virtual to the fresh context. Pipal et al. (2021) used field emission scanning electron microscopy coupled with energy dispersive X-ray spectrometry (FESEMEDX) for morphological characterization (shape, size, mixing states, other morphology descriptor parameters) and surface elemental composition of individual particles in different microenvironments. They have used ImageJ software for individual particle image analysis and statistical tools for scientific data analysis and interpretation.

Habil et al. (2013) examined the acquaintance of children who are studying in schools of India to PM ranks and metal impurity along with their sources. Massey et al. (2012) characterized different air pollutant (PM_{10}, $PM_{5.0}$, $PM_{2.5}$, and $PM_{1.0}$) concentrations in roadside and urban households using Grimm aerosol spectrometer in Agra, India. Jan et al. (2017) measured coarse and fine particles and characterized

them in terms of anions, elements, morphology, and their threat calculation along with gaseous pollutants (CO_2, SO_2, NO_2, and O_3) in obviously ventilated schools in Pune, India. IAP surveys with outdoor air pollution offer a realistic data of personal air pollution revelation and for evaluating actions of health safety. Zhao et al. (2020) measured different sizes of PM concentrations and assessed individual exposure in 40 homes in the German cities of Leipzig and Berlin. Vardoulakis et al. (2020) reviewed air pollutant concentration and their sources in indoor environments linked with adverse health problems. They suggest the requirement for consistent IAQ measurement and systematic methods for long-time monitoring system over several locations.

The many indicators and sicknesses have been connected to poor IAQ in households in the last decades. Exposures to inorganic, organic, physical, and biological toxins in indoors at small ranks are mutual, pervasive, and constant. Building-related sickness is caused by various indoor ecological factors which are allocated into various groups according to the WHO such as sick building syndrome (SBS), building-associated sickness (BAS), and manifold chemical sensitivity (MCS)/Environmental Disorder (ED) (USEPA 2020).

- *Sick Building Syndrome (SBS)*: It is defined as group of symptoms (experienced by 30% of occupants) that are associated with the bodily atmosphere of definite erections (Marmot et al. 2006). These effects or symptoms are either confined in specific zones or extensive in a house (Redlich et al. 1997; Joshi 2008). These symptoms are inclining to exacerbate as a function of disclosure time in buildings and dissolve as people occupy major time away from the house (Guo et al. 2013). According to the WHO, SBS indications caused by IAP can be classified into different categories such as mucous membrane annoyance (the eye, throat, and nose), neurotoxic effects (headaches, irritability, and fatigue), asthma (chest tightness and wheezing), and skin irritation (dryness) (Kreiss 1989; USEPA 1991).
- *Building-Associated Sickness (BAS)*: BAS is a medical term used for diagnosable sickness linked to building habitation which defines sicknesses and signs with an known relevant chemical agent (formaldehyde, xylene, pesticides, and benzene along with biological agents which are much extensive). The sources of biological pollutants in houses are cooling towers, humidification systems, filter wet surfaces, and water-damaged building constituents (USEPA 2020). The BAS health symptoms are flu, fever, chills, chest tightness, muscle aches, and cough along with the grave lung and breathing complications (USEPA 2020). It has been mentioned that indoor air pollutants could be responsible for BRI symptoms in four main tools such as immunologic, infectious, toxic, and irritant (Seltzer 1994). Moreover, there are different factors like physical, chemical, biological, and psychosocial environments which are also linked to BRI.
- *Manifold Chemical Sensitivity (MCS)/Environmental Disorder (ED)*: IAQ can effect on production, individual coziness, house preservation charges, and health and care. It is an offensive situation where a distinct has or grows feeling to minor ranks of certain chemicals due to prolonged disclosure.

IAQ Guidelines and Standards

The deprivation of IAQ and its substantial hazards to human healthiness has been reported in various studies due to the long-term exposure of air pollutants and anthropogenic activities in indoor environments. Thus, the relevant organizations and the scientific community have developed indoor air standards and guidelines to assess the scenario of air quality and its problems which are established on an assimilated house tactic (Avgelis and Papadopoulos 2004). The part of IAQ strategies is to deliver a serious database that will be used as a reference for the avoidance of risky concerns of indoor pollutants and defense of community healthiness (WHO 2020). Table 2 reviews the IAQ rules for IAPs formulated by the WHO and USEPA (Al-Hemoud et al. 2018). However, it is essential to differentiate nonoccupational (such as inhabited houses, schools, and offices) plans from working (industrial) values (Abdul-Wahab et al. 2015). However, the IAQ guidelines are non-applicable to occupational sectors (Mandin et al. 2009) as these guidelines are applied for the control of air quality risks in different indoor environments such as households, schools, hospitals, public buildings, and offices (WHO 2010).

The IAQ is dynamic as people used a significant time in diverse indoor places and the presence of several pollution sources (traditional and building materials, furniture, cooking methods, and dusting causes). Therefore, the worldwide societies have set guidelines and inception standards to keep an ideal IAQ (Table 2). The guidelines of various indoor air pollutants and control policies in Indian perspective still are not available; therefore, policymakers, government bodies, and scientific societies should take action to formulate standard guidelines for indoor air pollutants. The crucial endorsements for logical exploration communities and the significance of indoor air quality program development are listed in Table 3.

Monitoring System for IAQ

Measurement and characterization of air quality are very important to examine its probable effects on human health and indoor environment. IAQ monitoring methods are very useful for the measurement of various types of air pollutants in indoor environments. The air quality measurement system which is based on various scientific methods and technologies is defined in different sections. These sections describe the required measurements to develop an IAQ profile with special emphasis on parameters of attentiveness in non-research studies and practically underlining.

Overview of Sampling Devices

There are different types of methods which can be used for measurement of indoor air pollutants as given below:

Table 2 Guidelines of indoor air quality for the different indoor air pollutants given by various scientific bodies

Toxins	Concentration levels (mg/m^3)	Coverage time	Organization
CO	100	15 m	WHO
	60	30 m	
	30	1 h	
	10	8 h	
	29	1 h	USEPA
	10	8 h	
CO_2	1800	1 h	WHO
NO_2	0.4	1 h	WHO
	0.15	24 h	
	0.1	1 year	USEPA
PM	0.15	25 h	USEPA
	0.05	1 year	
O_3	0.15–0.2	1 h	WHO
	0.1–0.12	8 h	
	0.235	1 h	USEPA
SO_2	0.5	10 m	WHO
	0.35	1 h	
	0.365	24 h	USEPA
	0.08	1 year	
Pb	0.0005–0.001	1 year	WHO
	0.0015	3 months	USEPA
Rn	100 Bq/m3	1 year	WHO
Xylene	8	24 h	WHO
Formaldehyde	0.1	30 m	WHO

Selecting Measurement Devices

The increasing attention in IAQ interests the expansion of devices for examination purposes and house surveys. For evaluating the measurement device, the following criteria should be considered:

- **Simplicity of use**
  - Convenience
  - Direct interpretation vs. scrutiny mandatory
  - Sharpness
  - Real-time monitoring essential
- **Eminence pledge**
  - Accessibility of facilities and client sustenance
  - Preservation and standardization desires

Table 3 Recommendations for scientific research and the importance of indoor air quality policy management

Research theme	Scientific confidence in current knowledge and understanding	Precise resolution to meet vital slits in awareness	Prominence for strategy provision (passivity or well-being)
Indoor air pollution emissions	Characterization of IAPs (medium: further research is required)	Development of IAQ models with accurate description processes (imperatively essential to stop science gap)	Systematic quantification of IAP sources (high: highly vital for developments of new policies)
	Quantification of the IAP source fluxes (medium: further research is required)		Role of indoor sources in the entire experience to air contaminants (high: highly essential for developments of new policies)
	Chemical and physical processes affecting IAPs (short: growth is beneficial but might not need in the short term)		Interactions between outdoor and indoor pollutants

- **Productivity**
  - Time-averaged vs. prompt appraisals
  - Compassion
  - Compatibility with computer or data-logging decorations
- **Price**
  - Solo usage vs. refillable
  - Acquisition vs. rental

Strategies Used for IAQ Measurement and Monitoring

Material Development for IAQ Devices

The two-dimensional (2D) nanostructured material has exclusive somatic and chemical assets which fascinated excessive consideration for their usefulness in the plan and invention of gas-sensing devices in the last decade. In addition, this type of materials keeps unresolved features, like a huge surface-volume ratio, superb semiconducting goods, and great apparent compassion. The permutation of this kind of material with other dimensional materials is also planned as a capable method for developing high-performance IAQ monitoring sensors (Bag and Lee 2019). Recently, MOS gas sensors have been deliberated as a feasible stage for VOCs and CO finding in the indoor air atmosphere (Kim et al. 2016; Oosthuizen, et al. 2019). It is described that numerous metal oxides, such as SnO_2, ZnO, TiO_2, In_2O_3, Fe_2O_3, MoO_3, Co_3O_4, CuO, NiO, and CdO, have been used in IAQ sensing applications.

There are several categories of sensors which are currently available and used by various researchers in the field of environmental science. MOS (resistive sensor and semiconductor) respond on the sensor exterior in the air and amend its resistance. Some typical features of different types of sensors are:

(a) *Metal oxide sensors (NO_2, O_3, and CO)*:
- Low-cost sensor.
- Decent warmth (mg/m^3-$\mu g/m^3$).
- Due to variations in temperature and humidity, results may be affected.
- 5–50-minute-long response time.
- Output depends on input history.
- Instability could be observed.

(b) *Electrochemical sensors (NO_2, SO_2, O_3, NO, and CO)*: This type of sensors is formed on a chemical reaction between diverse gases:
- Average cost sensor
- Decent sensitivity (mg/m^3-$\mu g/m^3$)
- Dissolute answer time (30–200 s)
- Extremely delicate to temperature and humidity disparities which depend on electrolyte
- Discrimination: display cross-reactivity with comparable molecule

(c) *A photo ionization detector* ionizes volatile organic compounds and trials the electrical present.

(d) *Optical particle counters* perceive particulate matter contamination by computing the light scattered due to atmospheric particles.

(e) *Optical sensors* detect gases (CO and CO_2) by assessing the absorption of infrared light.

(f) *Photo ionization detector* (VOCs measurement):
- Reasonable cost sensor and handled device
- Respectable sensitivity (mg/m^3-$\mu g/m^3$)
- Partial temperature dependency and humidity effects
- Very fast response time
- Not selective: responds to VOCs that can be ionized by the UV lamp
- Important signal drift

(g) *Optical particulate counter ($PM_{2.5}$ and PM_{10})*:
- Moderate-cost sensor and handled device.
- 1-second response time.
- Compassion (1 $\mu g/m^3$).
- Capable to detect (PM_{10} and $PM_{2.5}$) particle size.
- Based on theoretical model, able to convert particle counts to PM mass.
- A diversity of parameters including particle shape, size, color and compactness, humidity, and refractive index are responsible for measurement of signal.

(h) *Optical sensors (CO and CO_2)*:
- Moderate-cost sensor and handheld device.
- Decent compassion for CO_2 (350–2000 ppm).

- Selectivity is good through characteristic of CO_2 IR spectra.
- Response time (20–120 s).
- Imperfect drift over time of the sensor calibration.
- Constraint for correction for the effects of temperature, humidity, and pressure.

Table 4 shows the different types of sensors and their measurement method.

Table 5 depicts the characteristics and various features of sensors which are used for monitoring of air pollutants.

The advanced rate and immense power ingesting of sensor nodes is one of the major alarms in the development of IAQ schemes. The sensor units are generally fitted in an industrial situation, inside homes, offices, and outdoor areas for considering the real-time applications of IAQ systems. However, the intention of the sensor is much emphasized on size, plan cost, power depletion, and message protocol along with presentation requirement on temperature and humidity disparities. In order to confirm the accurate real-time monitoring using LCS, the sensor standardization is the key trial for the researchers. The MOS is cheaper as associated with the optical and electromechanical sensors. However, numerous techniques such as wireless sensor network (WSN) and Internet of Things (IoT)-created models have been developed for real-time IAQ monitoring system.

Advanced IAQ Monitoring Technologies

There have been numerous techniques developed and publicized for real-time observing of IAQ (Saini et al. 2020). Among them, low-cost sensor (LCS), wireless sensor network (WSN), and Internet of Things (IoT)-based systems are the most current tools developed for IAQ monitoring due to their increasing possibility in the Industry 4.0 revolution.

Measuring IAQ with Low-Cost Sensors (LCS)

The LCS technology is attracting more attention to the measurement of air quality nowadays due to the minimum cost for air quality monitoring than conventional methods. This kind of sensor technology could be a game changer in measurement

Table 4 Different sensors and their measurement method

S. no.	Measurement process	Device	Abbreviation
1	Gravimetric	Gravimetric filter impactors	N/A
2	Optical	Photometers	N/A
		Optical particle counter	OPC
		Condensation particle counter	CPC
		Scanning mobility particle sizer	SMPS
		Fast mobility particle sizer	FMPS
		Aerodynamic particle sizer	APS
3	Electrical	Diffusion size classifier	DiSC
		Nanoparticle surface area monitor	NSAM

Table 5 Sampling approaches and key features of every sensor

Sensor for pollutants	Detection method of sensors	Sensor minimum resolution	Sensor correctness	Measurement range
CO	Electrochemical detection	$<1746\ \mu g\ m^{-3}$	<+/−10% of reading or 2% of full scale	0–58,200 $\mu g\ m^{-3}$
Formaldehyde	Electrochemical detection	$62.5\ \mu g\ m^{-3}$	<+/−10% of reading or 2% of complete measure	0–5000 $\mu g\ m^{-3}$
NO_2	Electrochemical detection	$41\ \mu g\ m^{-3}$	<+/−10% of reading or 2% of full scale	0–41,000 $\mu g\ m^{-3}$
O_3	Electrochemical detection	$2.14\ \mu g\ m^{-3}$	<+/−10% of reading or 2% of full scale	0–1070 $\mu g\ m^{-3}$
TVOC	Photoionization detection	$230\ \mu g\ m^{-3}$	<+/−10% of reading or 2% of full scale	0–115,385 $\mu g\ m^{-3}$

of air pollution, traffic organization, personal exposure and health inspection, citizen science, and assessment of air pollution in order to further improve the measurement quality in developing countries. The potential of LCS to abridge personalized sign about IAQ including citizen exposure to PM aims to tenacity-probable dichotomies between indorsing healthy IAQ and energy-effective houses. In order to measure spatial distributions of PM in indoor environments, the LCS networks are one of the capable scientific solutions in indoor air quality scenario. This kind of technological progress will positively change the picture of air quality measurements in the near future. Moreover, to understand uncertainties in LCS signals, it is necessary to assess and authenticate sensors with field and laboratory measurements.

The LCS technology has innovated rapidly with new research, expansions, and requests as published by numerous studies that have verified LCS technology in ambient air monitoring system (Mead et al. 2013; Miskell et al. 2017; Schneider et al. 2017; Spinelle et al. 2017; Fishbain et al. 2017; Lewis et al. 2016; Zheng et al. 2018; Liu et al. 2017). Due to the fast rising sensing technology, a wide variety of low-cost devices/sensor modules was made accessible in the market for indoor air measurement determinations. These devices are informal to use and deliver numerical evidence of air pollutant concentrations in diverse indoor environments (Chojer et al. 2020; Fanti et al. 2021; Kang et al. 2021; Howard et al. 2022). Rai et al. (2017) reviewed the scientific literature and reveals that there is a need to provide systematic guidance for selecting suitable LCS sensor and evaluated their performance which commercially existed for $PM_{2.5}$ and PM_{10} and gaseous air pollutant (CO, O_3, NO_2, and SO_2) measurement in outdoor environments. Several studies have stated that IAQ is exaggerated by outdoor air (Shrestha et al. 2019; Tofful et al. 2021; Kang et al. 2021) and noted the significant differences between outdoor and indoor air

qualities. Thus, there is concern and ambiguity for choosing the environment for suitable scientific monitoring system (Han et al. 2016).

There are several air pollutant sources which are spotted in indoor environments that depend on the carefulness of separate indoor space (Soreanu et al. 2013).

Furthermore, few review articles intensive on LCS are used for monitoring of IAP (Kumar et al. 2016a; Kumar et al. 2016b; Schieweck et al. 2018). Morawska et al. (2018) and Kang et al. (2022) showed the necessity for a scientific review of published studies with indoor and outdoor applications of LCS technology. Moreover, there is an urgent need to thoroughly review studies which compared LCS technology with other instruments used for IAQ monitoring in diverse indoor places (homes, offices, and schools). This technology is extremely significant due to the circumstances under which sensors calibrated in the laboratory do not overlay with the situations met in an indoor atmosphere (Morawska et al. 2018). In order to recognize the application of the low-cost sensing technology for indoor air observation, the current assessment attentive on studies concurrently used low-cost equipment/devices and other tools for contrast at indoor surroundings, with laboratory studies simulating indoor situations.

WSN-Based Systems

The effectiveness of air eminence observation and measurement was enhanced significantly by the WSN systems due to the huge number of nodes arranged to offer pertinent evidence of the IAQ spreading in diverse zones. The WSN is an automatic monitoring system with a self-directed, exact, and instantaneous real-time measurement of indoor air pollutants in dissimilar parts (Pitarma, et al. 2017). This method is generally useful for several VOC (benzene, ethyl benzene, toluene, and xylene) determination (Arroyo et al. 2019). It is also used for measurement of meteorological parameters (relative humidity, temperature), CO, CO_2, and luminosity (Pitarma et al. 2017). These structures regularly comprise a circulated sensor network associated with a cloud method (Arroyo et al. 2019). The improved cloud computing systems have been employed for monitoring, storing, processing, and visualizing achieved data from the sensor setup (Arroyo et al. 2018). In addition, the gained data is further analyzed and processed by artificial intelligence (AI) skills for optimization of air pollutant exposure.

Various researchers have functioned on WSN-built intentions with Zigbee in the last decade and found that WSN is the reliable communication protocol for the development of the monitoring system for IAQ.

In such situations, to improve the whole system performance, the scholars desired to effort on battery power executive structure. Nevertheless, it is noticed that few researchers successfully implemented energy and charge redeemable checking schemes using WSN (Yu and Lin 2015). Mostly, web servers are used as data access platforms in the WSN IAQ monitoring systems because it strains few surplus struggles to make real-time warnings on smart phone user to avoid dangerous circumstances.

IoT-Based Systems

The Internet of Things (IoT), big data, and machine learning (ML) technologies have been announced as trending tools with the expansion of mobile skills which provide excessive aptitude for IAQ real-time monitoring in recent years. The IoT built movable devices that can be used for real-time air quality monitoring and its control. These devices are proficiently transferring real-time data to a cloud accumulation constructed web server using an IoT sensor setup (Benammar et al. 2018; Chiesa et al. 2019).

Several IAQ watching schemes and IoT-based devices have been planned and familiarized; this includes open-source machineries for data processing and transmission (Pitarma et al. 2016). The "electronic nose" (E-nose) is one of the imperative applications of the IoT in IAQ observation method. These are biomimetic kind devices that mimic the functionalities of mammals' olfaction system (Persaud and Dodd 1982). E-nose systems contain four simple modules such as (i) a multisensor array, (ii) software with numerical pattern respect algorithms, (iii) an information processing unit (ANN), and (iv) reference library databases (Freund and Lewis 1995). E-noses can simply monitor various gas concentrations by using chemical sensor collections coupled with the grouping algorithms (Scott et al. 2007). Consequently, E-noses have worldwide concern over excessive curiosity for IAQ monitoring due to its low cost and portability (Chen et al. 2016). Tastan and Gökozan (2019) have proposed this technology system with a series of sensors for monitoring CO_2, CO, PM_{10}, and NO_2 and atmospheric meteorological constraints (temperature and RH) in real time.

Jo et al. (2020) presented a smart air method which collects consistent and precise data for IAQ. Figure 2 represents IoT-based summary for IAQ monitoring.

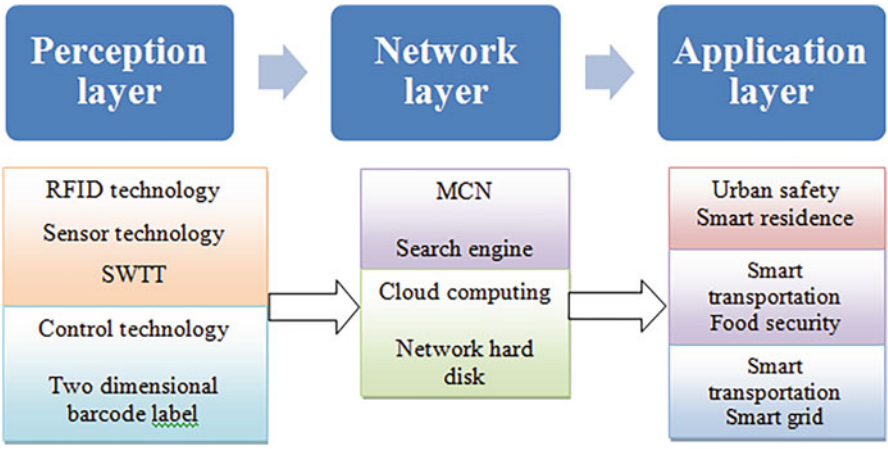

Fig. 2 IoT architecture for measurement of IAQ (Sung and Hsiao 2021). (*RFID* radio frequency identification, *SWTT* short-range wireless transmission technology, *MCN* mobile communication network)

The IoT smart monitoring methods are supposed to be the best trustworthy explanations for IAQ real-time measurement nowadays. Subsequently, researchers and industrial manufacturers are attracted toward this scientific technology system.

This IoT system can monitor a huge number of parameters, even without negotiating scheme enactment. Idrees et al. (2018) and Sivasankari et al. (2017) provided advantage monitoring systems for IAQ with impactful IoT architecture intention. However, few studies have been working on IAQ monitoring prediction systems in the past years. Therefore, in order to start a dependable forecast conclusion system, it is calmer to associate IoT checking methods with ML and profound learning linkages.

Other Technologies

Few researchers have been working on architecture-based technologies which are different from WSN and IoT and found a low performance as compared to IoT real-time monitoring systems. This type of newly developed monitoring system, i.e., C-Air platform, has been designed by Wu et al. (2017), and it is limited only to PM measurements. This is the major weakness of this kind of measurement system because IAQ system is exaggerated by different additional contaminants. Zampolli et al. (2004) have worked on several pollutant measurements, but the study was constrained to the replication atmosphere, and the practical process of such systems still is the real task. Cheng et al. (2014) implemented a forecast model with CAN edge which is again limited to PM. Moreno-Rangel et al. (2018) presented an appreciated study with Foobot monitors and deliberated for numerous real-time IAQ parameter analyses. But again the sensor adjustment was the applicable task to confirm desired performance. Therefore, it is necessary and highly required to do more scientific and technical research in order to overcome this type of issues to develop a smart IAQ measurement system.

Table 6 depicts the details of the air parameters and their working technology and other characteristics.

Indoor Air Quality and Modeling

The studies of chemical constituents and its modeling for diverse uses are extensively amplified due to the interest of scientific research. Air quality forecast (AQF) and evaluation method is help to conclusion creators for refining air quality with respect to community fitness via alleviating the event of severe air pollution periods in town zones and decreasing their connected influence on agriculture, ecosystems, and climate. The progressive tactics in AQF is association and collecting the state-of-the-art models, great resolution release portfolios, satellite explanations, and surface measurements of the applicable chemical components.

This system provides the study and forecast from global- to regional-level air pollution and downscaling for labeled nations, areas, and urban zones.

AQF was mostly executed using realistic methods and statistical models proficient with or fitted to antique air quality and weather data. These approaches have numerous normal problems for air quality forecast system which were reviewed by

Table 6 Air pollutant measurements and their technology

Parameters	Architecture	Communication interface	MCU	Data access	References	Remarks
VOC, PM_{10}, CO, temperature, and RH	IoT	Bluetooth, Wi-Fi, and RF communication module	TI MSP430	Wb server	Kang and Hwang (2016)	Real-time IAQ level indicator designed
RH, temperature, O_3, SO_2, NO_2, CO, $PM_{2.5}$, and PM_{10}	IoT	Zigbee and Wi-Fi ESP8266	ATmega328P	Web-based IBM Watson IoT platform, mobile app	Idrees et al. (2018)	Instinctive standardization method established for the sensor system. It executes power feeding and computer charge enquiry
RH, temperature, NO_2, CO, and smoke	IoT	UART	Raspberry Pi	IP address on the Web	Sivasankari et al. (2017)	Data can be monitored by logging into IP address

Zhang et al. (2012) and Baklanov and Zhang (2020). According to the recent data analyses and the literature reviewed, it was shown that there are various factors such as study gaps, challenges, applications, and advances which should be rectified to overcome the issues occurring in AQF approaches. In addition, the trends and research desires are also required in advance improvements of atmospheric constituent and air quality modeling and prediction.

IAQ models offer a mode to tie evidence about sources and home issues to guess concentration of indoor pollutants. The role of indoor air models in assessing the threat of indoor pollutants is displayed in Fig. 3. Numerous models have been developed to study IAQ which depends on the study's intended uses in the model. The most models used for f IAQ are based on the following points:

- Assessing the inhabitants' coverage to numerous indoor air pollutants
- Assessing the effect of separate sources on air pollutant concentration
- Guessing the influence of distinct sources and IAQ control options on personal exposure

The modeling data used for estimation of indoor exposure to $PM_{2.5}$ accounts for the huge popularity of the mortality load ascribed to whole exposure of $PM_{2.5}$ (Azimi Stephens 2018).

Risk analysis process and assessment for air pollutants are given in Fig. 3, and IAQ model categories are shown in Table 7.

The indoor environment is a very complex vibrant system where the heat and mass transfer and air flow phenomenon take place. In addition, there is a constant interface between the outdoor and the indoor atmosphere, and social involvement through building expertise is strengthened to control the relief situations. Figure 4 depicts the indoor house atmosphere resolute by several sources such as outdoor situation, occupants, and HVAC system. The different origin source over diverse

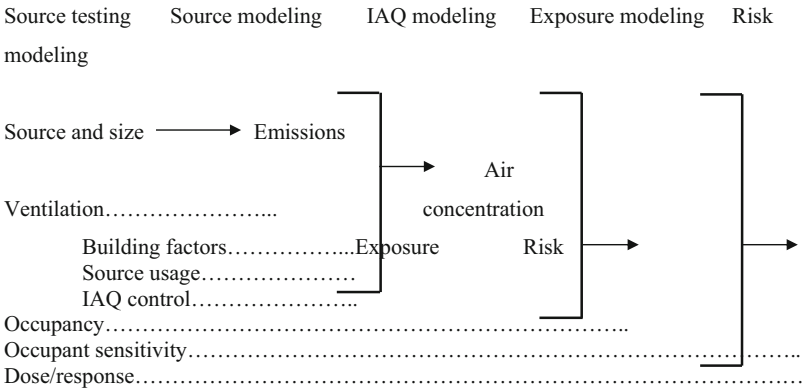

Fig. 3 Indoor air quality modeling system

Table 7 Indoor air model classes

Type of model	General purpose	Example
Statistical	Assessing population exposure	Ott (1984)
Mass balance	Source effect estimation	Sparks (1996), Axley (1988)
Computational fluid dynamics	Assessing close source individual exposure	Brohus (1997)

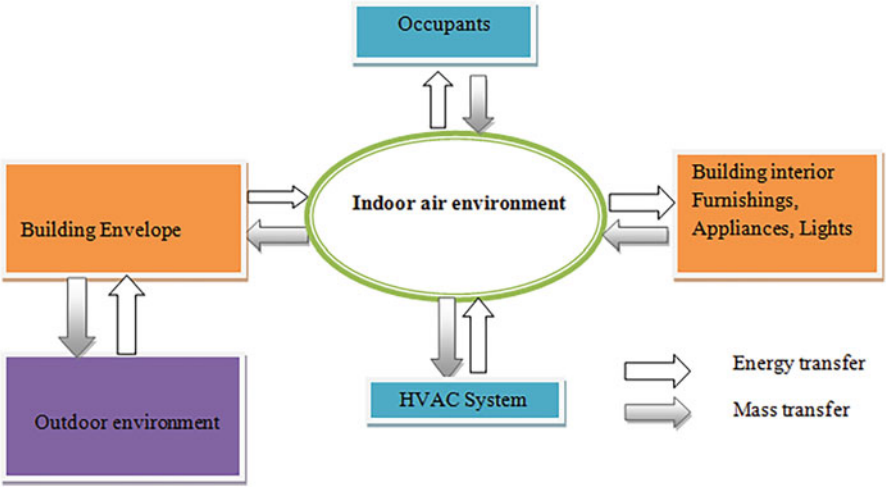

Fig. 4 Indoor air atmosphere as an addition of vibrant methods

heat and mass transfer paths and routes which are managed in the indoor climatic conditions is also presented in Fig. 4.

Various researchers have developed and modified numerous models which are generally used for prediction of air pollutants and their solutions.

Goyal and Khare (2011) have modified the solo partition mass balance-based model which was earlier established by Hayes (1989, 1991) for forecasting PM_{10}, $PM_{2.5}$, and $PM_{1.0}$ concentrations in classrooms of an urban school. The quantitative simulation was conducted by He et al. (2022) using the inclusive air quality model with additions (CAMx) on the vehicle influence of $PM_{2.5}$ between Zhongyuan Urban Agglomeration and adjacent cities in 2017.

The magnitude of IAP can be assessed with arithmetic models, and mass balance equations are used to forecast indoor air pollutant concentrations as the function of outdoor concentrations. This could be used to evaluate penetration rates, indoor source assets, pollutant decline amounts, and mixing causes.

The existence of IAQ has been examined constantly, and different researchers observed greater level of pollutant inside the buildings as compared to outside atmosphere (Lee 1997; Blondeau et al. 2005; Goyal and Khare 2011; Challoner and Gill 2014; Massey et al. 2012). Challoner and Gill (2014) observed that either

certainly or automatically ventilated houses are not active outfits to lessen IAP which derives from outdoor atmospheres. Goyal and Khare (2011) examined numerous limitations surviving in indoor location (PM and CO_2) and also establish that contaminated air imminent from the outdoor environments disturb the inhabitants' well-being and respiratory problems. IAQ control plans could be applied for reducing the contamination threat of COVID-19 through airborne communication (Zhang et al. 2020; Morawska et al. 2018). Refining indoor ventilation methods in homes using air scrubbing tools can develop the IAQ. Wearing a mask in indoors significantly cut the septicity threat of COVID-19. These approaches have been presented and conferred by various researchers (Zhang et al. 2020; Morawska et al. 2018; Dai and Zhao 2020) which was recommended by the WHO (2020). As per the literature, numerous models have been established, but only few have been certified against the observational data.

Statistical Models

In order to appreciate the acquaintance of entire inhabitant system or delicate subpopulations to indoor air pollutants, it is precisely and significantly required to study IAQ system for decreasing the human health risk caused by air pollution.

The charge and difficulty of defining resident's revelation practically have resulted in the improvement of numerous IAQ models. These models deliver the distribution of indoor pollutant exposure to complete inhabitants which depend on the nature of health hazard of disquiet. For instance, overall lifetime disclosure is typically allied with cancer threat, and chronic and annoyance hazards are openly linked with highest exposure.

Database of concentration as a function of time for various atmospheres, residents' movement, and breathing rates are essential for the numerical models. This model generates disclosure and probable quantity circulation using Mono Carlo techniques to associate the database. The basic algorithm is as follows:

1. Select an environment.
2. Sample the concentration database to produce a pollutant concentration.
3. Sample the activity design database to regulate time spent in the environment.
4. Calculate exposure in the environment.
5. Sample the breathing rate record to define breathing rate.
6. Calculate potential dose.
7. Repeat steps 2 through 6 to generate disclosure passage for particular atmosphere.
8. Replicate stage 1 over 7 till all atmosphere of concern are covered.

Mass Balance Models (MBM)

MBMs are designed to assess the source influence on IAQ control in indoor pollutant concentrations. These models are based on the principal of mass conservation which

have single or multiple compartments. The whole house is characterized as a solo planetary, and a building is signified by a sum of allied places for single and multi-compartment models, respectively. Some of these models are discussed in several studies for instances: Hayes (1989) has discussed the multichamber customer disclosure model (MCCEM), and Koontz et al. (1999) and Koontz and Nagda (1991) have estimated individual exposure.

Computation Fluid Dynamics Models

Computation fluid dynamics (CFD) models attempt to pretend the communication of fluids and gases where the surfaces are demarcated by edge circumstances. It provides useful information on the fundamental carriage phenomena in chemical and biochemical manners (heat, momentum, and mass transfer). The revision suggested by Furtaw et al. (1994) may be acceptable for the different conditions. Conversely, this alteration does not provide the desired information to the MBMs in different circumstances. These conditions encompass the necessity to estimate a native concentration instead of an average in room concentration. In such cases, models based on CFD offer the anticipated expectations.

CFD models are dissimilar from MBMs as (1) CFD models envisage air rate and pollutant concentration at separate points in a room instead of the average concentration expected by MBMs and (2) CFD models solve a set of partial differential equations instead of the ordinary equations solved by MBMs. It is revealed that mass balance models provide the necessary information on average air pollutant concentrations, while CFD models deliver the required evidence on air pollutant concentrations fact by fact. This means that CFD models are computationally more expensive than MBMs as are intended for individual computers, while CFD models are planned for small or bigger computers. The diffusion on native or town scales reflects hindrance effects which have been explored by Badeke et al. (2021) using CFD model.

In order to develop IAQ models with precise explanation of chemical and physical methods elaborated in outdoor-indoor air interface as well as treating and carriage of IAP in homes, it is desired to accurately report construction between the outdoor air quality and IAP sources. Further, innovative modeling is desirable for air-surface interfaces aiming releases and basins on diverse surfaces such as ventilation setup (Liu et al. 2013) and authentication of the indoor air models with measurements in environments.

Several researchers have reported comprehensive thorough reviews and observed the expansion and principles of worldwide and local 3D AQF models. They also acknowledged areas of enhancement in climatic predictions, chemical ideas, and model actions of atmospheric physical, dynamic, and chemical processes (Bai et al. 2018; Baklanov and Zhang 2020).

Improvement of Indoor Air Quality

There are different simple tactics to recover IAQ, and they provide significant information on the basis of recent systematic research and nominal appreciative of the indoor air quality matters at local as well as global level. There are different methods such as source control, ventilation improvement system, air cleaner techniques, and potted plants that have been used for improving the indoor air (Zhang 2020).

Zhang (2020) has applied these different scientific strategies in existing ventilation principles for refining and standard IAQ for comfortable lifestyle. These approaches had the possibility to advance IAQ by a factor of 200 outside the present standard, which would surge inhabitant fulfillment from ~80% to 100% (Fanger (2006).

Source Control Methods

The source controlling is the major and utmost imperative method among all IAQ approaches. It is the best effective method to eliminate the individual sources of air pollutants and reduce their emissions from the indoor environment. Few sources contain asbestos that could be bounded, and other sources such as gas ovens can be accustomed to decline the discharge amount of the pollutants. The source control is the price-proficient tactic for defending IAQ than growing ventilation. Native air dissipation is an alternative active source control plan which has the prospective to expand the air quality and cut the cross impurity by a factor of 1.4–10. This phenomenon depends on the local divider pattern, deplete screen, and stream amount (Dygert and Dang 2012).

Ventilation Improvement System

It is another alternative method to dropping the concentrations of air pollutants in homes by increasing the quantity of outdoor air to indoor environments. In maximum household warming and chilling methods containing forced air heating arrangements and do not automatically carry new air into the household. An advanced strategy in new home construction has started the mechanical systems that transport outdoor air into the indoor environments.

Few of these design homes contain energy-able heat retrieval ventilators (air-to-air heat exchangers). Ventilation and covering can help to control indoor temperatures and remove/dilute indoor contaminants imminent from diverse indoor sources. This kind of system decreases the level of impurities and recovers IAQ.

Maximum housing forced air heating, and air conditioning systems do not get air from the outside into the house by instinctively and penetration. Hence, the ventilation is used for bringing an adequate quantity of fresh outdoor air and delivering it

to the inhalation region and efficiently diluting the deteriorated air in indoor atmospheres. The automatically ventilated schoolrooms and workplaces in USA zones have ~20% of their air delivered from outdoors, and the respite air is recirculated (Zang et al. 2020). This was completed to except warming and freezing energy while preserving tolerable IAQ levels. To lessen the threat of the SARS CoV-2 virus septicity, the outdoor ventilation degree should be enlarged to the extreme operative volume of the house ventilation method (Zang et al. 2020). Movement ventilation is a well method for renewed air distribution and dipping the pollutants concentration in the occupied zone by a factor of 1.2–2 released from dwellers (Chen and Glicksman 2003).

Air Cleaner Techniques for Improving IAQ

Air cleaning approaches comprise air percolation/cleansing in the outdoor source, recirculated/assorted air duct, and at personal level. There are several kinds and sizes of air domestics in the market reaching from reasonable table top models to classy and posh full household methods. Out of them, some air cleaners are extremely active for particle elimination, while others (table top models) are very fewer capable. The success of an air cleaner depends on how well air cleaner gathers the air pollutants from indoor atmospheres and how much air these air cleaners pull through the sieving component. Zhao et al. (2020) conveyed a series of clean air carriage degree from 170 to 800 m^3/h with a median cost of $361 and electrical feeding of 56 W per unit. The results were consistent with an earlier laboratory study done by Chen et al. (2006) in which six movable air cleaners were tried for particulate and VOC deduction enactment.

Among the various interventions and tools, air purifiers are required to recover IAQ which is usually engaged in households, clinics, and workplaces. In order to control discharge sources of air pollutants in indoor environments, expansion of air refining tools and optimization of ventilation systems are the key slants to increase IAQ (Huang et al. 2016). Among them, the exploration of original skills to sieve and sanitize IAP has concerned an excessive consideration over the last era. Adsorption machineries (using carbon found in filter media) are the leading technologies for removing gaseous pollutants (Haghighat et al. 2008). There are several inhabited and profitable HVAC filters which have been established and used in several houses (domestic, shopping mall, schools, and workplace buildings) for removing numerous toxic contaminants (O_3, aerosols, VOCs, and PMs) (Zhao et al. 2007). The HVAC strainers can be intended in various shapes like filter cassettes made of flat sheet filter media and containers implanted by refined triggered carbon (Ligotski et al. 2019). Conversely, this expertise has showed a substantial restriction in terms of the adsorption ability due to its stability adsorption capability which ominously diminished the pollutants (Carter et al. 2011). Dubey et al.'s (2021) study has shown short-term use of air purifiers to remove the concentration levels of air pollutants from indoor environment of Agra, India, and found that some air purifiers have good efficiency for removing indoor air pollutants.

Potted Plants

Some studies have been suggested that potted plants have been reducing the ranks of chemicals in laboratory tests and indoor air pollutants (Pipal et al. 2012). However, a reasonable number of potted plants eliminate substantial amounts of air contaminants in indoor environments (households and workplaces).

Smart Home for IAQ Control

The term "smart home" is related with numerous home robotic methods (home utilizations, transportations, and entertaining electronics). In latest years, home robotics and the smart home mainly have fascinated excessive concern. It is governable via smartphone solicitations and IoT-based wearable devices which is an energetic part of smart cities. Its groundwork was the projected home energy management system (HEMS) (Zhou et al. 2016; Patil et al. 2019). In order to improve the energy usage effectiveness and elevate ventilation technology, the smart home was settled (Paetz et al. 2012; Missaoui et al. 2014; Chenari et al. 2016).

The future growth of smart home skill is probable to keep in two broad ways: (i) the control of ventilation, usages for a decrease of energy charges, and improvement of human fitness, care, and comfortability and (ii) support to old and spiked persons by the use of robotic machines and smart sensor tools (Schieweck et al. 2018). In addition, the smart home technology deals with chances to cut bad influences of IAP on human well-being. Kraakman et al. (2021) grant the latest developments in biological system for indoor air purifying methods as a "green" substitute to physicochemical methods, with prominence on present trials and occasions. This method can compromise for filtering IAQ, erection energy price reserves, and enlargements on indoor ease and well-being. This system has major challenges which are required to correctly discourse the bioavailability of air pollutant at low concentrations, assurance microbial safety, and integrate CO_2 removal.

Way Forward

The implementation of real-time IAQ monitoring system is preferred than an organized laboratory atmosphere or on imitation methods in real scenarios. With ease to control the adverse impact of IAP, the development of prediction systems remains a crucial alarm for forthcoming studies.

The core zones of research work for future researchers can be summarized as follows:

- An IAQ monitoring system should be developed which can work more efficiently in real-time measurements instead of replicated/laboratory built observations.
- Designing a cost-effective IAQ observing method to offer a harmless result for improved active locations in rural areas.

- Working on IAQ forecast methods so that suitable defensive trials can be followed on time.
- Designing a power-proficient and strong system for simple monitoring situations in urban and rural zones.
- Mounting novel effective method which can produce direct sirens to the users via email and SMS when IAP reached to threshold levels.
- The mobile app-based checking schemes should be developed which can be functioned by non-technology awareness persons as well.
- Increasing rapid aware systems with probable defensive actions such as switch on/off air conditioner, open/close frames, and check gas leakage. This will help to monitor people for strong control solutions of air pollutants in the active atmosphere.

Conclusion

This chapter entails about the IAQ scenario and their related effects of exposure to airborne and gas compounds which were considered as harmful products in different studies. The following lasting movements could help to endorse auspicious IAQ in indoor environments: (i) developing IAQ guidelines for significant air pollutants and giving credits for their decline and prevention; (ii) evolving an IAQ index or metrics; (iii) presenting acknowledgments for testing of releasing from goods used in indoor environments; (iv) conducting IAQ measurements inside the building environment; (v) accounting for cross-category effects of elucidations in other groups of IAQ system; (vi) steady recertification based on IAQ ranks, and (vii), usually, evolving incentives to recover IAQ that will profit to inhabitants, employers, and holders staying in indoor environments which create greater obligation of IAQ in greenhouse assignments. Overall, this chapter is an inclusive scientific document which covers the entire aspects of IAQ system such as measurement techniques, characterization methods, and source apportionment tools along with health risk assessment methods. In addition, this chapter is introducing the new scientific technology and its applications which are used to develop smart tools and devices for improving IAQ system. This will benefit and be very useful for researchers, policymakers, and government's agencies for developing a new strategy and policies for better IAQ system.
