Preface

There is a significant infrastructure of services, resources, transportation, and communication networks in today's society, much of which is invisible. Most of the time, their presence and efficient operation are taken for granted, even though they are necessary for daily living. The science of measurement known as metrology is a part of this lesser unnoticed infrastructure. Metrology includes the theoretical and practical aspects of measurement, instrumentation, and related standards. Metrology aims to ensure that measurements are accurate, reliable, and consistent across different systems and contexts.

Metrology plays an important role in all areas of human endeavors and across all the sectors of industry, trade, regulations, legislation, defense, environment, education, science, food, transport, health, and quality of life. It involves the development and maintenance of measurement standards, the calibration of measurement instruments, and the application of measurement techniques to solve problems and improve processes. Metrology is primarily classified into three sub-fields: scientific or fundamental metrology; applied, technical, or industrial metrology; and legal metrology. Scientific metrology focuses on the development of units of measurement, the advancement of measurement techniques, the realization of measurement standards, and the dissemination of traceability from these standards to users in society. Industrial metrology ensures the applicability of measurement devices, their calibration, and quality control while applying measurement to manufacturing and other processes and their use in society. Legal metrology is concerned with ensuring accuracy and uniformity in weights, measures, and weighing and measuring instruments.

This handbook provides comprehensive and up-to-date information on the topics of scientific, industrial, and legal metrology in 15 parts with 94 chapters. These chapters discuss the state-of-the-art review of various metrological aspects of metrology and quality infrastructure, redefinition of SI Units and their implications, applications of time and frequency metrology, certified reference materials, industrial metrology, Industry 4.0, metrology in additive manufacturing, digital transformations in metrology, metrology for advanced communication, environmental metrology, metrology in biomedical engineering, legal metrology and global trade, ionizing radiation metrology, advanced techniques in the evaluation of measurement uncertainty, etc.

The chapters in Part I provide detailed information about the evolution of metrology and quality infrastructure. The ability of a nation to assess its level of conformity depends on its quality infrastructure, which primarily consists of metrology, standardization, and accreditation. Part II discusses the advancements related to the updated International System of Units (SI) system and its implications. The chapters include the scientific and policy details about the historic decision to update the SI by the world scientific community in November 2018 at the 26th meeting of the General Conference on Weights and Measures (CGPM). The basic units are now defined in terms of the constants that characterize the natural world, which are the most reliable referencing methods. The establishment of time and frequency standards, as well as their dissemination, are both covered in the chapters of Part III. Part IV deals with studies related to Certified Reference Materials/*Bharatiya Nirdeshak Dravyas (BNDs)*. The *Bharatiya Nirdeshak Dravya (BND)* is an Indian trademark of Certified Reference Materials (CRMs) produced by CSIR - National Physical Laboratory (CSIR-NPL), India, independently as well as in association with Reference Material Producers (RMPs). The BNDs are the primary standards, which ensure the reliability and comparability of the measurements as a benchmark for the quality assurance achieved through international networking. Part V elaborates the industrial metrology with several chapters on diverse sub-fields of it. Part VI is dedicated to Industry 4.0 and engineering metrology. As a result of the widespread usage of digital technology, the industry has undergone a revolutionary digital transition known as Industry 4.0. Due to its nearly unlimited design freedom, capacity to make individualized parts locally, and effective material usage, additive manufacturing is a rapidly expanding industry that has the potential to spark a revolution in manufacturing. Part VII deals with the advancement in the metrology for additive manufacturing. Part VIII comprises chapters related to digital transformations in metrology. Digital technology is one of the most fascinating trends in society today and is revolutionizing metrology. Part IX conations chapters related to optics in metrology as well as nanometrology. Part X is dedicated to the metrology for advanced communication. This comprises the development and application of cutting-edge communications technologies through the collection of measurements, information, and study of the metrology and comprehension of physical phenomena, material capabilities, and communication systems and components. The studies centered around both the global issues related to climate change and the local environmental challenges for the quality of the air, water, and soil. Part XI includes chapters related to the diverse issues of environmental metrology. The use of metrological evaluations and conformance assessment, particularly where measurements support health, is becoming more and more prominent. Part XII deals with the studies related to metrology in biomedical engineering. Global commerce of commodities and services is essential for maintaining global financial stability, economic progress, and population welfare. Part XIII consists of chapters related to legal metrology and global trades. Part XIV comprises chapters related to radiation metrology. It includes the chapters focused on measuring of radioactivity and the standards for radiation dosimetry. Ionizing radiation has numerous uses in both industry and healthcare. Ionizing radiation may be controlled and used in a way

that doesn't endanger patients, radiation technicians, the general public, or the environment thanks to accurate metrology. Finally, Part XV discusses the research works related to the introduction and various techniques used in the evaluation of measurement uncertainty. These chapters explain the most used methodologies for the evaluation of measurement uncertainty in metrology with practical examples.

In the present handbook. the internationally recognized team of editors adopts a consistent and systematic approach and writing style, including ample cross-reference among topics, offering readers a user-friendly knowledgebase greater than the sum of its parts, perfect for frequent consultation. Moreover, the content of this handbook is highly interdisciplinary in nature, with insights from not only metrology but also engineering, material science, optics, physics, chemistry, bio-medical, and much more. This handbook acts as a single window source and reference to researchers, metrologists, industrialists, university graduates, masters, academicians, administrators, policymakers, regulators, and other stakeholders for a better understanding of metrology and related decision-making. The sections on different topics are each presented differently in a single window. Data are provided in all of the chapters as tables, block diagrams, pictures, layouts, and line diagrams, which keeps the chapters interesting for readers without compromising the technical depth of the material.

The editors would like to express sincere thanks to all the authors who contributed the chapters to this handbook. We gratefully thank all of the reviewers involved in the chapters' peer-review process. We acknowledge the great contribution made by each section editor. We especially thank Professor William D. Phillips, a Noble Laureate, and Professor Peter J. Mohr, the authorities in the field of metrology for their contribution to this handbook. Finally, we thank the Springer team for their steadfast assistance in bringing out this useful handbook.

Contents

Volume 1

Part I Metrology and Quality Infrastructure 1

1 **International and National Metrology** 3
Shanay Rab, Meher Wan, and Sanjay Yadav

2 **Wake-Up India to Build Self-Reliant Metrology Structure for Modern India** 29
R. Sadananda Murthy

3 **Quality: Introduction, Relevance, and Significance for Economic Growth** 49
Alok Jain, Shanay Rab, Sanjay Yadav, and Prapti Singh

4 **Accreditation in the Life of General Citizen of India** 71
Battal Singh

5 **Quality Measurements and Relevant Indian Infrastructure** 95
Anuj Bhatnagar, Shanay Rab, Meher Wan, and Sanjay Yadav

6 **An Insight on Quality Infrastructure** 113
Shanay Rab, Sanjay Yadav, Meher Wan, and Dinesh K. Aswal

Part II Redefinition of SI Units and Its Implications 133

7 **The Quantum Reform of the International System of Units** 135
William D. Phillips and Peter J. Mohr

8 **Realization of the New Kilogram Based on the Planck Constant by the X-Ray Crystal Density Method** 167
Naoki Kuramoto

9 **Quantum Redefinition of Mass** 189
Bushra Ehtesham, Thomas John, H. K. Singh, and Nidhi Singh

10 **Optical Frequency Comb** 219
Mukesh Jewariya

11 Quantum Definition of New Kelvin and Way Forward 235
Babita, Umesh Pant, and D. D. Shivagan

12 Realization of Candela 269
Shibu Saha, Vijeta Jangra, V. K. Jaiswal, and Parag Sharma

13 The Mole and the New System of Units (SI) 299
Axel Pramann, Olaf Rienitz, and Bernd Güttler

14 Progress of Quantum Hall Research for Disseminating the Redefined SI 329
Albert F. Rigosi, Mattias Kruskopf, Alireza R. Panna, Shamith U. Payagala, Dean G. Jarrett, Randolph E. Elmquist, and David B. Newell

15 Quantum Pascal Realization from Refractometry 363
Vikas N. Thakur, Sanjay Yadav, and Ashok Kumar

Part III Applications of Time and Frequency Metrology 401

16 Time and Frequency Metrology 403
Poonam Arora and Amitava Sen Gupta

17 Atomic Timescales 409
J. M. López-Romero and C. A. Ortiz-Cardona

18 Atomic Frequency Standards 431
Poonam Arora and Amitava Sen Gupta

19 Precise Time Transfer Techniques: Part I 455
Pranalee Premdas Thorat, Ravinder Agarwal, and Dinesh K. Aswal

20 Time Transfer via GNSS 509
P. Banerjee

21 Precise Time and Frequency Transfer: Techniques 529
Huang-Tien Lin

Part IV Certified Reference Materials/Bharatiya Nirdeshak Dravya (BND): Need and Boon for Atma Nirbhar Bharat 555

22 Certified Reference Materials (CRMs) 557
Nahar Singh

23 Bharatiya Nirdeshak Dravya for Antibiotics and Pesticide 565
Arvind Gautam and Nahar Singh

24 Bharatiya Nirdeshak Dravya for Assessing Mechanical Properties 591
Ezhilselvi Varathan, Vidya Nand Singh, Umesh Gupta, S. S. K. Titus, and Nahar Singh

25 Role of Certified Reference Materials (CRMs) in Standardization, Quality Control, and Quality Assurance 613
S. K. Breja

26 Precious Metals: Bharatiya Nirdeshak Dravya for Pure and Sure Jewelry 635
Vidya Nand Singh, Dinesh Singh, Pallavi Kushwaha, Ishwar Jalan, and Nahar Singh

27 Indian Reference Materials for Calibration of Sophisticated Instruments 651
N. Vijayan, Pallavi Kushwaha, Asit Patra, Rachana Kumar, Surinder Pal Singh, Sandeep Singh, Anuj Krishna, Manju Kumari, Debabrata Nayak, and Nahar Singh

28 Certified Reference Material for Qualifying Biomaterials in Biological Evaluations 679
N. S. Remya and Leena Joseph

29 Alloys as Certified Reference Materials (CRMs) 697
Nirmalya Karar and Vipin Jain

30 CRMs 731
S. K. Shaw, Amit Trivedi, V. Naga Kumar, Abhishek Agnihotri, B. N. Mohapatra, Ezhilselvi Varathan, Pallavi Kushwaha, Surinder Pal Singh, and Nahar Singh

31 Petroleum-Based Indian Reference Materials (BND) 747
G. A. Basheed, S. S. Tripathy, Nahar Singh, Vidya Nand Singh, Arvind Gautam, Dosodia Abhishek, and Ravindra Nath Thakur

Part V Industrial Metrology: Opportunities and Challenges 767

32 Industrial Metrology 769
Sanjay Yadav, Shanay Rab, S. K. Jaiswal, Ashok Kumar, and Dinesh K. Aswal

33 Importance of Ultrasonic Testing and Its Metrology Through Emerging Applications 791
Kalpana Yadav, Sanjay Yadav, and P. K. Dubey

34 Mechanical and Thermo-physical Properties of Rare-Earth Materials 809
Vyoma Bhalla and Devraj Singh

35 **Hardness Metrology** 843
Riham Hegazy

36 **Torque Metrology** 867
Koji Ogushi and Atsuhiro Nishino

37 **Recent Trends and Diversity in Ultrasonics** 891
Deepa Joshi and D. S. Mehta

38 **Calibration of Snow and Met Sensors for Avalanche Forecasting** 909
Neeraj Sharma

39 **Pressure and Its Measurement** 955
Vinay Kumar

40 **Traceable Synchrophasor Data for Smart Grid Metrology and Its Application in Protection and Control** 999
Avni Khatkar and Saood Ahmad

Volume 2

Part VI Industry 4.0 and Engineering Metrology: A Perspective 1023

41 **Using AI in Dimensional Metrology** 1025
Arif Sanjid Mahammad

42 **Artificial Intelligence** 1043
Kirti Soni, Nishant Kumar, Anjali S. Nair, Parag Chourey, Nirbhow Jap Singh, and Ravinder Agarwal

43 **Fusion of Smart Meteorological Sensors, Remote Sensing Techniques, and IoT in Context of Industry 4.0** 1067
Kirti Soni, Parag Chourey, Nishant Kumar, Nirbhow Jap Singh, Ravinder Agarwal, and Anjali S. Nair

44 **Machine Learning in Neuromuscular Disease Classification** 1093
Niveen Farid

Part VII Metrology in Additive Manufacturing: Present Scenario and Challenges 1119

45 **Role of Metrology in the Advanced Manufacturing Processes** 1121
Meena Pant, Girija Moona, Leeladhar Nagdeve, and Harish Kumar

46 **Additive Manufacturing: A Brief Introduction** 1141
Mansi, Harish Kumar, A. K. S. Singholi, and Girija Moona

47 Additive Manufacturing Metrology 1165
Mansi, Harish Kumar, and A. K. S. Singholi

48 Metrological Assessments in Additive Manufacturing 1181
Meena Pant, Girija Moona, Leeladhar Nagdeve, and Harish Kumar

49 Advances in Additive Manufacturing and Its Numerical Modelling 1193
Shadab Ahmad, Shanay Rab, and Hargovind Soni

Part VIII Digital Transformations in Metrology: A Pathway for Future **1215**

50 Role of IoT in Smart Precision Agriculture 1217
Kumar Gaurav Suman and Dilip Kumar

51 Soft Metrology 1239
Marcela Vallejo, Nelson Bahamón, Laura Rossi, and Edilson Delgado-Trejos

Part IX Optics in Metrology: Precision Measurement Beyond Expectations and Nano Metrology **1271**

52 Optical Dimensional Metrology 1273
Arif Sanjid Mahammad and K. P. Chaudhary

53 3D Imaging Systems for Optical Metrology 1293
Marc-Antoine Drouin and Antoine Tahan

54 Speckle Metrology in Dimensional Measurement 1319
Niveen Farid

55 Necessity of Anatomically Real Numerical Phantoms in Optical Metrology 1347
Vineeta Kumari, Neelam Barak, and Gyanendra Sheoran

56 Microscopy Using Liquid Lenses for Industrial and Biological Applications 1369
Neelam Barak, Vineeta Kumari, and Gyanendra Sheoran

Part X Metrology for Advanced Communication **1397**

57 Quantum Microwave Measurements 1399
Yashika Aneja, Monika Thakran, Asheesh Kumar Sharma, Harish Singh Rawat, and Satya Kesh Dubey

58 **Electromagnetic Metrology for Microwave Absorbing Materials** 1421
Naina Narang, Anshika Verma, Jaydeep Singh, and Dharmendra Singh

59 **Phased Array Antenna for Radar Application** 1443
Ashutosh Kedar

60 **Antennas for mm-wave MIMO RADAR** 1471
Jogesh Chandra Dash and Debdeep Sarkar

61 **Radar Cross-Section (RCS) Estimation and Reduction** 1491
Vineetha Joy and Hema Singh

Part XI Environmental Metrology **1517**

62 **Environmental Metrology** 1519
Ravinder Agarwal and Susheel Mittal

63 **Physical Quantities of Sound and Expanding Demands for Noise Measurement** 1527
Hironobu Takahashi, Keisuke Yamada, and Ryuzo Horiuchi

64 **Strategies and Implications of Noise Pollution Monitoring, Modelling, and Mitigation in Urban Cities** 1571
S. K. Tiwari, L. A. Kumaraswamidhas, and N. Garg

65 **Development of Calibrated and Validated SODAR with Reference of Air Quality Management** 1595
Kirti Soni, Anjali S. Nair, Nishant Kumar, Parag Chourey, Nirbhow Jap Singh, and Ravinder Agarwal

66 **Measurements of Indoor Air Quality** 1621
Atar Singh Pipal and Ajay Taneja

67 **Instruments for Monitoring Air Pollution and Air Quality** 1657
S. K. Gupta and Balbir Singh

68 **Traceability in Analytical Environmental Measurements** 1707
Shweta Singh, Monika J. Kulshrestha, and Nisha Rani

69 **Particulate Matter Measurement Techniques** 1749
Kritika Shukla and Shankar G. Aggarwal

Volume 3

Part XII Metrology in Bio-medical Engineering **1779**

70 **Precision Measurements in Healthcare Systems and Devices** 1781
Ravinder Agarwal, Amod Kumar, and Sanjay Yadav

71 **Assessment and Elimination of Surgeon Hand Tremor During Robotic Surgery** 1791
Amod Kumar, Sanjeev Kumar, and Akhlesh Kumar

72 **Metrological Aspects of Blood Pressure Measurement** 1827
Rahul Kumar, P. K. Dubey, and Sanjay Yadav

73 **Glucose Monitoring Techniques and Their Calibration** 1855
Deepshikha Yadav, Surinder Pal Singh, and P. K. Dubey

74 **Advancements in Measuring Cognition Using EEG and fNIRS** 1879
Sushil Chandra and Abhinav Choudhury

75 **Metrological Aspects of SEMG Signal Acquisition, Processing, and Application Design** 1919
Rohit Gupta, Inderjeet Singh Dhindsa, and Ravinder Agarwal

76 **Artificial Intelligence for Iris-Based Diagnosis in Healthcare** 1963
Ravinder Agarwal, Piyush Samant, Atul Bansal, and Rohit Agarwal

77 **Use of Metrological Characteristics in Ultrasound Imaging and Artificial Intelligence Techniques for Disease Prediction in Soft Tissue Organs** 1995
Kriti and Ravinder Agarwal

Part XIII Legal Metrology and Global Trade 2029

78 **Legal Metrology and Global Trade** 2031
G. R. Srikkanth

79 **Standardization and Regulatory Ecosystem in India** 2053
Bharat Kumar Yadav

80 **Sanctity of Calibrations** 2095
Anil Jain

Part XIV Radiation Metrology and National Standards 2115

81 **Radiation Dosimetry** 2117
Subhalaxmi Mishra and T. Palani Selvam

82 **Equipment for Environmental Radioactivity Measurement: Calibration and Traceability** 2143
Manish K. Mishra and A. Vinod Kumar

83 **Radiation Metrology and Applications** 2179
V. Sathian and Probal Chaudhury

84 Occupational Radiation Monitoring in Indian Nuclear Industry 2207
M. K. Sureshkumar and M. S. Kulkarni

85 Relevance of Radiometric Metrology in NORM Industries and Radiological Safety 2237
S. K. Jha, S. K. Sahoo, M. S. Kulkarni, and Dinesh K. Aswal

86 Metrological Concepts for Ionizing Radiation in Medical Applications 2265
Hala Ahmed Soliman

87 Nuclear Forensics: Role of Radiation Metrology 2293
S. Mishra, S. Anilkumar, and A. Vinod Kumar

Part XV Advanced Techniques in Evaluation of Measurement Uncertainty **2321**

88 Advanced Techniques in Evaluation of Measurement Uncertainty 2323
N. Garg, Vishal Ramnath, and Sanjay Yadav

89 Monte Carlo Simulations in Uncertainty Evaluation for Partial Differential Equations 2331
Vishal Ramnath

90 Modern Approaches to Statistical Estimation of Measurements in the Location Model and Regression 2355
Jan Kalina, Petra Vidnerová, and Lubomír Soukup

91 The Quantifying of Uncertainty in Measurement 2377
Ahmed A. Hawam

92 Measurement Uncertainty 2409
C. V. Rao

93 Evaluation and Analysis of Measurement Uncertainty 2441
H. Gupta, Shanay Rab, and N. Garg

94 Application of Contemporary Techniques of Evaluation of Measurement Uncertainty in Pressure Transducer 2457
Shanay Rab, Jasveer Singh, Afaqul Zafer, Nita Dilawar Sharma, and Sanjay Yadav

Index 2471

About the Editors

Dr. Dinesh K. Aswal is the present Director of Health, Safety and Environment Group, Bhabha Atomic Research Center, Mumbai. He is an accomplished scientist of international repute in the areas of metrology and condensed matter research (molecular electronics, organic solar cells, thermoelectrics, superconductivity, low-dimensional materials, gas sensors, etc.). His current focus is to enhance the metrological capabilities of India at par with international standards and to strengthen the "quality infrastructure (metrology, accreditation, and standards)" of India for inclusive growth and for its quick transformation from a developing state to a developed state. His "Aswal Model" puts accurate and precise measurements traceable to SI units at the core of four helices (government, academia, industry, and civil society) responsible for the inclusive growth. He has edited 9 books, contributed over 30 book chapters, published over 500 research papers (H-index of 53), and filed 9 patents. He is an elected fellow of National Academy of Sciences, India (NASI); Academician, Asia Pacific Academy of Materials; and Fellow, International Academy of Advanced Materials (Sweden). He had visiting Professor/Scientist positions at Institut d'Electronique de Microelectronique et de Nanotechnologie (France), Shizuoka University (Japan), Commissariat à l'Energie Atomique (France), Weizmann Institute of Science (Israel), University of Yamanashi (Japan), University of Paris VII (France), Karlsruhe Institute of Technology (Germany), University of South Florida (USA), etc. He is recipient of several international/national fellowships, including JSPS (Japan), BMBF (Germany), EGIDE (France),

Homi Bhabha Science and Technology Award, DAE-SRC outstanding Research Investigator Award, HBNI Distinguished Faculty award, etc. He has also served as Chairman (Interim), National Accreditation board of Testing and Calibration Laboratories (NABL), Gurugram (2019–2020); Director, Additional Charge, CSIR-Central Electronic Research Institute, Pilani (2019–2020); Director, Additional Charge, CSIR-NISTADS, New Delhi (2018–2019); and Secretary, Atomic Energy Education Society (AEES), Mumbai (2012–2015).

Prof. Sanjay Yadav born in 1962, obtained his master degree in science (M.Sc.) in 1985 and Ph.D. degree in Physics in 1990. Presently, he is working as the Editor-in-Chief (EIC) of the MAPAN: The Journal of Metrology Society of India. He is also Vice President of Metrology Society of India (MS), New Delhi, as well as Vice President of Ultrasonic Society of India (USI), New Delhi. He is Former Chief Scientist and Head, Physico-Mechanical Metrology Division of NPL and also Former Professor, Faculty of Physical Sciences, Academy of Scientific and Innovative Research (AcSIR), HRDG, Ghaziabad. He had taught "Advanced Measurement Techniques and Metrology" course, taken practical classes, and supervised graduate, master, and Ph.D. students since 2011. He is the recipient of research scholarships from the Ministry of Home Affairs, India (1986); CSIR, India (1988); Col. G.N. Bajpayee Award of Institution of Engineers, India (1989); Commendation Certificates from Haryana Government (1991 and 1992); JICA Fellowship of JAPAN (1998), Commendation Certificates from SASO, Saudi Arabia (2003); three Appreciation Certificates from Director, NPL (2005); Managing Editor, MAPAN (2006–2014); nominated as Member of APMP Technical Committee of Mass Related Quantities (TCM), Australia (2013–2019); Nominated as Country Representative in APMP, China (2019); Vice President, Metrology Society of India (2020); Member, National Advisory Committee, NCERT, Delhi (2019); Members, Testing and Calibration Advisory Committee, BIS (2019, 2020, and 2021); and very recently received a prestigious International award, i.e., APMP Award for Developing Economies,

China (2020). He has significantly contributed in the field of pressure metrology, biomedical instrumentation, ultrasonic transducers, and instrumentation systems. His current research interests include research and developmental activities in physico-mechanical measurements; establishment, realization, maintenance, and up-gradation of national pressure and vacuum standards; dissemination of national practical pressure scale to users through apex level calibration, training, and consultancy services; inter-laboratory comparisons, proficiency testing program, and key comparisons; implementation of Quality System in the laboratory as per ISO/IEC 17025 standard; and Finite Element Analysis (FEA) and Monte Carlo Simulations for pressure balances. He has published more than 450 research papers in the national and international journals of repute and conferences, 20 books, 14 patents and copyrights, supervised 8 PhDs (another 5 in waiting), drafted several projects, scientific and technical reports, documents, and policy papers.

Dr. Toshiyuki Takatsuji was born in 1964, graduated from Kobe University in 1998, finished the master course in 1990, and received PhD in 1999. He started his carrier as a scientist from National Research Laboratory of Metrology (NRLM) in 1990. From 1994 to 1996, he stayed in National Measurement Laboratory (NML), Commonwealth Scientific and Industrial Research Organization (CSIRO) of Australia as a visiting scientist. In 2001 NRLM was restructured to National Metrology Institute of Japan (NMIJ), National Institute of Advanced Industrial Science and Technology (AIST). From 2015 to 2020 he was the director of Research Institute for Engineering Measurement (RIEM), NMIJ.

His research interests are on length and dimensional metrology, in particular laser interferometry and coordinate metrology and he has published numerous research papers.

He was awarded the Best Paper Award by Japan Society of Precision Engineering in 2006, The Commendation for Science and Technology by the Minister of Education, Culture, Sports, Science and Technology, Prizes for Science and Technology, Research Category

in 2009, 46th Ichimura Science Award, and a Contribution Award by The New Technology Development Foundation in 2014.

He has taken lots of national and international positions including the Chair of Asia Pacific Metrology Programme (APMP) from 2016 to 2019, a member of CIML International Committee of Legal Metrology) from 2020, an expert of ISO/TC 213 (Geometrical Products Specifications)/WG 10 (Coordinate Measuring Machines), the project leaders of ISO 10360-8 (CMM with optical distance sensors) and ISO 10360-11 (X-ray CT), and an expert of ISO/TC 172 (Optics and Photonics)/SC 4 (Telescopic systems).

Prem Rachakonda is a mechanical engineer in the Intelligent Systems Division at NIST. His work primarily addresses technical and standardization activities for industrial metrology, automation, autonomous vehicle perception, and strategic planning. His current research efforts are focused on developing the necessary measurement science to verify and validate 3D vision systems used for manufacturing automation, and autonomous vehicle applications.

Dr. Harish Kumar received the B.Tech. degree in Mechanical and Automation Engineering and the Ph. D. degree in Mechanical Engineering from Guru Gobind Singh Indraprastha University, New Delhi, India, in 2003 and 2015, respectively. His thesis was on design and development of force transducers. He worked at National Physical Laboratory, New Delhi, India, during 2007 to 2017 as Scientist and worked in the force and mass metrology. He has worked in the design and development of Kibble balance. Since 2017, he has been working at the National Institute of Technology Delhi, India, and currently working in additive manufacturing in addition to metrology. He has published more than 100 papers in peer-reviewed journals/conferences of repute.

About the Associate Editors

Dr. Meher Wan is a Scientist at CSIR - National Institute of Science Communication and Policy Research, New Delhi. He completed his Ph.D. in Physics from the University of Allahabad and worked as an Institute-Post Doctoral Fellow at the Indian Institute of Technology-Kharagpur, India. He has been actively involved in setting up a Micro/Nano-Robotics and Fabrication Facility at the Advanced Technology Development Centre, Indian Institute of Technology-Kharagpur. He played a key role making the design of the facility, from pre-installation preparations to installations of sophisticated instruments. He has expertise in electron microscopy, micro-nano-fabrication technologies like focused ion beam lithography, electron beam lithography, two-photon polymerization-based 3D lithography, etc. including micro-robotic manipulation. His interests span through materials sciences, ultrasonics, and metrology in general. He is an Associate Editor of a popular science magazine *Science Reporter* and a Scientific Editor of the *Indian Journal of Pure and Applied Physics* (IJPAP). He is a member of the prestigious Indian National Young Academy of Science (INYAS-INSA). He is a member of executive councils of several scientific societies such as Ultrasonic Society of India, Indian Science Writers' Association, etc. and is a life member of a number of prestigious professional bodies.

Dr. Shanay Rab is currently a Lecturer at the School of Architecture, Technology and Engineering, University of Brighton, United Kingdom. He is a Mechanical Engineer, obtained his M.Tech. from IIT (ISM), Dhanbad, India, with specialization in Machine Design. He has obtained his doctorate degree from Jamia Millia Islamia and CSIR - National Physical Laboratory, New Delhi, India, in the area of pressure metrology and mechanical system design. He has published several scientific research papers in reputed journals like *Nature Physics*, *Measurement*, *Review of Scientific Instruments*, *Journal of Engineering Manufacture*, *Mapan*, *JSIR*, *IJPAP*, etc. His research interests include Manufacturing Processes, Machine Design, Pressure/Force metrology, Quality Infrastructure, Finite Element Analysis, and Additive Manufacturing. He is also actively involved in science communication.

Abstract

Metrology, the science of measurement, has evolved significantly throughout human history. Early forms of the measurements were based on human body parts, such as the foot and the hand, which were later standardized in ancient civilizations such as Egypt and Greece. With the invention of more advanced tools, such as the telescope and the microscope, measurements of astronomical and subatomic phenomena became possible. In the eighteenth and nineteenth centuries, the development of the metric system and the use of precision instruments, such as the balances and clocks, have greatly improved the accuracy of the measurements. Today, metrology continues to evolve with the use of computer technology and advanced sensors, allowing for even greater precision and automation in measurement. For that, the International System of Units (SI) plays an important role and is considered as the heart of the metrology and measurement system. Thus, it is of utmost importance to understand how the SI system is evolved historically. This system provides a standardized set of

https://doi.org/10.1007/978-981-99-2074-7_2

units for all types of measurements, making it easier for scientists, engineers, and researchers to communicate and share data across different countries and disciplines. One of the main benefits of the SI system is its consistency and coherence. The SI system also allows for easy updates and improvements. The current SI system is based on fundamental constants of nature; it can easily be updated to reflect new scientific discoveries or technological advancements. The historical development of the measurement system is the primary subject of the present chapter. The chapter focuses on how measurement systems have changed and grown throughout history, from the ancient scriptures to the present-day SI unit system. Various time periods have been taken into consideration as per available literature on measurement systems that show the paradigm shifts in the measurement of different quantities. Also discussed is the current state-of-the-art SI unit system. The current study would provide a succinct report on numerous metrological advancements from the prehistoric to modern eras.

Keywords

Metrology · SI units · Fundamental constant · Measurement · Traceability

Introduction

Humans realized a long ago that they needed to rely on each other as they developed into a civilization, began to cultivate, and lived in communities. Due to the opening up of trade, a measure was definitely needed. Various parts of the body used as points of reference for measurements are clearly evident throughout recorded history. The units that were based on the body parts were arbitrary and unseemly but surely relevant during the period of use. Due to the fact that each individual's body part size is unique, the results of the measurements vary from person to person. This led to issues with both international trade and day-to-day business dealings. The necessity for precise measurement was recognized in order to get over the limitations of using body parts as units and to ensure that the measurement methods remain uniform. To achieve this, the need for the development of universally accepted measurement standards was in focus to improve the reliability and accuracy of the measurements. As a result, measurements performed become coherent and consistent. This resulted in a standardized set of measurement units, known as standard units, for the sake of uniformity (Fanton 2019; Gupta 2009; Rab et al. 2020; Aswal 2020a; Frisinger 2018; Himbert 2009; Fletcher 1968; Shalev 2002).

The International System (SI) of Units for physical quantities is very important in the present era and serves as a tool for any scientific advancement in different countries. Modern metric systems of measurement are almost universally accepted and used in science, engineering, technology, international trade, and commerce. As science progresses, cutting-edge technologies emerge that necessitate measurements

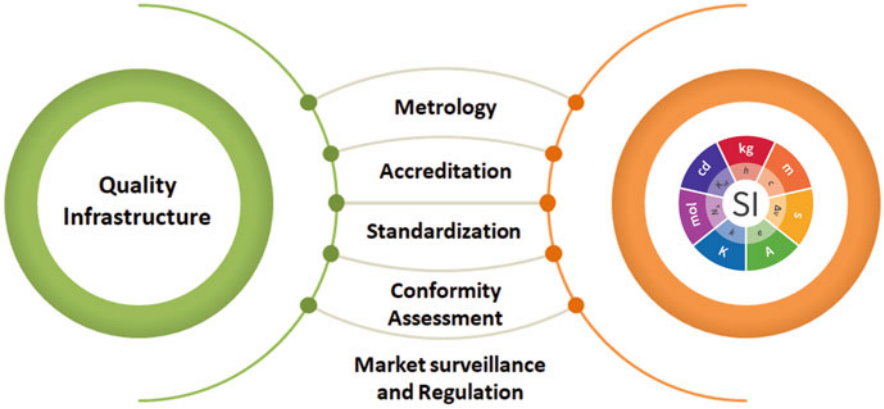

Fig. 1 Linkage of quality infrastructure and SI units

that are ever more exact and accurate. New and improved measurement procedures, measurement standards, and their definitions have been developed as a result of the introduction of new technologies, which have increased the accuracy of the products (Yadav and Aswal 2020; Schlamminger et al. 2020; Stock et al. 2019; Abd Elhady 2020; Göbel and Siegner 2019; Milton and Donnellan 2019).

The foundation of a robust national quality infrastructure (QI), which is necessary for any country's overall growth and success, is profaned by the SI unit system. It consists of the three basic pillars of metrology, standardization, and accreditation that support a strong QI in any nation. Figure 1 shows the basic linkage of QI and SI units. The QI, a fundamental enabling system for providing conformity assessment such as calibration and testing, certification, and inspection, was developed on a technical hierarchy to ensure the accuracy and precision of measurements traceable to SI units (Rab et al. 2020, 2021a, b; Aswal 2020b; ▶ Chap. 5, "Quality Measurements and Relevant Indian Infrastructure"; Kumar and Albashrawi 2022; Mandal et al. 2021; Harmes-Liedtke and Di Matteo 2011).

The advancements in metrology that brought about the current state of the art in the SI unit system are discussed in the section that follows. The early historical method of uniform measurement is discussed in section "Early Historical Evolution of Measurements" of this chapter. The history of measurements was presented through a timeline that concentrated on significant events. The process of uniform measurement is discussed in section "French Revolution and Progress Toward the Uniform Measurement System" in relation to the French Revolution and its impact. At its 26th conference, the CGPM finalized the redefined SI unit system. The reasons for the changes are discussed in section "Current Status of SI Unit System" along with the current status of seven SI units and the 27th CGPM's significant decision on SI unit prefixes. Section "Future of Metrology" provides the future of metrology with the connection of digital transformation and its implications for metrology going forward.

Early Historical Evolution of Measurements

The expansion of agriculture necessitated the establishment of a system of measurements in order to quantify the distribution of crops and the amount of food consumed by families. In order to manage population growth and combat hunger throughout the shift of humankind from nomadic bands to settled agricultural settlements, metrology was essential.

China, India, Egypt, and Mesopotamia (modern Iraq) are the four great antiquity civilizations. All possessed an early understanding of metrology (Maisels 1999; McClellan III and Dorn 2015; Moore and Lewis 2009). The precise measurements of Egyptian pyramids demonstrate a high level of meticulousness even during that period (Procter and Kozak-Holland 2019; Baker and Baker 2001). The earliest known samples from the early Indus Valley Civilization, dating approximately 5000 BCE, are where the history of measurement methods in India began (Rab et al. 2020; Javonillo 2011). Along with Mesopotamia and Egypt, the *Harappa* civilization is regarded as one of the earliest and largest civilizations in recorded history. Standardized weights and measurements were significant innovations of this civilization, which was located along the banks of the *Indus* Valley. It has been discovered that the *Harappan* civilization had well-established length measurement standards. Bricks' length, breadth, and width were all significantly adopted in 4:2:1 regulation ratio. This ratio, which was found to stay constant when brick constructions were being built, indicates that civilization had at least a fundamental understanding of the requirement for a measurement standard in construction. It is considered that *Mohenjo-Daro* was the largest city of the *Harappan* civilization (Jansen 2014). In the city, every building was connected by subterranean drainage pipes as part of sanitation. This perspective demonstrates the significance of measurements in the technological advancements as well as their rise and growth in this civilization. The corbelled drain that serves as the Great Bath's (Vidale 2010; Das 2022) exit at *Mohenjo-Daro* is around 1.8 m tall (Fig. 2), or 108 *Angulas* at a length of 16.764 mm apiece. The reference (Gupta 2009; Rab et al. 2020; Singh 2019; Shrivastava 2017; Sharma et al. 2020a; Kenoyer 2010) gives a list of the various length measurement units used throughout the *Harappan* period.

As previously mentioned, the history of Indian measurement systems indicates that the earliest existing samples belong to the fifth millennium BC, marking the beginning of the early Indus Valley Civilization. Yet, some of the historical statements/mentions on the history of measurement were also witnessed in numerous ancient books like Vedas, Bhagavata Purana, Vishnu Puran, Mahabharata, Suryasidhanta, etc. The ancient Indian scriptures include a wealth of knowledge on the many ways and methods used in ancient India to measure length and time. It was then observed that, interestingly, the speed of light as described in the Vedic literature worked out to be exactly equal to the speed of light as determined by modern measurements when compared to this formerly utilized unit of length measurement used during the Harappa civilization period. Many works of Vedic

Fig. 2 *Mohenjo-daro*'s Great Bath (Public domain)

literature make evident the Yojana's use as a prehistoric length measurement unit (Rab et al. 2020; Gupta 2020a).

In the Indian subcontinent, three important Mughal structures – the Taj Mahal, Moti Masjid, and Jamah Masjid – are described in great detail in the Persian text "*Shah Jahan Nama*." The "*Shah Jahan Nama*" also provides the size of these three structures in "*Gaz*" unit (Andrews 1987). It is important to note that the length of a *Gaz* to be 80.5 cm, which is precisely equal to half of a *Dhanusha*, or 96 *Angulas*, in Taj Mahal and River Front columns of Agra. The "*Angulam*" and its multiples "*Vitasti*" (12 *Angulam*) and "*Dhanusha*" (108 *Angulam*) have been used as the units of measurement from the *Harappan* era up until the premodern era when the Taj Mahal was constructed (Rab et al. 2020; Balasubramaniam 2005, 2009, 2010a). For example, the uniform dimensions in the construction of Mughal structures are shown in Fig. 3.

Further, it is assumed that the weights, which were used in conjunction with a crude balance for commerce, were most likely seeds, beans, or grains. There is no evidence of any attempt to establish a permanent standard before the enormous Khufu Pyramid was built in Egypt around 2900 B.C. Natural standards of length like the hand, span, palm, and digit were employed from the beginning. The first pharaoh to order the establishment of a fixed unit of measurement was Khufu (Moffett et al. 2003). The

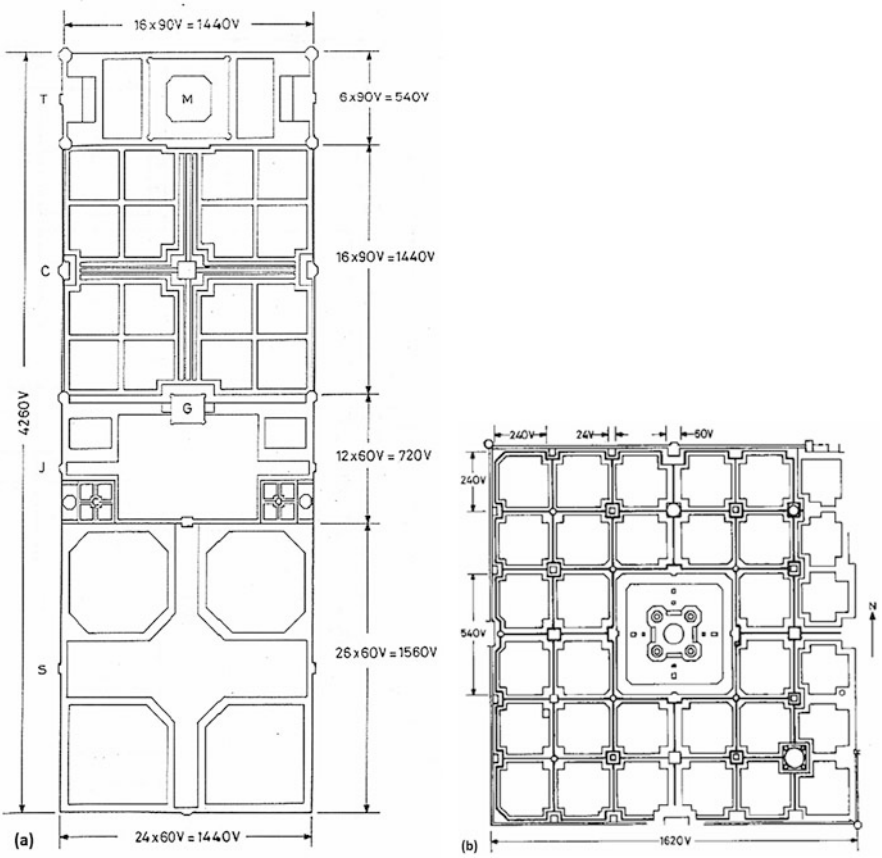

Fig. 3 (**a**) Dimensions of entire complex of Taj Mahal in Agra. (**b**) Dimensions of entire complex of Humayun's tomb at New Delhi; The *Vitasti* (V) equals 12 *Angulams* and each *Angulam* measures 1.763 cm (Balasubramaniam 2010b)

Royal Egyptian Cubit, a standard constructed of black granite, was selected (Hirsch 2013). According to history, it was as long as the forearm and hand of the ruler Pharaoh. For a while, the Egyptians, Greeks, and Romans were only partially successful in creating practical measurement systems and standards that were recognized and followed across their countries (Lewis 2001; Heath 2013; Cuomo 2019). These systems were rather robust and practical despite all of their flaws, but, more importantly, the craftspeople that used them appreciated and accepted them.

As previously indicated, the rise and fall of numerous dynasties and empires occurred in the region over the course of the history of measuring, which spans a period of more than five thousand years. The historical chronology in Table 1 includes significant developments in ancient and medieval metrology.

Table 1 Timeline of the major ancient events related to metrology

Year	Metrological history/Progress	References
~5000 BCE (Before Common Era)	Egypt, Elam (now in Iran), Mesopotamia (currently in Iraq and its environs), and the Indus Valley (now parts of India, Pakistan, and Afghanistan) appear to have employed various standards. The early measurement standards and several measurement instruments are still on display at different museums. Some structures, like the Egyptian pyramids, are still standing and can be measured precisely. Early techniques for determining length relied on using human body parts. It seems that the lengths and widths of fingers, thumbs, hands, hand spans, cubits, and body spans were often used as measurements	Rab et al. (2020), Moore and Lewis (2009), Lyonnet and Dubova (2020), Cooperrider and Gentner (2019)
~3100 to 2181 BCE	During the time known as the Old Kingdom in Egypt, the construction of pyramids began	Bárta (2005), Spence (2000)
~3000 BCE	The people of ancient India are thought to have used length measures such as the *Dhanusha* (or bow suggesting a length based on how far you could shoot an arrow); the *Krosa* (or cow-call suggesting a distance from which you could hear a cow); and the *Yojana* (or stage suggesting a distance of how far you would walk before taking a rest break) The peoples of Egypt, Mesopotamia, the Indus Valley, and in Iran devised the earliest known uniform weights and measures at about this time. Many different cubits of different lengths were used. In addition, the cubit, the length from your elbow to the tip of the middle finger, was divided in different ways	Rab et al. (2020), Gupta (2020a, b), Kher (1965)
~3000 BCE	The Sumerian numeric system was introduced. Living in what is now known as Southern Iraq, the ancient Sumerians had a numeric system with 60 as its base. It is thought to have come from their observations of the stars	Powell Jr (1971), Diakonoff (1983)
~2750 BCE	The cubit is found in ancient Egypt and is considered the first recorded standard of length measurement. The Pharaoh's forearm, measured from the end of his forefinger to the middle of his elbow, served as its standard	Hirsch (2013)

(continued)

Table 1 (continued)

Year	Metrological history/Progress	References
~2600 BCE	The people of the Indus Valley were highly accurate at measuring length, mass, volume, and time	Rab et al. (2020), Jarrige and Meadow (1980)
~2500 BCE	The great pyramid of Giza was built in Egypt. Along each side of the base, 440 royal cubits (about 230 meters) were used to construct this pyramid	Bartlett (2014), Herz-Fischler (2009)
~1800 BCE	At this period, water clocks (clepsydra) were also in use in Mesopotamia. The Babylonians, Assyrians, and Persians were the Sumerian civilization's successors, and they all continued to utilize a variety of standards	Brown et al. (1999), Woods and Woods (2011)
~1766 to 1122 BCE	During the Shang Dynasty, China adopted a decimal-place number system. Ten was written as ten-blank, eleven as ten-one, and zero was left as a blank space for numbers like 405, which was represented as four-blank-five in Chinese characters	Lay-Yong (1986), Lay-Yong and Tian-Se (1986)
~1500 BCE	Egyptians used sundials to keep track of the position and length of the shadows cast on a defined circular surface, which allowed them to measure the passing of time	Sloley (1931), Remijsen (2021)
~800 BCE	The foot was used as a unit of measurement by the ancient Greeks and Romans. In Greece, its size might range from 270–350 mm. An average Roman foot typically measures about 295.7 mm, but in the provinces, a larger length of 334 mm is employed. Today's foot measures 304.8 mm, or 12 inches, which is slightly longer than the original Roman foot	Parvis (2018), Stone (2014)
~425 BCE	Greek philosopher Plato studied under Socrates and instructed Aristotle. All three laid the foundation for our current conceptions of reasoning, philosophy, and mathematics, many of which are frequently used in metrology	Peters (1967), Koutsoyiannis and Mamassis (2021), Dossey (1992)
~321 BCE to 185	The Arthashastra contains extensive documentation on the foundations of legal metrology and other measurement systems	Rab et al. (2020), AM (2003), Rahman et al. (2014)
~300 BCE to 185 AD	One of the longest-reigning dynasties in history was the Chola, a Tamil thalassocratic empire in Southern India. They have well-established water storage	Datta-Ray (2009), Raj et al. (2017)

(continued)

Table 1 (continued)

	tanks, canals, and shipping technology for trade and commerce	
~250 BCE	Archimedes of Syracuse wrote that the earth revolved around the sun. Archimedes is considered to have invented astronomical devices which could identify the positions and motions of the sun, moon, and planets	Pfeffer (n.d.), Wright (2017)
~221 BCE	Chinese weights and measurements were defined by Shih Huang Ti. As part of a plan to unite the country, Emperor Shi Huang Ti intended to implement a significant change in Chinese measurement	Martzloff (2007)
~200 BCE	Before 200 BCE, the Indian mathematician Brahmagupta is credited with inventing "0" in the *Bakhshali* Manuscript. The word "zero" comes from the Sanskrit word *Shunya*, which means "empty" or "blank." By Arab writers, this was rendered as "sifr (empty)," then by Latin writers as "zephirum," and lastly by English speakers as "zero" or "cypher"	Kaye (1919), Puttaswamy (2012), Dutta (2002), Mattessich (1998)
~9 CE (Common Era)	China's measurements were standardized by Emperor Wang-Mang. These are referred to as "the Wang-Mang good measures"	Wang (1996), Hegesh (2020)
~40 CE	A device that Heron of Alexandria described as a "*Dioptra*" may have been invented around 150 BCE. The word "*Dioptra*" is a Greek word that means "to see through." A *Dioptra*, the predecessor of the modern theodolite, was used to measure angles precisely	Papadopoulos (2007)
~830 CE	In his book *Kitab fial-jabrw'al-Muqabala*, the Arab mathematician Abu Ja'far Muhammad ibn Musa al-Khwarizmi discussed the use of 0 (zero). From that term, the area of mathematics where symbols are used to establish fundamental mathematical ideas is known as "algebra"	Sen and Agarwal (2015)
~1196 CE	The first record of a standardized unit of measurement was established during an "*Assize of Measures*" that was declared by King Richard I of England	Scorgie (1997), Williams (2020a)
~1215 CE	The Barons of the English King John, sometimes known as "Lackland," made him sign a contract known as the Magna	McKechnie (2022)

(continued)

Table 1 (continued)

Year	Metrological history/Progress	References
	Carta, which included a provision for standard weights and measures	
~1543 CE	The solar system as proposed by Nicolas Copernicus, with the sun at the center and the planets revolving around it, was published	Zielinska (2007), Sagan (1975)
~1636 CE	In order to determine the speed of sound, Marin Mersenne measured how long it took an echo to travel a predetermined distance. His sound speed was within 10% of the current standard value	Finn (1964), Lindsay (1966)
~1643 CE	The mercury barometer was invented by Evangelista Torricelli	Karwatka (2015)
~1672 CE	Regarding the nature of light and color, Isaac Newton published new theories. When two flat pieces of glass were pressed together, he observed circular bands of rainbow-like colors. It became known as Newton's rings	Naughtin (2012), Greated (2011)
~1687 CE	*Philosophiae Naturalis Principia Mathematica*, also known as *Principia Mathematica*, is a work by Sir Isaac Newton that was published by the Royal Society	Newton (1833), Bussotti and Pisano (2014)
~1742 CE	Anders Celsius built his Celsius thermometer for his meteorological measurements, using 0 °C for the boiling point of water and 100 °C for the freezing point	Beckman (1997)
~1744 CE	Swedish naturalist, Carl Linnaeus suggested reversing the temperature scale of Anders Celsius so that 0 degree represented the freezing point of water (273.15 K) and 100 degrees the boiling point (373.15 K). The centigrade temperature scale was developed from this, and it gradually spread over the globe	Naughtin (2012), Clarke (2017)
~1750	The Industrial Revolution begins. Every facet of daily life is altered by the Industrial Revolution, which transforms rural cultures into ones that are dominated by large-scale industry and urbanization. These advancements are driven by significant coal and iron ore resources, which offer an alternate source of energy to traditional human power. In 1713, the first practical steam engine is developed; by the turn of the century, upgraded versions of the engine are powering	Hill (2018), Hills (1993)

	equipment, trains, and ships. Together with the development of the telegraph, these advancements in transportation have shrunk the planet and sped up communication. Globalization starts, and with it the demand for trustworthy, precise measurement increases	
1790s	The metric system was first implemented during the French Revolution	Frey et al. (2004), Hallerberg (1973)

French Revolution and Progress Toward the Uniform Measurement System

The French Revolution made an impact in the measurement and metrology fields for social and ethical reasons. According to the Republic's motto and the aspirations of the populace as recorded in the *cahiers de doléances* (peoples' claim books), the unit system should be distinct and equal for all. The planned reforms were successful in the majority of areas, and eventually other nations, first in Europe and then beyond, copied them (Hunt 1840). Figure 4 shows the graphical illustration used during the late 1800s to represent the various standards for measurement. During the Revolution in 1789, various quantities connected with each unit might vary from town to town and even from trade to trade; it has been claimed that there were up to a quarter of a million alternative definitions for the 800 or so units of measure in use in France on the eve of the Revolution. Many traders opted to use their own measuring tools, which opened the door to fraud and hampered trade and industry. Local entrenched interests encouraged these discrepancies, which hampered trade and taxation.

The *Académie des sciences* appointed eminent French scientists to explore weights and measures in 1790 (Crosland 2005). After examining numerous options, scientists came up with a number of suggestions for a new system of weights and measures throughout the course of the following year. They proposed that the definition of a unit of weight is a cube of water whose dimension was a decimal fraction of the unit of length and that the definition of a unit of length is based on a fractional arc of a quadrant of the earth's meridian. On March 1791, the French Assembly approved the proposals. Two explorers, Pierre Méchain and Jean Baptiste-Delambre, were given the task of measuring this distance – the earth's quarter circumference – in 1792. After more than 6 years, the meter was established in 1798 (Sharma et al. 2020a; Murdin 2009). The initial step in the establishment of the current International System of Units was the deposit of two platinum standards, one for the kilogram and one for the meter, at the *Archives de la République* in Paris on June 22, 1799 (Fischer and Ullrich 2016; Nelson 1981).

Napoleon III authorized the formation of an international scientific commission in 1869 to spread the new metric measurement system and enable measurement comparisons across nations. The French government extended an invitation for

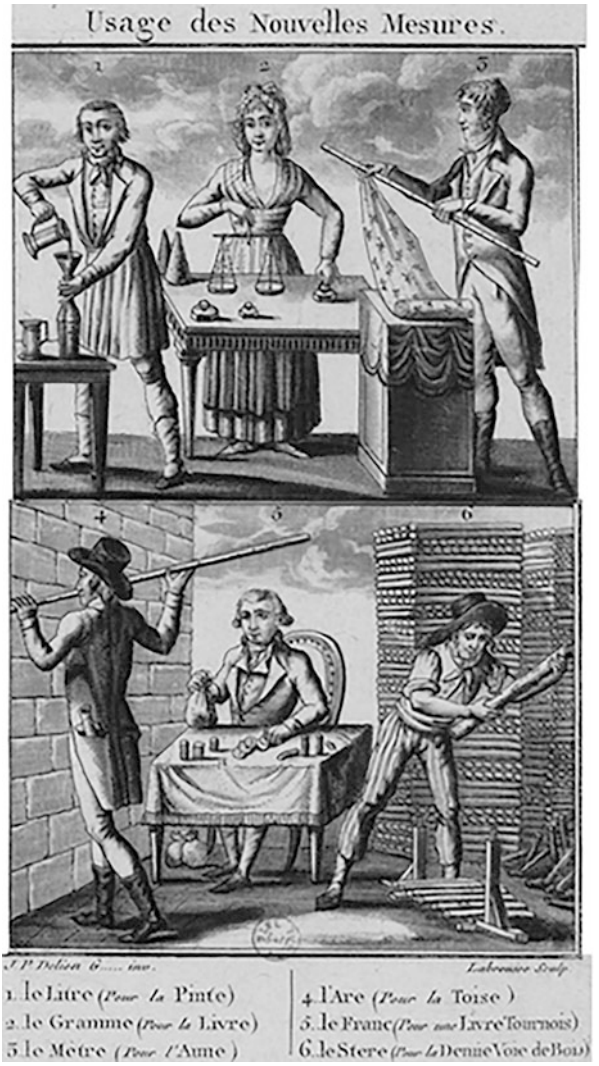

Fig. 4 Illustration of uniform measurement during the French Revolution (Public domain)

nations to join the panel later that year. In 1870, the newly established International Metre Commission held its inaugural meeting. This community ultimately resulted in 17 countries signing the Metre Convention on May 20, 1875. The meter and kilogram, which were determined by the physical artifacts that had been made, and the second, which would be based on astronomical time, were the three units that were agreed upon, regardless of the fact that the agreement was termed the "Metre Convention" (Quinn 2004). The first General Conference on Weights and Measures (CGPM) delegates approved new international prototypes of the meter and kilogram in 1889 (Quinn 2017a; Gupta 2020b; Stock 2018). The time-to-time progress of world metrology is listed in Table 2.

Table 2 Major development in metrology after the French Revolution

Year	Progress in metrology	References
1790s	The meter and kilogram were the only unit of measurement used when the metric system was originally introduced during the French Revolution	Quinn (2004), Smeaton and Ely (2000)
1791	The French Assembly authorized a survey between Dunkirk and Barcelona to determine the length of the meridian and endorsed the suggested guidelines for the new decimal system of measurement made by the expert committee	Williams (2014), Quinn (2011)
1792	The units of length, area, capacity, and mass were given the designations meter, square, liter, and grave, respectively, by the expert's committee	Quinn (2017a)
1795	The eight SI prefixes that were officially adopted are deca, hecto, kilo, myria, deci, centi, milli, and myrio, derived from Greek and Latin numbers. Initially, all were represented by lowercase symbols	Brown (2022, 2019)
1799	The final standard *mètre des Archives* and *kilogramme des Archives* were deposited in the Archives nationales after Pierre Méchain and Jean-Baptiste Delambre finished the meridian survey	Smeaton and Ely (2000), Swindells (1975)
1830s	The principles of a coherent system based on length, mass, and time were established by Carl Friedrich Gauss	Williams (2020b)
1860s	The demand for a coherent system of units comprising base units and derived units was developed by a group working under the auspices of the British Association for the Advancement of Science (BAAS)	Nye (1999)
1874	The CGS system, based on the three mechanical units of the centimeter, gram, and second, and using prefixes ranging from micro to mega to indicate decimal submultiples and multiples, was introduced by the BAAS	Quinn (2001)
1875	The signing of the Metre Convention. At the Pavillon de Breteuil in Sèvres, the International Bureau of Weights and Measures (BIPM) was established, officially initiating the development of new metric prototypes. The obligation for comparing the kilogram and meter to established prototypes was transferred from French to international management by the Treaty of the Metre. The convention originally included standards for only meter and kilogram	Quinn (2017b)
1889	First General Conference on Weights and Measures (CGPM) approved the eight prefixes (deca, hecto, kilo, myria, deci, centi, milli, and myrio) for use	Cardarelli (2003a)
1889	The British company Johnson, Matthey & Co. produced a set of 30 prototype meters and 40 prototype kilograms, which were approved by the CGPM. In each case, the prototypes were built of an alloy consisting of 90% platinum and 10% iridium	Grozier et al. (2017), Ehtesham et al. (2020)

(continued)

Table 2 (continued)

Year	Progress in metrology	References
1921	All physical quantities, including electrical units as originally specified in 1893, are now covered by the Treaty	Nelson (1981)
1946	The magnetic constant, μ_0, also referred to as the permeability of free space, was approved to be fixed exactly as 4×10^{-7} N/A^2 in the new definition of the ampere, which was being used before as mechanical units for measuring length, mass, and time	Goldfarb (2018)
1948	The International Committee for Weights and Measures (CIPM) was commissioned to conduct an international study of the measurement needs of the scientific, technical, and academia by the International Union of Pure and Applied Physics (IUPAP) and by the French Government at the Ninth General Conference on Weights and Measures (CGPM). They also asked the CIPM to make recommendations for a single practical system of units of measurement, suitable for adoption by all countries adhering to the Metre Convention	Stock et al. (2019)
1954	The 10th CGPM included two more base quantities – temperature and luminous intensity – making a total of six base quantities. Electric current was identified as the fourth basis quantity in the practical system of units. The meter, kilogram, second, ampere, degree Kelvin (later renamed kelvin), and candela were suggested as the six base units	Yadav and Aswal (2020), Newell (2014)
1960	The International System of Units, also known as SI, was given as the system's name by the 11th CGPM. The SI is also referred to as "the modern metric system" by the BIPM	Newell and Tiesinga (2019), Petrozzi (2013)
1960	In the SI system, two prefixes were made obsolete (myria and myrio) and six were added, including three for forming multiples (mega, giga, and tera) and three for forming submultiples (micro, nano, and pico)	Petrozzi (2013), Foster (2010)
1964	In the SI system, two prefixes for forming submultiples were added (femto and atto), creating a situation where there were *more* prefixes for small than large quantities	El-Basheer and Mohamed (n.d.)
1971	The 14th CGPM expanded the definition of SI by including a seventh base quantity, the amount of substance represented by the mole	Quinn (2001), Liebisch et al. (2019)
1975	The 15th CGPM introduced the grey (symbol Gy) for ionizing radiation and the becquerel (symbol Bq) for "activity referred to a radionuclide" to the list of named derived units	Newell and Tiesinga (2019)
1975	Two prefixes for forming multiples were added (peta and exa) in the SI unit system	Brown (2022)
1979	The sievert (Sv) was added to the list of named derived units by the 16th CGPM as the unit of dose equivalent in order to distinguish between "absorbed dose" and "dose equivalent"	Glavič (2021), Allisy-Roberts (2005)

(continued)

Table 2 (continued)

Year	Progress in metrology	References
1983	The definition of meter was changed at the 17th CGPM. The length that light would have traveled in a vacuum over a time span of 1/299,792,458 s was predicated on the exact value of the speed of light, c = 299,792,458 m/s	Giacomo (1984, 1983)
1991	Four prefixes were added to the SI unit system. Two for forming multiples (zetta and yotta) and two for forming submultiples (zepto and yocto)	Cardarelli (2003b)
1999	Catalytic activity's symbol kat was added to the list of named derived units in the 21st CGPM	Dybkaer (2000)
2007	In order to make the switch from explicit unit definitions to explicit constant definitions in the 23rd CGPM meeting, the CGPM recommended that the CIPM keep looking into ways to provide exact fixed values for physical constants of nature that could then be used in the definitions of units of measure in place of the International Prototype of Kilogram (IPK)	Milton et al. (2014), Cabiati and Bich (2009)
2018	The redefinitions of SI units have been adopted at the 26th CGPM. The redefined kilogram, the ampere, the mole, and the kelvin in terms of fundamental physical constants	Stock et al. (2019)
2019	Outcome of the CGPM at its 26th meeting in November 2018 has come into force from 20 May 2019, i.e., World Metrology Day	Davis (2019), Quinn (2019)
2022	Four prefixes in SI units were added in the 27th CGPM. Two forming multiples (ronna and quetta) and two for forming submultiples (ronto and quecto) are included in the family of SI unit prefixes	Brown and Milton (2023)

The creation of the decimal metric system during the French Revolution, as well as the subsequent deposit of two platinum standards representing the meter and kilogram in the *Archives de la République* in Paris on June 22, 1799, can be considered the first step in the development of the modern International System of Units. Since the SI is not static in nature, but it evolves several developments in the science of measurement, some decisions have been abrogated or modified; others have been clarified by additions. The development of the SI unit system and the current state of the art of the seven base units are discussed in the subsequent sections. The timeline diagram (Fig. 5) shows the decisions of the CGPM and CIPM in chronological order regarding the development of SI.

Current Status of SI Unit System

As described earlier, modern metrology has its roots in the French Revolution and was initially introduced in 1960 at the 11th CGPM meeting with the redefinition of the SI unit of length. Since then, numerous important and groundbreaking efforts have gone into establishing the SI unit system and relating it to really invariant

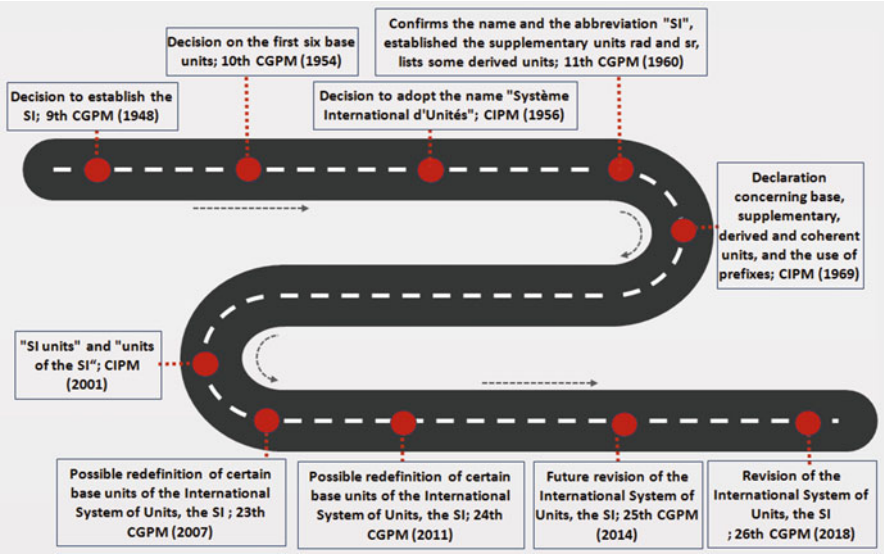

Fig. 5 Timeline development of SI unit system

quantities expressed in terms of natural constants or fundamental constants. In accordance with seven fundamental physical quantities, the SI chooses seven units to act as its base units. The base units are a preferred set for describing or analyzing the relationships between units in the SI because all SI units may be represented in terms of them. The system supports an infinite number of additional units, referred to as derived units, which are always expressed as products of base unit powers, optionally with a nontrivial numerical multiplier. The unit is referred to as a coherent derived unit when that multiplier is 1. A coherent system of units is created by the SI's base and coherent derived units (the set of coherent SI units). The special names and symbols have been given to 22 coherent derived units. The 22 derived units with unique names and symbols can be used in conjunction with the seven base units to represent other derived units that have been chosen to make it easier to measure a variety of quantities.

More notably, the CGPM mandated the CIPM to investigate the adoption of fundamental constants as the basis for all units of measure, rather than the artifacts in use at the time, at its 23rd meeting in 2007. Since then, a considerable measure of work has been conducted around the world to redefine the SI unit system in terms of fundamental constants. The journey toward revision of SI unit is fully documented in the resolution, which was overwhelmingly adopted by CGPM attending 60 member states from around the world.

The CGPM approved the SI redefinition during its 26th meeting in November 2018, and implemented it with effect from 20 May 2019 (World Metrology Day). Table 3 contains all seven definitions for the SI unit system's base units. Various articles provide a detailed overview of how these base units were formed (Rab et al.

Table 3 Definition of SI base units on the basis of physical constants

Base quantity	Name	Symbol	Definition
Length	Meter	m	It is defined by taking the fixed numerical value of the speed of light in vacuum c to be 299,792,458 when expressed in the unit $m \cdot s^{-1}$, where the second is defined in terms of the cesium frequency Δv_{Cs}
Mass	Kilogram	kg	It is defined by taking the fixed numerical value of the Planck constant h to be $6.626,070,15 \times 10^{-34}$ when expressed in the unit J·s, which is equal to $kg \cdot m^2 \cdot s^{-1}$, where the meter and the second are defined in terms of c and Δv_{Cs}
Time	Second	s	It is defined by taking the fixed numerical value of the cesium frequency Δv_{Cs}, the unperturbed ground state hyperfine transition frequency of the cesium-133 atom, to be 9,192,631,770 when expressed in the unit Hz, which is equal to s^{-1}
Electric current	Ampere	A	It is defined by taking the fixed numerical value of the elementary charge e to be $1.602,176,634 \times 10^{-19}$ when expressed in unit C, which is equal to A·s, where the second is defined in terms of Δv_{Cs}
Temperature	Kelvin	K	It is defined by taking the fixed numerical value of the Boltzmann constant k to be $1.380,649 \times 10^{-23}$ when expressed in the unit $J \cdot K^{-1}$, which is equal to $kg \cdot m^2 \cdot s^{-2} \cdot K^{-1}$, where the kilogram, meter, and second are defined in terms of h, c, and Δv_{Cs}
Amount of substance	Mole	mol	One mole contains exactly $6.022,140,76 \times 10^{23}$ elementary entities. This number is the fixed numerical value of the Avogadro constant, N_A, when expressed in the unit mol^{-1} and is called the Avogadro number The amount of substance, in a system, is a measure of the number of specified elementary entities. An elementary entity may be an atom, a molecule, an ion, an electron, or any other particle or a specified group of particles
Luminous intensity	Candela	cd	It is defined by taking the fixed numerical value of the luminous efficacy of monochromatic radiation of frequency 540×10^{12} Hz, K_{cd}, to be 683 when expressed in the unit $lm \cdot W^{-1}$, which is equal to $cd.sr.W^{-1}$, or $cd.sr.kg^{-1}.m^{-2}.s^3$, where the kilogram, meter, and second are defined in terms of h, c, and Δv_{Cs}

2020; Yadav and Aswal 2020; Stock et al. 2019). The new definitions aimed to strengthen the SI without changing the value of any units, ensuring that measurements were consistent. Figure 6 depicts the representation of these constants in SI base units. In November 2022, the world scientific community voted to expand the range of prefixes used within the International System of Units, meaning that four new prefixes will now be used to express measurements worldwide. The progress of the SI unit prefixes is listed in Table 2.

Future of Metrology

As discussed, metrology is an ever-evolving field of science. It has come along far from human body parts–based measurements to fundamental constants-based SI units. However, the metrology fraternity through CIPM keeps upgrading the technology behind metrology. During the 27th meeting of CGPM, it was decided to redefine the second. The CGPM has noted that several National Metrological Institutes (NMIs) have already surpassed the accuracy defined by the present realization of second through the unperturbed ground state hyperfine transition frequency of cesium-133 atom. Several NMIs have already achieved better accuracy in achieving the realization of second by a factor of up to 100 with the help of optical frequency standards. The CGPM invited the member states to support research activities toward the adoption of the new definition of second (Sharma et al. 2020b; ▶ Chap. 18, "Atomic Frequency Standards" Chang et al. 2022).

The CGPM observes that the digital transformation of metrology is the need of the hour. The word "digital metrology" can be used to describe potential advances and substantial modifications to existing metrological services, as well as new metrological services necessitated by digital trends. With the help of digitalization, intelligent data-driven solutions will manage responsive, productive, and efficient production systems, enabling the circular economy. Further, virtual verification and calibration will be possible, thanks to digital calibration certificates (DCCs) stored on global distributed ledgers and paired with digital and machine-readable standards and regulations. Several examples such as process analytics, manufacturing process control, quick demand forecasting, and reliable data through digital certification will all be enabled through measurement (Chang et al. 2022; Rab et al. 2022; Mustapää et al. 2020; Thiel 2018; Eichstädt et al. 2021; Garg et al. 2021).

Artificial intelligence (AI) and machine learning are also supposed to help improve the metrological process. AI and machine learning can help to analyze large sets of data to identify patterns and trends. AI and machine learning can be used

to automate measurements, reducing the need for human intervention and increasing efficiency. This can be useful in identifying sources of error and in improving the accuracy and precision of measurements. AI will be useful in the predictive maintenance of metrological processes. It can help to predict when equipment used for metrology is likely to fail or require maintenance, allowing for proactive maintenance and reducing downtime. During the calibration process, AI and machine learning can help to optimize calibration procedures and reduce measurement uncertainty which can subsequently improve the reliability and accuracy of measurements. It will also impact real-time quality control, identifying defects and errors in products and processes. However, there are several challenges which are important to address in the employment of AI and machine learning in metrological processes. To train the AI and machine learning models, very high quality data is required as accuracy and reliability of AI or machine learning models depend on the primary data through which these are trained. Inaccurate or incomplete data can lead to incorrect predictions and unreliable results. AI and machine learning programs may provide accurate results but it is many times difficult to understand and explain the process of these models to achieve these results. Explainable AI (XAI) techniques need to be developed especially for metrological operations to avoid confusion and maintain transparency. XAI must be the prioritized area of research for NMIs and individuals. Regulatory compliances in the case of critical industries such as healthcare are very critical and challenging for AI and machine learning–based metrological techniques as failure in such industrial processes may lead to loss of life and significant ethical considerations (Eichstädt et al. 2021; Cunha and Santos 2020; Temenos et al. 2022).

The potential for design and maintenance is endless due to cloud computing and digital metrology. Digital measurement equipment is much simpler to use and calibrate. But soon these devices will be able to communicate with one another across entire manufacturing networks. This enables workflows to audit themselves, finding, isolating, and repairing errors, or foreseeing them and preventing them from happening in the first place. Networks that are fully digitalized could automate performance reports and incorporate their insights into the production process. There are several NMIs which are leading the efforts in the direction of the digitalization of metrology (Toro and Lehmann 2021). National Physical Laboratory-UK (NPL-UK) is attempting to embed measurement data into a trusted digital infrastructure that will ensure future traceability chains (Cheney et al. 2021). It is developing techniques to improve data analytics for analyzing the experimental data with the help of statistical learning, machine learning, and clustering. It is working in the field of software verification and validation to process the generation of reference data, design of performance metrics, and automated self-verification of the software. It is also working to develop standards and platforms for quality and provenance for ensuring high-quality reproducibility of it. Overall, NPL-UK is trying to update the available metrological services and creating new techniques for the generation of high-quality data and its assessment of quality. Physikalisch-Technische Bundesanstalt (PTB), Germany, is working for digital transformation of metrological processes and services through big data, communication systems,

simulations, and virtual systems (Thiel 2018). The Federal Institute of Metrology METAS of Switzerland is attempting to create various technologies and platforms toward the digitalization of metrology (Barbosa et al. 2022a). It encompasses the approach digitalization of metrology through metrology for digitalization and vice versa. The National Institute of Standards and Technology (NIST), USA, is taking up the challenge to achieve digital transformation with legacy components and cybersecurity components in the digitalization of metrology (Barbosa et al. 2022b; Barcik et al. 2022). Several other NMIs are taking up the new challenges in the field of metrology presented by the twenty-first-century circumstances. The NMIs aim to shorten the traceability chains and reduce uncertainty in measurements. It is being attempted to embed the traceability of SI directly into measuring instruments including in situ calibration of sensors and local standards.

Technological, social, and industrial progress changes ongoing demands on metrology and measurement systems. To have faith in emerging technologies, stimulate mass use, and ensure a safe rollout, measuring infrastructure must be established in tandem with these advancements. Metrology will become a fundamental step inside industrial processes in the future for inspection and quality control operations. Traditional metrology techniques are not available online, and as a result, involve removing pieces from a production line and transporting them to a quality control department for inspection. The goal is to find quality assurance flaws. As a result, framing metrology as a value-adding process is not always straightforward. This is beginning to change as a result of Industry 4.0 and 5.0 manufacturing technologies combined with automated, 3D, noncontact in-line metrology systems. In-line metrology solutions work alongside the production line as it runs. This allows items to be measured and inspected without the need for human intervention. It will not only rectify any form of default, but it will also assess the impact of any changes on adjacent areas. As a result, metrology will provide flawless control over collateral harm. Furthermore, with the rapid advancement in technologies, metrology has grown to handle vast measuring requirements, including an assortment of sensors to make your production processes more complete.

Metrology will support automated decision-making even in critical cases. Through the digitalization of metrology, decisions made by machine learning algorithms and artificial intelligence will be supported by metrology directly. Even in safety-critical situations, automated decisions will be made accurately with the help of agile and responsive regulation of metrological operations. In future, metrology will also boost confidence during the process of understanding complex and large systems, in general.

Conclusion

Originally, metrology was shaped to ensure that human economic operations such as commerce and exchanges were secure. Because of established measurement standards, humanity has come together. The existing level of metrological performance much exceeds the industry's success standards; further, development is now more

urgently required to promote scientific progress. Specific branches of research, such as geography, astrophysics, medical treatment, and so on, now demand even more precision; all of these fields contribute to human well-being.

The study gives historical viewpoints on the development and expansion of the measurement system. The study emphasizes the development of measurement systems across different eras in ancient times, the legal issues of metrology, the growth of metrological frameworks around the world, and the current status of SI units. The chapter also discusses the need and potential outcomes of the development of a framework for digital metrology.

Our drive to comprehend the world has led us to develop instruments that have benefited humanity for decades. We will only continue to develop and produce increasingly more complicated measures as technology advances. It is necessary to notice that measurement history is as complicated as human history. Every major civilization understood the necessity of a standardized measurement for continuing development. Everything in the world today is measurable, from the speed of the universe's expansion to the tiniest quantum particles that make up all matter. Significant measuring methods, tools, and terminology are employed in disciplines that did not previously exist due to new developments in technology and processing capabilities. Since the advent of the computer, databases of measurements have been compared and processed to identify trends that enable quick and precise forecast. The exponential rate of technological progress we are currently seeing points to a future that is virtually beyond comprehension.

Disclaimer The discussion focused on the various stages of global metrology evolution, which were derived from publicly available data or other reliable sources. Measurement systems have altered drastically from the ancient past to the contemporary metric system. Despite the writers' best efforts to include references and citations from old historical epics, stories, research papers, and publications published in several local languages, spelling and translation errors are inevitable, but they are not done on purpose. Some of the historical information in this chapter is provided for the sole purpose of accumulating knowledge and information, and should not be used or considered in the resolution of any legal difficulties.

Abstract

Metrology, the science of measurement, is unimaginable without correct measurements in modern era. Modern society cannot function without metrology. A world without measurement tools means there would be no modern medicine, healthcare, pharmacology, or surgery among many other critical services. Metrology is not just the routine of making measurements; it's also about the infrastructure that ensures the accuracy of measurement. It establishes a common understanding of units and processes. Metrology also covers the aspects of accuracy, precision, repeatability, and measurement uncertainties. Quality infrastructure involves metrology, standardization, testing, and calibration. In this aspect, quality management certifications and accreditation play a major role in conformity and compliance. To achieve this, India can capitalize on its long history of scientific excellence and progress in research to implement science education across all layers of society. Due to the rapid industrialization of the world over the past decades, demand for specialists in the field of metrology has been rising very quickly. The supply is not able to keep pace with the demand. If we study the history of world economics, the dramatic relationship between technological invention and economic growth is apparent. The present chapter briefly discusses the role of metrology in modern India. It is clear that economic growth cannot happen without technological innovation and invention. The convergence approach requires the involvement of all stakeholders like government agencies, national institutions, educational institutions, manufacturers, R&D establishments, calibration and testing laboratories, end users, private and public undertakings, and the relevant public on a single platform to identify the needs and establish a road to success for encouraging relevant inventions, innovations, and technology development suitable to take India forward. A proper ecosystem for developing a robust metrology structure and establishments for innovations and inventions in science, technology, and institutions for the promotion of skill and knowledge development in metrology are essential for any economy to progress and compete, survive, and thrive in this competitive progressive world.

Keywords

Measurement · Metrology · Economy · Quality infrastructure · Indian infrastructure

Impact of Measurement on Daily Life

Time, length, area, speed, weight, volume, force, torque, pressure, light, energy, and temperature are just few of the physical properties for which we have defined the accurate measures. Without these measures, we would have great difficulty in conducting our normal lives. Yet we live without paying much special attention to them.

The society in the twenty-first century cannot progress without the indispensable tools of measurement on which our civilization is built. A world without measurement tools means there would be no modern medicine, healthcare, pharmacology, or surgery among many other critical services. In fact, measurement is being used in engineering, construction, and other technical fields, physics, and other sciences as well as psychology, medical, pharmaceutical, chemical, aerospace, etc. For any development requires science and technology, but without metrology there is no science and technology (Gupta et al 2020; Rab et al. 2020; Yadav and Aswal 2020; Aswal 2020a; Rab et al. 2021a).

What Is the Importance of Measurement?

Measurement is a scientific, economic, and social necessity. The results of measurement are used to increase the understanding of a subject, for example, to confirm the design specifications, or to determine the quantity/quality of any commodity, or in control process of any commercial transactions, or to predict future events/developments, etc.

Measurements are key wherever decision-making is involved based on the measurements. If the measurements are not accurate/correct, then it may have grave consequences with respect to money, environment, safety and health of people involved, etc. It is therefore imperative that the measurements on which decision-making is done are totally dependable and reliable (Fanton 2019; Squara et al. 2021).

Measurement Protects People

- Vitally important activities involving public health like dosing of drugs or radiotherapy measurements, food safety, etc. require accurate measuring operations. Similarly, reliability of measuring instruments in intensive care units or operation theatre is highly critical.
- Measurement of quantities like working hours, ambient temperatures, or noise and lighting levels of a professional premises aids in the application of labor laws and rules.
- Measurements also ensure compliance to road safety standards by measuring speed, alcohol levels in blood, vehicle braking efficiency, etc.
- Measurements of quality of air and water help in protection of environment by ensuring that statutory requirements are met.

Measurement Governs Transactions

- All transactions between individuals and companies involve measurements during packing of food and consumables, metering gas consumption of subscribers, counting petrol at the fuel pumps or on pipeline retail agency or bulk weighing transactions, etc.
- Measurement becomes an essential factor between customers and subcontractors. Without reliable measurements, it is not possible to guarantee that the subcontracted parts or items match the customer's requirements.

Measurement Makes Industries to be more Innovative and Competitive

- The more accurately the industry meets the customer's and user requirement defines how competitive the industry is in the market. Meeting this competitiveness is impossible without the measurements which study and meet the customer's expectations. Performance measurements for industrial products play a key role in defining quality metric of the industries.
- Quality is also demonstrated to the customers through industry certifications which itself are based on measurement.
- To be competitive in the market, it is expected that the industry precisely measures and controls the production volumes and performances of tools so that it minimizes the cost of rejections/rework operations.

Measurement Increases Knowledge Base

- Metrology is present at every step in the field of fundamental research. It is used to design the conditions of observations, to build and quality the instruments required for observations, and to qualify the results obtained. In research field, the characterization of force fields, determination of physical constants, and observation of physical phenomena all involve measurements.

Measurement Help Make Decisions

- To continue or end a process.
- To accept or reject an item/product.
- To decide whether to rework or to qualify a design.
- To take corrective actions or not.
- To establish facts, be it scientific or legal.

The measurements become unnecessary if the data from measurements are not utilized in the decision-making process or in establishing the facts. "The more

critical the decision, the more critical the data. The more critical the data, the more critical the measurement."

What Is the Meaning of Measurand?

Measurand is defined as the "particular quantity subject to measurement," Quantity intended to be measured (Kacker 2021).

What Is Not Measurement?

There are some processes seem to be measurement but are not: -

- Comparing two pieces of spring or rod to see which is longer is not a measurement.
- Counting.
- Tests (Yes/No, Pass/Fail).

Where Would the World be Without National and International Standards?

Life in the world would be very difficult if trusted standards, based on measurements, didn't exist. Signs in public places use the same basic symbols wherever we go. We trust our favorite imported or local foods and beverages are safe. Credit cards work almost anywhere in the world. All these are the benefits formulation of standards. Standards established by measurements ensure consistency in terms of quality, ecology, safety, economy, reliability, compatibility, efficiency, interoperability, and effectiveness of goods and services. Standards codify the latest technology and facilitate its transfer.

Relevance of Calibration and Testing Laboratories

The start of the twentieth century brought quality control to the limelight with more emphasis on the quality of the final product, thus enabling customer satisfaction. Implementing ISO 9001 process and procedures and then objectively monitoring the quality of product became significant. To check the quality, different types of equipments were required as per the process requirements. This paved the way for the metrological equipment industry to start spreading its roots.

Today this industry is linked to almost every other industry like oil and gas, automotive and ancillary, plastics, rubber, steel, food, R&D, cement, textile, construction, chemical, mining, etc. With the rapid progress of the industries, QC is considered the most important department of any organization to accept or reject a

product. Organizations are investing millions buying quality instrument brands to ensure their product satisfies the protocols meeting high-quality standards. With these huge potential requirements, metrological equipment's manufacturers have cemented their products in the market (Aswal 2020a, b; Yadav et al. 2021; Rab et al. 2022a, b).

Metrology, National/International Standards, and Regulations

Metrology is not just the routine of making measurements; it's also about the infrastructure that ensures the accuracy of measurement. It establishes a common understanding of units and processes. Metrology also covers the aspects of accuracy, precision, repeatability, and measurement uncertainties. It also involves traceability or verification with a "Standard" or reference measuring systems. Metrology involves all theoretical and practical aspects of measurement, whatever the measurement uncertainty or the field of application. In this modern world, in view of importance of safety of living beings, safety of environment, safety of products and processes, safety of natural resources and the universe, and safety of economic growth and development is very critical. Various standards and statutory and regulatory guidelines are formulated by various national and international agencies in the field of legal metrology, pharmaceutical, medical, automotive, chemical, defense, etc. which are to be adhered to (Yadav et al. 2020; Garg et al. 2021; Rab et al. 2021b).

What Is Metrology?

Metrology establishes a common understanding of units, crucial in linking human activities, or is the science of measurement, embracing both experimental and theoretical determinations at any level of uncertainty in any field of science and technology. It comprises the administration of measuring instruments, application for units of measurement, and testing procedures which are commonly established in either legislation or documented standards. The purpose is to provide accurate and reliable measurements for trade, health, etc. Measurement is fundamental to almost all human activity, and so it is important that the accuracy of any measurement is fit for its intended purpose.

Measurement can be classified into two parts: direct measurement and indirect measurement. Direct measurement – When measurement is done using direct measurement or modern instruments, it is called direct measurement. Examples include length and weight. Indirect measurement – When measurement is done through a formula or other calculations, it is called indirect measurement. Example includes measuring the distance between two stars. Therefore, it's very important to have knowledge of measurement in today's life. According to James Cattell "*The history of measurement is the history of science.*" Current civilization is inconceivable

without the indispensable tools of measurement on which day-to-day life depends (Porter 2001; Czichos et al. 2011; Rab et al. 2020; Aswal 2020a).

Importance of Metrology in Modern World

The quality aspects of products and services have become forerunner of all activities in industries with the introduction of ISO 9000 and in view of globalization and international competitiveness in trade and commerce. Measurement and calibration play a vital role in meeting the requirement of industries in order to produce quality product and services. Measurement is the basis for the development of trade and economy. Measurements also need to be uniform and internationally compatible in order to eliminate technical barriers to trade and promote international cooperation. The validity of precise and accurate measurements across different stakeholders is essential for trade, efficiency, quality, and safety (Stock et al. 2019; Rab and Yadav 2022). Metrology drives and influences much of what we do or experience in our everyday lives. It is often unnoticed or beyond our awareness. Industry, trade, regulations, quality of life, science, and innovations all rely on metrology considerably. Thus, metrology forms a natural and vital part of everyday life.

Globalization of trade requires that the measurements be traceable, comparable, and mutually acceptable across the globe. This is applicable not only in trade of raw materials and manufactured products but also in all aspects of trade. The world demands for confidence in the results of measurements. Decisions made based on measurement results are increasingly seen as having direct influence on the economy and human safety. Even in the areas of science, the measurements can be validated if it is made through a well-defined system of units and verified equipment. Quality infrastructure involves metrology, standardization, testing, and calibration. In this aspect, quality management certifications and accreditation play a major role in conformity and compliance (Rab et al. 2022c).

Who Is a Metrologist?

Metrologist – with Skill and Knowledge *"Understanding the benefits of having sound knowledge, perspective, and the appropriate skill sets in metrology is just as crucial in today's technological world as it was 50 years ago. The same goes for key decision making based on solid processes, procedures, methods, and data analysis. Taking responsibility and ownership of those decisions makes good metrologists vital to a successful organization's reputation, quality, and cost containment." – Keith Bevan.*

Measurement scientist or metrologist is one who studies and practices metrology. He is capable of finding and using measurement science resources. Some metrologists are involved in designing of measurement instruments or systems while others perform calibration of those instruments. Still others may do basic research into the underlying principles of metrology. Metrologists can help in increasing business

productivity and efficiency. They can also improve reliability of a process for internal/external customer satisfaction, to achieve and maintain compliance. They can also help in cost saving through advances in computer technology and by minimizing human errors. Considering the large verity of people in the field, you can imagine how broad the subject matter is. Metrology after all borrows the concepts from physics, mathematics (mostly statistics), chemistry, all kinds of engineering, and even a little biology and medicine at times.

Metrology is everywhere, but metrologists are very few. Curricula in technical fields do not even mention metrology. How do metrologists get education, then? The people who come from diverse backgrounds in engineering, math, and science, and become metrologists, have had very little exposure in the field of metrology. A metrologist with a broad well-rounded education should have a strong knowledge of pure sciences like physics and knowledge of applied statistics. A metrologist should also have specialized knowledge in several engineering areas, the most common being mechanical and dimensional measurements, electrical measurements, and physical areas where measurement of time, mass, temperature, pressure, force, torque, flow, etc. are involved. Not only this, the understanding of more than one field is needed at a time. For example, some physical measurements like mass are strongly influenced by temperature. Therefore, it is important to understand how to measure temperature well in order to measure mass or mass-related parameters.

Finally, one also has to understand specific international and national standards and practices specific to metrology. Comprehending "the guide to expression of uncertainty in measurement," for example, is critical for every professional metrologist. At present, most of metrology education is accomplished through short courses (Fuschino 2021; Priimak and Razina 2021).

Metrology Training Centers

Science and technology are changing so rapidly and irreversibly today. Hence, the fundamental principle for progress must be the convergence between different sciences, technologies, and peoples, while each of them mutually benefiting from the convergence. To achieve this, India can capitalize on its long history of scientific excellence and progress in research to implement science education across all layers of society.

Even though India has a large-scale infrastructure base in science and technology which is fast expanding, it still has a long way to go in realizing its potential in becoming world leader in science and technology. Education in the fields of science and technology is still not at par with international benchmark. Scientific research, education, and innovation are imperative for any nation to achieve continuous development. Measurements are everywhere, but measurement scientists or metrologists with skill and knowledge are very few (Sharma et al. 2020).

Challenges Faced

The laboratory may have the best high accuracy standard equipment that was purchased from reputed manufacturers; the equipment may have traceability to national and international standards and may have the best accommodation and environmental conditions too. The high accuracy standards are not realized unless there is a sound knowledge on basic principles of measurements and influential quantities during calibration or testing, and correct analysis and precautions are taken during measurements. In fact, considerations which are often overlooked, can result in total error of several percent, either in deviation or in measurement uncertainty. "It is like this — a person may own the best race car from the most reputed company but cannot automatically take part in a race until he is qualified enough to participate. Hence, a sound knowledge and expertise is the basics are a necessity in building a credible and reliable laboratory."

With the market evolving rapidly, calibration services of these equipments have also gained importance. Thus, a huge number of calibration and testing laboratories found themselves registered with the NABL accreditation. The accreditation is done as per ISO 17025:2017. Besides other medical laboratories, reference material manufacturers and proficiency test providers are gaining momentum into the industry. Today NABL has accredited more than 6000 different types of laboratories which in itself is a huge network.

This has given rise to many more entrepreneurs entering this market, which was once considered a niche, creating an ecosystem nurturing many families. Our Indian manufacturers have made us proud by taking a share of the international market competing with the multinationals. So, the Indian metrology ecosystem strives in the world and has created a benchmark. Many Indian companies have found their associates, while some have set up their own offices internationally to cater to the growing market as per the organization strategy. Many engineers, senior executives, managers, technical experts, and management staff work in different companies from the metrology industry. Thus, the Indian economy opened itself to a diversified product mix for all types of consumers. Today customers have options like never before right from the higher-end accurate product to lower-end ones. This is decided by the end user as per the application. The overall scenario looks poised for growth in this rapidly evolving industry.

The challenges faced in acquiring skill and knowledge in the field of manufacturing testing equipment and calibration have eventually led to the difficulty in establishment of a ISO17025 accredited laboratory. But there is lack of organized institutions, training centers, technically competent trainers with sound knowledge and skill, effective metrology course materials and books that can be used by workforce at every level, and implementing theory and practice to meet a current day requirement. Upcoming calibration and testing laboratories, as well as the ones that have already been accredited, are facing similar challenges. They are either

unable to acquire sufficiently trained workforce or fulfill the needs of their appointed personnel for upgradation of the required skill and knowledge. Due to rapid industrialization of the world over the past decades, demand for specialists in the field of metrology has been rising very quickly. However, the supply is not able to keep pace with the demand.

Therefore, to meet the ever-growing demand for accurate measurements in line with global requirement, effective quality infrastructure becomes paramount importance in any developing country for robust economic growth. Development of quality infrastructure involves metrology, standardization, testing, and calibration, and quality certification and accreditation are important for assessing conformity. To have an effective quality infrastructure, any country requires technically competent and professionally trained workforce in the fields of metrology, science, and technology.

They should have skill and knowledge (theory and practice) in the field of metrology in the following areas:

(a) Routine operation and maintenance of equipment and conducting calibration and testing activity.
(b) Review and interpretation of results of calibration and testing.
(c) Auditing and assessing in the field of calibration and testing.
(d) Required training for the above workforce.
(e) Development and innovation in the fields of science, technology, and metrology.

The following must be satisfied in order to produce technically valid calibration certificates or test results with the global metrology system:

- Measurements made at one place or country should be acceptable in any other country without technical barriers for free trade, as per the WTO.
- One standard, one test accepted everywhere as per international organization like ILAC, OIML, etc. To produce internationally acceptable measurement and test results depends on the technical competency of the laboratory. In order to achieve technical competency, personnel involved are required to acquire in-depth professional knowledge, expertise, skill, aptitude, and continual training.

Science, Technology, and Engineering of Modern World

It is important to understand the difference between science, technology, and engineering. Science is the methodical study of the natural world, through observation of physical systems, gathering evidence, and performing experimentation. It is concerned with "understanding the fundamental laws of nature and the behaviour of matter and living things." Science explores new knowledge methodically through observation and experimentation. There are many specialized branches of science which deal with different fields of study such as physics, chemistry, biology, or cosmology (Atrens and Atrens 2018; Onalbek et al. 2020; Mehra et al. 2021).

Engineering

Engineering involves the practical application of the principles of science and utilizes technology to create useful products and services for mankind, within economic, environmental, and resource constraints. Engineers specialize in specific branches of engineering such as electronics, electrical, mechanical, chemical, or civil. Engineering metrology is one of the branches of engineering which deals with measurement.

Technology

Technology is the body of knowledge system, process, and artifacts that result from engineering. "Technology" is the application of science to achieve practical results, especially in industry. Technology involves the development of devices, processes, and systems to address society's practical problems.

Impact of Science and Technology on Modern Society

Impact of science and technology in modern society: Science and technology impacts the modern society in wide-ranging and broad ways influencing each and every aspect of society such as politics, diplomacy, defense, economy, healthcare, medicine, transportation, agriculture, and many more. The products of science and technology are found in each and every corner of our lives. Science has served the humanity and will continue to do so until needs are fulfilled.

"*Science creates basic knowledge of the world; engineers apply that knowledge in a practical way to create technology.*" Science and technology have had a big impact on all of humanity's activities. Science and technological inventions and discoveries such as theory of origin of the universe, the theory of evolution, etc. have had an immense role in influencing our understanding of the world and our outlook of nature.

The wide applications of technologies developed due to scientific discoveries made by humanity have led to the development of civilizations in every age. The developments due to science and technology have stimulated economic growth, enhanced standard of living, encouraged cultural development, and have also had impact on religion, thought, and many other human aspects. History is a rich secular nature of science, and technology has meant that scientists from all backgrounds have contributed to different fields of science, free of politics, religion, caste, and region. Every human being has the right to use science and technology for beneficial purposes. However, mutual cooperation and coordination between academia and industries is very important for the growth and evolution of science and technology would no doubt be a boon to the world because human beings will come to know a lot about the world in which they live and carry out their activities:

Development in technology leads to the advancement in science and helps to revolutionise several fields including medicine, agriculture, education, etc, the science of today is the technology of tomorrow. (Edward Teller)

Since science and technology are changing at a rapid pace, there must be a convergence, a creative union of sciences, technologies, and peoples while aiming and mutually benefiting each other. India can capitalize on its long history of excellence in science and its progress in scientific research to further science education to make sure it is implemented across all layers of society. Science and technology have a broad and wide-ranging influence on areas such as politics, diplomacy, defense, economy, health and medicine, transportation, agriculture, and many more. The end results of science and technology are found in every corner of our lives. Science has served the humanity from time immemorial and will continue to do so till human needs exist.

The study of history of economics brings out the dramatic relationship between technology and economic growth, leaving no room to doubt that the latter could not happen without the former. In today's technology-driven world of the twenty-first century, a country is considered powerful only on the basis of developmental parameters, among which the most important is the advancements in science and technology a country has made by virtue of its scientific acumen and human resources.

Glory of Ancient Indian Contribution to the World in Metrology, Science, and Technology

India is one of the oldest civilizations in the world, and it is a fact that India had a strong tradition of science and technology. In the ancient civilization, the growth of the civilization was the result of incredible ancient engineering and technology during those days. Indian heritage and culture is among the oldest and richest among all civilizations. Many of the findings of science which we consider to have been made in the west were made and documented in India many centuries ago. This is the land of Aryabhatta the father of astronomy as listed in ancient India contributions (Gupta 2009; Rab et al. 2020):

We owe a lot to the Indians, who taught us how to count, without which no worthwhile scientific discovery could have been made. (ALBERT EINSTEIN)

Historical research has revealed that from manufacturing the best steel to teaching the world to count digits, India was instrumental in contributing to the advancement of science and technology. These developments were made centuries before modern laboratories were set up. Many theories formulated by ancient Indian scientists have reenforced the fundamentals of modern science and technology. While some of these ancient contributions have been acknowledged today, some are still unknown.

Few of Ancient Indian Contributions to the World in Metrology, Science, and Technology

Here is a list of some of the major contributions made by ancient Indian scientists in the field of science and technology that will make everyone feel proud of their legacy:

- Little needs to be written about the idea of "zero," one of the most important concepts throughout the history of humanity. Indian mathematician Aryabhatta was the first person to create the symbol for zero "0" in 476 AD. Aryabhatta was the first of many mathematician-astronomers from the early age of Indian mathematics and astronomy.
- The decimal system – It was India which gave ingenious method of expressing all numbers in the form of ten base symbols which formed the decimal system.
- Numeral notations – Indians had devised a system of symbols for numbers from 1 to 9 as early as 500 BC.
- *Theory of gravity* – Theory of gravity: Indians knew of gravitation way before Newton. One of the first postulations on gravity was by the astronomer and mathematician Varahamihira (505–587 CE), and later Brahma Gupta exclaimed "bodies fall towards the earth as it is like the earth attracts bodies, just as it is like water to flow."
- *Fibonacci* – Fibonacci numbers and sequence first appeared in Indian mathematics through the Rishi Pingala, in connection with the Sanskrit tradition of prosody. Later mathematicians like Virahanka, Gopala, and Hemachandra also wrote about this sequence much before the Italian mathematician Fibonacci introduced this fascinating sequence to Europe.
- *Binary numbers* – Binary numbers: Binary numbers are the basic language which a computer understands. Binary refers to a set of two digits 1 and 0. The combinations of which are called bits and bytes. This binary number system was first introduced by Vedic scholar Pingala in his book *Chander shastra*.
- *Chakravala method* – This method of obtaining integer solutions was developed by one of the well-known mathematicians of the seventh century, Brahmagupta. Later, another mathematician Jayadeva generalized this method for a wider range of equations. It was further refined by the mathematician Bhaskaracharya.
- *Ruler measurement*. 2400 BC – In Indus Valley civilization. Excavations at Harappan sites have found rulers and linear measures made from ivory and shell.
- *The theory of atom* – The atomic theory developed 2600 years ago in ancient India by one of the noble scientists of ancient India kanad.
- *The Heliocentric theory* of astronomical predictions – Ancient Indian mathematicians often made accurate astronomical predictions by their applied mathematical knowledge, Aryabhatta being the most significant.
- *Wootz steel* – In 200 BC -A pioneers steel alloys matrix developed in India.
- *Smelting of zinc* – India is known to be the first to smelt zinc by distinction process.

- *World's first plastic surgery and cataract surgery* – Book written by Sushruta in the sixth century BC, the Sushruta Samhita details various illnesses, plants, preparations, and cures. The text also describes complex techniques of plastic surgery as well as a cure for cataract.
- *Ayurveda* – 5000 BC. Charaka authored a major foundational treatise Charaka samhita on the ancient science of Ayurveda.
- *Weighing scale* – 2400 BC. It has been revealed that balances were being used to compare and measure goods for trade in the Indus Valley civilization.
- *Pythagorean theorem* – Pythagorean theorem and geometrical proof for isosceles right angle were available 700 BC. The Baudhayana sulba sutra has postulated it in a sutra. The knowledge and teachings of our ancient scientists have taken a beating just because it hasn't been well documented.

Achievements/Success Stories of Modern India

The Indian Space Research Organisation (ISRO) has successfully managed to break the stereotype of an archaic in efficient public sector to emerge as an institution that is giving cutthroat competition to premium space agencies. India's vaccination drive shows its capability and moving ahead with new energy. The independent development of Covid-19 vaccine in less than a year marks an extraordinary achievement, more so for a developing country like India that was disadvantaged on so many fronts. It not only came out with locally produced vaccines but also indigenously developed its own.

Downfall of Development of Science and Technology and Its Education in India

Pre-Independence of India Era: Exploitation of Physical Raw Material and Intellectual Property

Science has been an integral part of the Indian culture from time immemorial. Many theories and techniques developed by the ancient Indian scientists have reenforced the fundamentals of modern science and technology. Some of these path-breaking contributions have been acknowledged, while some are still unknown to most. Gurukul system of education existed where ancient source of science and technology were taught. Nalanda and Takshashila universities are great examples of this. There was a decline in scientific activity in India during the pre-independence era. This was due to the frequent invasions by foreign rulers who caused a lot of destruction, especially of the native iron industry. These invasions also caused loss of many scientific documents. Regional and political instability could also be one of the reasons which disturbed the progress of scientific acumen in the country. "Necessity is the mother of invention," and people in the precolonial era were satisfied with their agro-based lifestyle and did not see the need for innovation and invention. Thus, India lagged behind in scientific advancements. The credit for most of the inventions

and discoveries has so far always rested about them in schoolbooks, heard in televisions or in movies, or talked about tirelessly. It's the ancient science and its knowledge and teaching that have taken a beating just because their achievements were well documented. It has been found time and again in our written and oral literature about the supremely advanced ancient Indian science that is not taught in school.

After Independence of India Era: Exploitation of Physical Raw Material and Intellectual Capability

Even after independence, Indian resources and talents have been exploited during the twentieth and twenty-first centuries. This is due to lack of interest in industrialization and development of science and technology by successive governments and lack of environment for inventions and innovations in the country. Even though India has glorious past in science, we could not use and materialize to continue the tradition. We were the front-runners in science. In the ancient civilization, the growth of the civilization was the result of incredible ancient engineering and technology during those days. This made us to be still developing country rather than making developed country by this time. Raw material and natural resources of India were exploited during the first industrial revolution in the nineteenth and twentieth centuries. Raw material was exploited, and finished products were to India at exorbitant price. In the twentieth century, India also exported its natural resources and raw material to other countries at lesser cost and imported products with value addition at their end at exorbitant cost.

In the twentieth century, India also exported human resources to other nations because of the lack of employment opportunities. In the twenty-first century, our technical skill and knowledge of our engineers were exploited by multinational companies at lesser cost and made huge profits again supplying value-added goods and services. The ability to establish infrastructure to make use of intellectual capability to produce products and services is the way to make self-reliant and progress for the benefit country and to become a global leader of the twenty-first century. However, India is now at a position to rise and thrive once again and prove its worth by making noticeable achievements as a science and technology expert in the coming future. Now we can reverse the process of exploitation and become self-sufficient and make developed country.

Position of India Compared to the World in Science and Technology Development

(a) The number of people in developed countries like DENMARK and SOUTH KOREA more than 8000 people gets into research and more than 5000 people in GERMANY, JAPAN, AUSTRALIA, BELGIUM, FRANCE, the UK, etc. Only 252 people get into research per million people in India.

(b) 2015, India filed only 2015 international patients, whereas Japan nearly 45,000 and South Korea nearly 30,000 and Korea nearly 15,000.
(c) India spends 0.64% of GDP on science and technology, whereas Israel and South Korea spend nearly 5% of GDP. Similarly, the USA, Japan, the UK, Germany, Denmark, Belgium, etc. spend more than 3% of GDP. That is why the USA, Russia, and Japan are considered as developed countries because of this spending on science and technology, while India is still counted among developing nations.

Convergence Approach to Build Modern India Through Development of Metrology, Science, Technology, and Their Education

If we study the history of world economics, the dramatic relationship between technological invention and economic growth is apparent. It is clear that the economic growth cannot happen without technological innovation and invention:

> *Prosperity in a society is the accumulation of solutions to human problems.* (Hanauer and Beinhocker)

Most modern metrology infrastructure, science and technology development institutions, and their skill and knowledge centers are essential for creating ecosystems, to encourage discoveries, inventions, and innovations in India. Because science and technology are changing so rapidly and irreversibly today, the fundamental principle for progress must be the convergence of different sciences, technologies, and people, while each of them mutually benefiting from the convergence. Convergence approach requires involvement of all stakeholders like government agencies, national institutions, educational institutions, manufacturers, R&D establishments, calibration and testing laboratories, end users, private and public undertakings, and relevant public on a single platform to identify the needs and establish road to success for encouraging relevant inventions, innovations, and technology development suitable to take India forward.

India can capitalize on a long history of scientific excellence and its progress in scientific research. This should reflect in science education which needs to be implemented across all layers of society. Robust national metrology institutions should be upgraded based on required needs. Without strong national metrology institutions support, there can be no progress in inventions or innovations or technology development. Substantial investment on science and technology development is made by the developed and developing nations to meet challenges of competitive and progressive world.

In the current twenty-first-century world which is technology oriented, any country is considered powerful purely based on development parameters, most important among which is the technological advancements a country has made with the use of scientific acumen of its human resources. The most powerful

creations of the human mind which are science and technology, driven by an ethical society, must become the engines of progress. They should be able to transport the world from suffering and conflicts to prosperity and harmony.

Development in technology reaffirms and re-enforces advancement in science and helps to revolutionize many fields of human activity like medicine, agriculture, education, etc. Technology is the single greatest factor that creates a distinction between modern economies from the primitive ones. This is because technology lowers the cost of production while innovating new products. It also increases both productivity and allocated efficiency of all industries. The quality aspects of products and services have become forerunner of all activities in industries with the introduction of ISO 9000 and in view of globalization and international competitiveness in trade and commerce. "*For any development requires science and technology, but without metrology there is no science and technology.*"

Results of progress in science and technology can be seen due to spending on metrology in other developed and developing countries compared to India. Most of the developed countries and developing countries have realized that only metrology, science, and technology can drive the economy for progressive development, and hence they spend more than 2–5% of GDP.

Encourage Discovery

A discovery is something that already existed at the time of discovery but had not been identified until then. Nothing changes as a result of the discovery apart from the increase in knowledge that it brings. Discoveries are therefore defined as the first description of a natural law or a law derived from the laws of nature.

Promote Inventions

Invention is the creation of a new idea. Innovation is the integration and/or conversion of an idea. Inventions are creative, innovative achievements that give rise to previously unknown solutions and the application of new technique. "Necessity is the mother of invention," but it is invention that drives the economy. The biggest utility of invention is that it solves real-world problems and brings changes in the way world functions. Innovation shapes the new way of life and it transcends the culture of the world. The modern era is arguably the greatest time in the history for innovation. None of this innovation would have happened without the invention of electricity supplied on demand. So, with this one advancement came the fastest-changing period in history of humanity and the greatest population growth, too. Invention is the process by which we devise and produce something which is useful which didn't previously exist, by independent investigation, experimentation, and mental activity. An invention involves such a high level of mental effort that the inventor is usually acclaimed in the society, even if the invention doesn't become a commercial success. The study of history of economics brings out the dramatic

relationship between technology and economic growth, leaving no room to doubt that the latter could not happen without the former.

Encourage and Promote Innovations

Innovations which may or may not involve invention are a complex process of introducing novel ideas and put them to use or practice while keeping entrepreneurship as an integral part. A curious aspect of innovation is that it's considered noteworthy only if it becomes a commercial success. Society thus benefits from innovation, not from invention alone, and it may happen that there is a significant time lapse from the stage of invention to innovation. Innovation is the integration and/or conversion of an idea into a product/service that creates significant new value in the marketplace. Importance of innovation in this VUCA (volatility, uncertainty, complexity, ambiguity) world is undeniable. Innovation is doing new things or doing things in a new way. Innovation excellence is essential for the survival of any business and organization. Getting innovation mindset should be at most priority.

Innovation is important for higher revenues, increased profits, new customers, and higher market share, increased customer loyalty, to motivate people, and to make a great place to work. Invention can be defined as the process of creating a product or introducing a process for the first time. Practical application of inventions into marketable products or services is extremely necessary. Innovation on the other hand happens when someone improves or makes significant contribution to changing of an existing product, process, or service, which changes lives and makes human race move forward. One of the most important contributions that inventions make is to create entirely new fields of studies.

Key Prerequisites to Invention and Innovation

(a) A skilled workforce educated in the best practices.
(b) Entrepreneurship.
(c) Patent and communications policies and practices while properly balancing intellectual property protection and free flow of information.
(d) Organizations, industries, and associations that create a network which can enable information flow.
(e) The use of economic statistics which can accurately and reliably measure the metrics of invention, innovation, prosperity, research and development, investment, economic benefits of digital technologies, and business finance.
(f) An economy that promotes equality and inclusiveness by seeking to improve living standards for all.
(g) Robust institutions of governance, like democracies, which ensure freedom of expression and civility and give free opportunity for everyone to experiment in life without fear of penalty.

Promote and Encourage Indigenous Technology Development

Technology can be defined as a body of knowledge of techniques, methods, and designs that accomplish a certain work in ways with certain consequences, even when one cannot exactly explain them. Technology may also be defined as an effort to organize the world to solve a problem by developing and producing goods and services for use in problem solving. We can improve things without invention or innovation, through a process of continuous improvement or parameter optimization, to improve value. However, inventions can lead to creation of new technologies which don't exist as of today, thus creating new jobs and improving quality of life in society.

Conclusion

Most modern metrology infrastructure, science and technology development institutions, and their skill and knowledge centers are essential for creating ecosystems, to encourage discoveries, inventions, and innovations in India. The above prerequisites for creating proper ecosystem for developing robust metrology structure and establishments for innovations and inventions in science, technology, and institutions for promotion of skill and knowledge development in metrology are essential to any economy to progress and compete, survive, and thrive in this competitive progressive world.

Abstract

Quality explicitly relates to "fitness for use"; thus, the quality of one product or service may be lower or higher than that of another. The quality of the goods or services may be accepted or rejected based on the specifications or guidelines/protocols set as per national or international standards. The next important issues are the ways the quality is implemented, maintained, retained, tested, verified, and performed and the identification of the organizations responsible for these

processes. Even though those things are undoubtedly important, controlling the quality is much more indispensable when producing goods or maintaining services without flaws. Organizations can manage quality efficiently through a strong management system adhering to national and international standards. The whole process is characterized as "Total Quality Management" and covers facets such as developing products and services, enhancing processes and systems, and ensuring that the entire organization(s) is efficient and functional. This chapter introduces in detail the quality concept; various terminologies used; historical aspects and evolution of quality across the globe; benefits, relevance, and significance of quality management, tools, and method; and its need and impact on global trade and economic growth. It is hoped that the chapter would provide a significant resource material and reference for the beginners, students, laboratory personals, researchers, and even for the regulators and quality experts in this terse and concise report.

Keywords

Quality · Quality Management System · Total Quality Management · Standards · Accreditation · Traceability · Metrology · Economy

Introduction

A good place to start a chapter on quality would be by asking what the term "quality" actually means. There have been innumerable definitions assigned to this seemingly simple word, owing to its relativity, but to fulfill our quest of understanding the term, the definition given by the ISO (1994) would suffice: "The totality of features and characteristics of a product or service that bear on its ability to satisfy stated or implied needs" (Shewfelt 1999; https://www.fao.org/3/w7295e/w7295e03.htm#:~:text=The%20term%20%22quality%22%20has%20a,satisfy%20stated%20or%20implied%20needs%22. Accessed 31 Oct 2022). Simply put, a product is said to be of good "quality" when it meets certain parameters that either satiate or exceed customer expectations or requirements. Through this definition, it can also be noted that there are several function-based definitions of quality, all of which help in illustrating the core of each function. They are as follows:

(i) **Transcendent Excellent** – Timeline of evolution of quality is the most recognizable way of using the term. A product or service that meets customer expectations is almost always deemed to be "excellent."
(ii) **Product-based definition** – Quantities of product attributes: This again alludes to the certain attributes of a product, in terms of either its functions or design, and the quantity in which these attributes are present, which makes a product a "quality" product. Example: If a smartphone contains some state-of-the-art functions or is coupled with an attractive and interactive design, it is often said to be of good "quality" by the consumer.

(iii) **User-based definition** – Fitness for intended use: As mentioned earlier, while discussing the ISO definition, a product is deemed to be of good "quality" when it either meets or exceeds customer expectations. This is where the definition "fitness for intended use" comes in. For the smartphone example given previously, it can be said that if a smartphone has a smooth user interface and navigation design, which fulfills the intended purpose, and has been equipped with trendy functions, which exceeds the expectations of a customer, then it will be considered a good "quality" product.

(iv) **Value-based definition** – Quality vs. price: There are a lot of products in a market that are manufactured to fulfill the same functions. This presents the consumer with an overwhelming array of choices to make and decide which products to choose from. What is it that sets a product apart from its identical counterpart, seeing that they both have functions that would make them a "quality" product? A seller can set its product apart through its price. It is imperative that sellers and firms strike a good balance between the rate at which the product is priced, which must be valued at a rate that is affordable, and the quality of the product, which is appropriate to its price, when put against the competition in the market. It is also worth noting that there are products that are deemed to be "basic," simply because there is a lack of extra features in comparison to their more expensive counterparts. However, even though a product may be of "low quality" in terms of style or features, this product still gives good value for money for its "overall quality." This does not mean that this "overall quality" of a product cannot be enhanced or improved upon.

(v) **Manufacturing-based definition** – Conformance to specifications: Philip B. Crosby, the author of *Quality Is Free*, one of the most prominent and influential bodies of work written on quality, says that quality is nothing but a "conformance to requirements" (Crosby 1979) (https://www.bl.uk/people/philip-crosby. Accessed 31 Oct 2022). It then becomes imperative to define what those "requirements" mean. A way of finding this is by identifying and applying the customer requirements as early as can be in the product/service development cycle. Crosby then expanded on this definition in 1992, stating that "Quality meaning getting everyone to do what they have agreed to do and to do it right the first time, is the skeletal structure of an organization, finance is the nourishment, and relationships are the soul." The thing that the organization has "agreed to do" which it intends to "do it right" would here refer to meeting the requirements and demands of the customers in a manner that strives to satiate or even determine the needs of the customers for them. The finances used in order to manufacture said product according to specified requirements and the relationships forged through a trust built upon the promise of quality are aspects that set a firm apart from its other competitors (Shewfelt 1999; https://www.fao.org/3/w7295e/w7295e03.htm#:~:text=The%20term%20%22quality%22%20has%20a,satisfy%20stated%20or%20implied%20needs%22. Accessed 31 Oct 2022; https://www.bl.uk/people/philip-crosby. Accessed 31 Oct 2022; Aswal 2020a; Merrick 1999; Juran et al. 2005; Mitra 2016).

The various key aspects of quality are as follows:

(i) The product must look good and have style.
(ii) The product should have good functionality.
(iii) The product should be reliable and should only have acceptable levels of breakdowns or failures.
(iv) It should have consistency.
(v) It should be durable and last as long as it promises.
(vi) It should have good after-sales service.
(vii) It should possess value for money. This aspect is the most important, as in any market, there are different levels of quality and the customers must be satisfied with the knowledge that the price reflects the quality.

It is important for a business to ensure that their product has a good design, which is fundamental in order to produce a product efficiently, reliably, and at the lowest possible cost. Quality helps in determining a firm's success in a number of ways:

(i) Enhancing the consumer trust worthiness and loyalty vide which the consumers come back and buy repeatedly, endorse and recommend the product or service to other users.
(ii) Quality ensures a firm has a strong brand reputation.
(iii) Retailers will want to purchase and stock the products.
(iv) If a product is perceived to possess a good value for its money, it may then be priced at a premium rate and may become more price inelastic.
(v) A decrease in the returns and replacements of a product or service will lead to reduced costs. It is the duty of a firm to ensure the good quality of their products consistently with minimal errors.

When the definition of quality is projected onto any analytical work, it is defined as the "delivery of reliable information within an agreed span of time under agreed conditions, at agreed costs, and with necessary aftercare." The "agreed conditions" mentioned here should specify the precision and accuracy with which a data must be prepared, which may determine its "fitness of use" that may vary for different applications (https://www.fao.org/3/w7295e/w7295e03.htm#:~:text=The%20term%20%22quality%22%20has%20a,satisfy%20stated%20or%20implied%20needs%22. Accessed 31 Oct 2022; https://www.bl.uk/people/philip-crosby. Accessed 31 Oct 2022; Jackson 1959; Hellsten and Klefsjö 2000; Venkatraman 2007). Despite this, there have been instances where the reliability of a data is left unquestioned and no requests for further specifications are made. Laboratories will continue to operate in accordance with the standard operating procedures and methods that have not changed. What complicates matters more is that no future use of this data can be foreseen, which would mean that it would be extremely difficult to specify the required precision and accuracy in the data. This creates a rather awkward situation where the laboratories are left unsure about their quality as they lack the necessary

documentation to account for the same (Nanda 2005; Wiengarten and Pagell 2012; Isaksson 2006; Aswal 2020b).

There are three levels that help an organization to maintain the quality of their production:

(i) Quality management (QM)
(ii) Quality assurance (QA)
(iii) Quality control (QC)

Before delving into these concepts, it is important to first look back into time at the history and evolution of quality and asks how the concept of ensuring "excellence" actually came about?

Historical Aspects and Evolution of Quality

It is fact universally acknowledged that human beings have been involved in the process of producing goods since the Paleolithic or Old Stone Age, when pots and weapons made of stones fulfilled the purposes of hunting and cooking. It was then, with the creation of a social system or structure, that professions such as masonry, pottery, farming, horticulture, etc., were created, which in turn introduced the system of trade. These traded goods would have to be of an acceptable or excellent "quality" in order to be sold, irrespective of the trading system. So where does this conscious effort of ensuring quality while producing certain goods and services come from? Are there any recorded instances of such practices being prevalent throughout the Ages, and how far must one look back in order to trace the evolution of the concept of quality through time? Figure 1 shows the timeline evolution of quality (Rab et al. 2020; Shah et al. 2011; Schroeder et al. 2005; Yong and Wilkinson 2002).

Going back to thirteenth-century Europe, craftsmen created unions of their own, called "guilds," to create stricter rules that would help in maintaining the quality of their products and services. One of the ways in which these rules were enforced was by

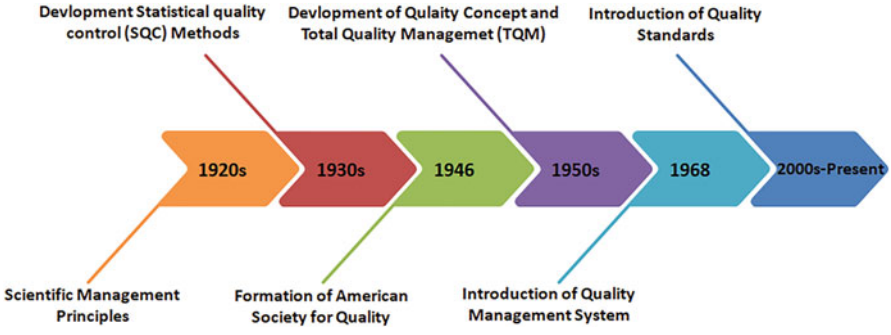

Fig. 1 Timeline evolution of quality

creating an Inspection Committee, which would assign a product of good or flawless quality with a special mark or symbol. In another practice, craftsmen themselves would imprint the symbol on products created by them. This mark originally came in handy when identifying the origin of a faulty item, but over the years, it evolved into a form of peer evaluation and came to represent what good craftsmanship looked like. These markers were the indicators and acted as a proof of the quality of a product sold throughout the medieval European market. This system managed to stay in relevance through several centuries, that is, until the smoke, emblematic of the Industrial Revolution, came sweeping in, changing the quality scene forever.

Up until the seventeenth century, the world of manufacturing was bound by the archaic rules of craftsmanship. The tide of change, however, came in the form of the factory system, which laid a heavier emphasis on product inspection, and its use was popularized in Great Britain, bringing about the onset of the Industrial Revolution starting in the 1800s. While Britain saw a paradigm shift in its quality assurance practices, the same could not be said about its neighbor across the pond. The Americans largely followed the craftsmanship model well into the 1800s, as they were shaped by changes in the predominant production methods. As most craftsmen were selling their goods locally, it meant that they had a personal stake in meeting customers' need of quality, a task in which, if they failed, a loss of customer trust was inevitable. This risk then gave rise to the process of conducting a quality control, wherein the goods were inspected thoroughly before being sold in the market.

But this wasn't the only form of quality assurance that was present. As mentioned above, by the turn of the nineteenth century, the Industrial Revolution had started to grip the United Kingdom and Europe, which brought with it "the factory system." In this system, the trades that were originally particular to their craftsmen were divided into specialized tasks. The craftsmen then became factory workers, and shop owners became production supervisors, changing the way in which commodities were produced. However, this practice initiated the decline of employee autonomy and empowerment at the workplace. The quality in the factory was then ensured through the laborer's work and audits/inspections, and defective products were either removed or scrapped altogether. While the Western world was settling into the factory system, the USA sought to defy tradition and adopt a new management approach, developed by Frederick W. Taylor, called the "the Taylor system," which aimed to increase productivity without expanding the workforce with skilled craftsmen (https://en.wikipedia.org/wiki/Scientific_management#cite_note-Mitcham05p1153-1. Accessed 25 Oct 2022). This was achieved by assigning the task of designing the factories to specialized engineers and making the craftsmen and supervisors the inspectors and managers who helped in executing the engineers' plan. While this led to an increase in productivity, it unfortunately resulted in the decline of the product quality. In order to tackle it amicably, the manufacturers focused their efforts on creating inspection departments exclusively devoted to keep defective products isolated and away from consumers' reach.

During the Second World War, the USA enacted legislation for fulfilling the demands of the civil society and military production. As such, ensuring quality became a paramount safety issue and played a significant role in the war effort. Since the existence

of faulty equipment can result in severe casualties, the US armed forces used to test and inspect each unit of war products for ensuring that it is safe for use. This practice, however, needed a massive pool of testing personnel, causing additional problems of recruiting and retaining well-trained and competent staff. In order to ensure the product quality, safety, and ease in operations, the US defense forces started following the practice of sample, test, inspection, and verification. The Bell Laboratories, in association with industrial experts, introduced the sampling tables, which were also made a part of military standard. MIL-STD-105, as well as integrated into military contracts to get the desired products from the suppliers. Quality, in turn, was ensured by supporting the suppliers and imparting trainings on Walter A. Shewhart's "Statistical Quality Control (SQC)" techniques (https://www.isical.ac.in/~repro/history/public/notepage/Statistical_Quality_Control-F.html. Accessed 25 Oct 2022).

The twentieth century is marked as the beginning of the insertion of "processes" in the quality systems. A "process" in literal sense is defined as a set of actions through certain inputs, which provides outputs with value addition. Later on, Walter A. Shewhart concentrated his efforts on controlling these processes in the mid-1920s, which made quality an integral part for the finished goods as well as the processes used for making them. Shewhart was very clear in his opinion and expertise. He expressed that industrial processes often generate a data bank, which can be easily analyzed statistically to ensure that the processes are stable and in control, or can be fixed if needed. Shewhart then created the "Control Charts," an essential quality tool, used even today. W. Edwards Deming, a statistician and follower of Shewhart's SQC techniques, became the leader of the quality movement in both the USA and Japan (https://asq.org/quality-resources/history-of-quality. Accessed 25 Oct 2022).

Total quality, in America, had started out as retaliation to the Japanese quality revolution following the Second World War, wherein total quality entered into the production of goods for civil society and trade from producing military goods. At first, however, Japanese products were shunned from international markets for their poor quality, and this forced them to re-evaluate their ways of thinking about quality. The Japanese then called upon the expertise of two American quality experts:

(i) W. Edwards Deming, who was frustrated to see the end of the practice of statistical quality control once the war and government contracts came to an end
(ii) Joseph M. Juran, who had foretold that the quality of the products made in Japan would outdo the products made in the USA by the mid-1970s considering the rate of quality improvements in Japan

The Japanese industries were more focused on improving all the organizational, manufacturing, management, and administrative processes, rather than banking on only product inspection and taking feedback from the consumers who used them. This resulted in the production and export of higher-quality goods at competitive prices, benefiting customers across the globe (https://en.wikipedia.org/wiki/Scientific_management#cite_note-Mitcham05p1153-1. Accessed 25 Oct 2022; https://www.isical.ac.in/~repro/history/public/notepage/Statistical_Quality_Control-F.html. Accessed 25 Oct 2022; https://asq.org/quality-resources/history-of-

quality. Accessed 25 Oct 2022; Harris 1995; Martínez-Lorente et al. 1998; Kaur et al. 2021; Kumar and Albashrawi 2022).

Total Quality Management (TQM) in USA

Initially, the manufacturers in the USA were under the impression that the secret of Japanese success lies in a competitive or lower price and accordingly responded with a reduction in domestic manufacturing costs and imposing severe restrictions on imports. However, despite these efforts, they could not get desired positive results for enhancing the competitiveness of the US-made quality goods. Later on, as time passed, the war between competitive prices weakened, while competition in the quality of goods continued to grow. The emergence of the wholesome approach of America, which stressed not only on statistical data but also the entire processes, was called Total Quality Management (TQM), which is still in use all over the world. This was followed by several other quality initiatives, for example, the introduction and implementation of ISO 9000 series standards; the introduction of the Baldrige National Quality Program, and the announcement of the Malcolm Baldrige National Quality Award during the year 1987. Initially, American industries were reluctant to follow the standards but slowly started to adopt them and finally came on board (Nasim et al. 2020; Lim et al. 2022; Dayton 2001). Figure 2 depicts the various elements and features of TQM.

The Practices beyond TQM

At the onset of the twenty-first century, the quality management movement became popular and mellowed. An array of new quality systems was introduced and

Fig. 2 Total quality management (TQM) principles

implemented, and schools of thoughts beyond the past practices established by Deming, Juran, and the earlier Japanese quality experts emerged and are listed as follows:

- The ISO 9000 series of quality management standards was amended, emphasizing customer satisfaction during the year 2000.
- The ISO 9001 series of standards was revised, emphasizing risk management in the year 2015.
- A business results criterion was added in the requirements of the Malcolm Baldrige National Quality Award in 1995 to assess the capabilities of the applicants.
- Motorola, a giant company, introduced the Six Sigma approach for improving business processes and optimizing defects, which achieved breakthroughs and significant bottom-line results.
- Yoji Akao (2014) introduced a new process for quality function based on consumer requirements for change in designs, goods, or services.
- Further revisions were made to the ISO 9000 series of standards based on sector-specific versions like QS-9000 and ISO/TS 16949 for automotive industries, AS9000 for aerospace, TL 9000 for telecommunications, and ISO 14000 for environmental management.
- Thus, quality system moved beyond the manufacturing sector to the services for healthcare, education, and government.

Quality: Perspectives of the Quality Experts

Quality management is not a policy derivative or an idea of an individual, but it is a contribution of several quality experts. The experts have a crucial and significant impact on the world's socioeconomic framework, especially trade and commerce, by improving not only businesses but also several stakeholders from governments, defense, academia, the medical field, and many more (Kher et al. 2010; Rab et al. 2021a, b; Grover et al. 2004). These experts, also sometimes known as Quality Gurus, can be categorized in three phases since the 1940s:

(i) The early 1950s: American quality experts who brought the ideas of quality to Japan.
(ii) The late 1950s: Emergence of Japanese quality experts who brought about new theories on quality in response to the Americans.

During 1970s–1980s:

(iii) American quality experts began to follow the Japanese theories on quality after the Japanese industrial success.

Let's now look at the theories of few of these Gurus. W. Edwards Deming opined that management has greater importance in and upholds the responsibility of

maintaining quality, at both the individual and organizational levels, as he believed that 94% of quality problems are caused by the management itself. He then introduced a philosophy of management for small or large organizations in the public-private or service sectors, emphasizing on 14 points of strategy (https://www.bl.uk/people/w-edwards-deming. Accessed 30 Oct 2022):

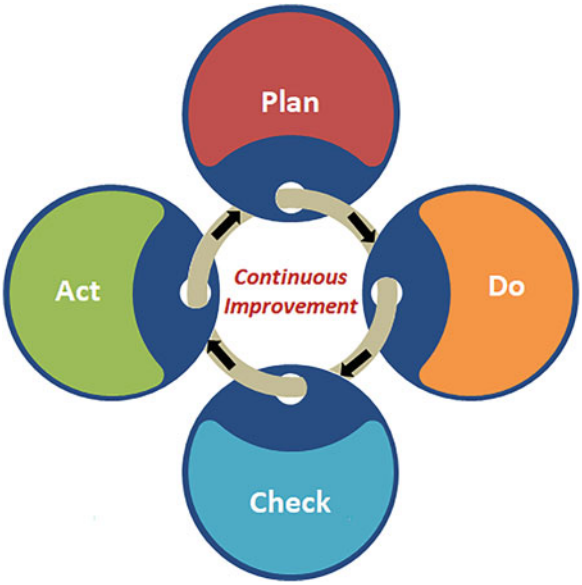
- Make reliable and consistent efforts for the improvement of goods and services.
- Implement the newfangled viewpoints and avoid working with commonly accepted stages of interruption and faulty and defective workmanship.
- Decrease the dependency upon mass inspection and rather focus on work based on data and statistical evidence of quality system.
- Stop the practice of taking decisions based on price but quality.
- Find problems. It is the management's job to work continually on the system.
- Implement contemporary training techniques on the job.
- Implement contemporary supervisory and monitoring techniques for the workers engaged in production. Change the responsibility of foremen from quantity to quality.
- Create a fearless working environment so that everyone works efficiently and effectively for the organization.
- Minimize or stop breaking down barriers between departments.
- Eliminate numerical goals, posters, and slogans for the workforce asking for new levels of productivity without providing methods.
- Eliminate work standards that prescribe numerical quotas.
- Remove barriers that stand between the hourly worker and their right to pride in workmanship.
- Implement a dynamic system of imparting training and educating staff.
- Create a management system of top brass for the implementation, monitoring, and corrective actions on all the above points on a daily basis.

He also encouraged the introduction of a systematic approach of Plan, Do, Check, Act (PDCA) for problem-solving, which is also called the Deming cycle, although it was his colleague, Dr. Shewhart, who was the originator of the idea. The PDCA cycle (Fig. 3) is elaborated as (i) Plan what is needed, (ii) Do it, (iii) Check that it works, and (iv) Act to correct any problem or improve performance.

The PDCA is still a universally well-accepted and implemented method for improvement and reducing the difference between the requirements of the customers and the performance of the process. It is about learning and continuously improving and repeats the cycle when a cycle is completed.

Joseph M. Juran (https://www.juran.com/blog/the-history-of-quality/#:~:text=Juran-Dr,quality%20control%2C%20and%20quality%20improvement. Accessed 30 Oct 2022) developed a methodology based on the quality trilogy. It encompassed tools such as Quality Planning, Quality Control, and Quality Improvement. A good quality management needs first quality actions to be planned, improved, and controlled. He was a firm believer that quality is related to customer satisfaction and dissatisfaction with the product and stressed the need for continuous quality improvement and summarized his

Fig. 3 PDCA cycle



methodology in a 10-point formula: (i) Build awareness of the need and opportunity for improvement, (ii) Set goals for improvement, (iii) Organize to reach the goals, (iv) Provide training, (v) Carry out projects to solve problems, (vi) Report progress, (vii) Give recognition, (viii) Communicate results, (ix) Keep score of improvements achieved, and (x) Maintain momentum.

Kaoru Ishikawa (https://asq.org/quality-resources/articles/quality-nugget-creating-ishikawa-fishbone-diagrams-with-r?id=6972c50861424b36966406e53618b367. Accessed 30 Oct 2022) made several contributions to quality. The Ishikawa fishbone diagram is the most popular tool, used all over the world for quality improvements. The diagram signifies and investigates the actual causes behind a problem or effect. The identified causes, highlighting the problem/effects, are used to minimize or Remove the application of possible or probable corrective actions. It also supports generating systematic ideas and presenting results to stakeholders.

Genichi Taguchi (https://www.qualitygurus.com/genichi-taguchi/. Accessed 30 Oct 2022) believed that quality and reliability should be implemented at the design stage itself where they really belong and describes quality in three stages: (i) system design, (ii) parameter design, and (iii) tolerance design. His developed methodology, popularly known as "Taguchi methodology," is a prototyping method that allows the staff to detect the optimal settings required to manufacture a vigorous product that can endure manufacturing time after time, piece after piece, and provide what the customer wants.

The Single Minute Exchange of Die (SMED) system was introduced by Shigeo Shingo (https://en.wikipedia.org/wiki/Single-minute_exchange_of_die#:~:text=Shingo%20moved%20to%20the%20US,%2C%20less%20than%20ten%

20minutes. Accessed 30 Oct 2022), an inventor known for his Just-in-Time manufacturing concept, wherein set-up times are abridged from hours to minutes. He also worked on the Poka-Yoke (mistake proofing) system where faults are examined, the manufacturing is stopped, and instant feedback is given to find out the root causes of the problem, and preventive and corrective actions are taken to avoid any reoccurrence. The inclusion of a checklist allows for the prevention of any errors. He further emphasized on the evitable errors to become defects at later stages rather than suggesting to stop errors before the product reached the consumer to avoid becoming defects.

The idea of "quality is free" and "zero defects" was proposed by Philip B. Crosby (https://www.bl.uk/people/philip-crosby#:~:text=Throughout%20his%20work%2C%20Crosby's%20thinking,performance%20standard%20is%20zero%20defects. Accessed 30 Oct 2022), describing the following four points for improvement in the quality process:

(i) Quality is conformance to requirements.
(ii) The system of quality is prevention.
(iii) The performance standard is zero defects.
(iv) The measurement of quality is the price of non-conformance.

He further marked and suggested 14 steps as follows:

- Ensure management commitment to framing a suitable and appropriate quality policy.
- Establishing a Quality Improvement Team (QIT) of the management with the responsibility of the planning, implementation, and execution of the quality improvement process.
- Find out the existing and possible glitches in the quality system.
- Make a detailed analysis of the cost of quality and utilize problems as management tools to assess waste.
- Arrange quality awareness programs and tools for the engaged quality staff.
- Take corrective actions using established formal systems to remove the root causes of problems.
- Set up a zero-defects committee and program.
- Impart training to staff in quality improvement.
- Celebrate a Zero Defects Day to transmit the management recommitment and the staff responsibilities.
- Inspire individuals and staff members, setting improvement goals.
- Inspire staff to connect and inform management of any hindrances to achieving their goals.
- Provide official credit to the participating staff.
- Set up quality councils for the exchange of sharing ideas and information about quality management.
- Do and repeat it and make a new QIT.

Quality Beyond – QC, QA, QMS, TQM, Etc.

As time goes by, the concept of quality has undergone a sea of changes, and several terms have emerged, which are multifaceted in practice, intricate and connected with quality, and elaborated as follows:

1. ***Quality Control (QC):*** The QC basically refers to the operational techniques used to fulfill the requirements of quality.
2. ***Quality Assurance (QA):*** It refers to methodical and prearranged actions that are essential to providing adequate confidence that a product or service would satisfy the specified requirements for quality.
3. ***Quality Management Systems (QMS):*** The QMS embodied an assortment of business processes ensuring constantly the fulfillment of customer requirements and enhancement of their satisfaction. It is aligned with an organization's purpose and strategic direction.
4. ***Total Quality Management (TQM):*** It refers to the process of individual and organizational development for ensuring the satisfaction level of all the stakeholders.

At first sight, these terminologies seem simple and easy to understand, but upon delving deeper into the evolution of quality, it is evident that they bring a significant change in the ways the enterprises work. Nowadays, customers are well aware of the quality and often buy quality products or services as well as follow the desired specifications on competitive pricing. In order to meet these demands, the business and trade houses used to adopt well-established management practices and systems that can design, fabricate, manufacture, and produce quality goods, fulfilling customer requirements, specifications, and outlooks with competitive pricing. However, nothing is everlasting and the quality system is too dynamic, and these practices continue to alter from time to time, with the emergence of varied quality concepts and definitions by quality experts, compelling enterprises to execute changed quality practices and systems for overall product quality.

By the end of the twenty-first century, quality was characterized as "conforming to the standard and specifications of a product." W. Edwards Deming stressed that "quality is to fulfill the requirements of customers and satisfy them," and accordingly, the quality remained "customer focused." This allowed enterprises to remain focused on satisfying consumer expectations and retaining their loyalty. The companies used to gather information regarding customer expectations through personal interaction, interviews, service feedback, and market surveys. Recently, the launch of Apple's products revealed that honing the attention only on customer satisfaction is not adequate, but consumers' inherent, latent, and emotional views are equally important to ensure the good quality of a product or service. Utilizing such inputs, Apple kept on introducing continuously new and innovative products (such as iPhone, iPad, Mac, etc.). This resulted in an exponential increase in their sales volumes, providing services with customer delight. As a result, the quality notion further changed to "customer delights." Such modifications/revisions always keep

participating enterprises on their toes and urge them to update their quality systems (Mukherjee 2006; Sroufe and Curkovic 2008; Charantimath 2017; Ibidapo 2022; Kumar et al. 2018; Rab and Yadav 2022).

The Concept of "Standard" and "Inspection" Control

The early twentieth century witnessed the introduction of control practices in industrial processing and manufacturing activities for ensuring quality products. In this period, manufacturers paid attention to the relative productivity and production costs. Accordingly, this period is called "product focused through quality control." The Ford Motor Company, USA, introduced the concept of the Assembly Line, their newly established manufacturing unit that resulted in a production volume manifold. Later on, this idea and concept was adopted and used by several other industries. Since this time was the "product-focused" era, industries focused their attention on control products. Therefore, the quality concept was intended to "conform to the standards and specifications of a product." This encouraged quality engineers to contrive the technique of "inspection," to control the quality of a finished good. This compelled the product designers, engineers, and quality experts to design and formulate the standards and specifications of the products and the standards of the manufacturing process and operations, i.e., the Standard Operating Procedures (SOPs). The workforce involved in manufacturing and quality system was advised to perform their duties and tasks as laid down in the SOPs (Rab and Yadav 2022; https://gacbe.ac.in/pdf/ematerial/18BMA64C-U5.pdf. Accessed 25 Oct 2022; Yadav and Aswal 2020; Lahidji and Tucker 2016; Wruck and Jensen 1994).

Development of Process for Quality Control

As reported earlier, the "full inspection" method is required by manufacturers to ensure product quality. This process was time-consuming, labor-intensive, and had additional high internal quality costs. Walter Shewhart, a quality control engineer in Bell Laboratories, designed a method for ensuring quality by introducing a control chart, suggesting random sampling inspection rather than 100% inspection to cut inspection cost and increase the overall effectiveness of the system (https://gacbe.ac.in/pdf/ematerial/18BMA64C-U5.pdf. Accessed 25 Oct 2022). The combination of the use of random sampling inspection and control charts increases the involvement of statistical tools, probability theory, and random sampling methods for improving the quality levels. Therefore, this method came to be popularly known as "Statistical Process Control (SPC)" or "Statistical Quality Control (SQC)." The sampling inspection ensuring method could not be considered a perfect tool for ascertaining product quality, and random sampling resulted in a few faulty goods being sent to consumers. This imposes additional costs beyond quality costs. Shewhart, however, suggested that additional cost on fewer defective pieces within the acceptable limit is not a big issue, considering the huge savings on inspection cost (Rab and Yadav

2022; https://gacbe.ac.in/pdf/ematerial/18BMA64C-U5.pdf. Accessed 25 Oct 2022; Yadav and Aswal 2020; Lahidji and Tucker 2016).

The QMS During the Mid-twentieth Century

Often, better quality and lower price of a product are normally the deciding factors for a consumer to buy a product. This is the reason why manufacturers focused their attention on the control of quality and prices. As a core issue, Juran (1951) advocated the concept of "quality costs"; bifurcating the quality costs into preventive costs, assessment costs, and internal and external failure costs. As per an estimate, the losses that occurred due to the manufacturing of defective pieces and failures are higher than the costs of quality control, especially the costs due to internal and external failures. Therefore, the implementation of SPC could not produce the desired results to control the quality costs. Several quality experts suggested other "invisible" or "hidden" quality costs. The term "invisible cost" is used to indicate failure costs that are inadequately recorded in company accounts, and/or failure costs that are never actually discovered. Yang (Snieska et al. 2013) addressed the hidden costs through the definition and addition of two new categories: "extra resultant cost" and "estimated hidden cost." As such, the quality costs can be categorized as (i) preventive, (ii) evaluation, (iii) internal failure, (iv) external failure, (v) extra resultant, and (vi) estimated hidden.

As pointed out earlier, several Quality Gurus including Feigenbaum were of the view that implementing an SPC system alone would not control quality costs successfully. During the intervening time, a new quality concept came into existence called "quality assurance," which was "users oriented," indicating that the product is fit for the intended purpose and quality requirements. Therefore, it was inferred that quality is defect-free or possesses zero defects and fulfills the required specifications.

A literature survey revealed that quality assurance may also not be adequate to achieve the desired results by controlling production processes. Therefore, the concept of Total Quality Control (TQC) was proposed in 1959, which stresses that product quality requirements, to be instigated at all the stages of the product life cycle, comprise product design, incoming quality approval, process quality control, product reliability, inventory, delivery, and customer service. The concepts and approaches of SPC, TQC, and "costs of quality" were introduced in Japan in 1960 by Deming and Juran (Aljuboury 2010). The Union of Japanese Scientists and Engineers (JUSE) introduced and developed the concepts, principles, and approaches of Statistical Process Control and Total Quality Control. The JUSE promoted the practices of TQC and the quality concepts, pursuing the zero-defect culture and executing the task right the first time (https://www.qualitygurus.com/genichi-taguchi/. Accessed 30 Oct 2022).

Emergence of Japanese Company-Wide Quality Control (CWQC)

The Japanese enterprises espoused the TQC practices and stressed on imparting education and training on quality for all the staff engaged in establishing a quality culture in the organization. Therefore, the implementation of TQC in Japanese

industries was very different from the original TQC (https://www.juran.com/blog/the-history-of-quality/#:~:text=Juran-Dr,quality%20control%2C%20and%20quality%20improvement. Accessed 30 Oct 2022). The Japanese TQC possessed several critical characteristics listed as follows:

(i) It is customer focused and quality first as the quality policies.
(ii) It advocates full participation and teamwork.
(iii) It emphasizes imparting education and training on quality to all staff members.
(iv) It stresses upon the concept of "do the right thing the first time."
(v) It advocates the concept and implementation of a "zero-defect" culture.
(vi) It stresses upon "continuous improvement" as the key quality activity.
(vii) It holds everyone responsible for achieving high-quality levels.
(viii) It emphasizes on preventive activities and quality assurance.
(ix) It instigates a quality culture regime in the organization.

The Japanese TQC system, when implemented with these crucial characteristics, is called a Company-Wide Quality Control (CWQC) system. The insinuation of CWQC in association with Japanese industrial competitiveness and tactical advantages enabled them to enter into Western markets. Based on this CWQC-driven system, high-quality products at lower prices were sold to consumers, and the Japanese industries enjoyed their enhanced market share globally, providing huge competition to Western and Asian industries and manufacturers.

Development of Total Quality Management

The Japanese competitive domination compelled the American and Western world to devise benchmarking projections, adopting Japanese CWQC performance indicators of quality management, which finally led them to develop a polished CWQC called Total Quality Management (TQM) system with the inclusion of refined characteristics listed as follows:

(i) Customer-focused management.
(ii) Continuous improvement of the key quality activity.
(iii) Top management promises persistence in pursuing quality.
(iv) Full participation and working as a team.
(v) Education and training on quality to staff.
(vi) Employees' good quality concept.
(vii) Quality leadership.
(viii) Long-term supplier relationship.
(ix) Implementation of the quality management system.
(x) Cultivation of quality culture.

The TQM was also fairly influenced by the Western Quality Gurus (Deming, Juran, and Crosby). As mentioned earlier, Deming's concept was that "quality is to

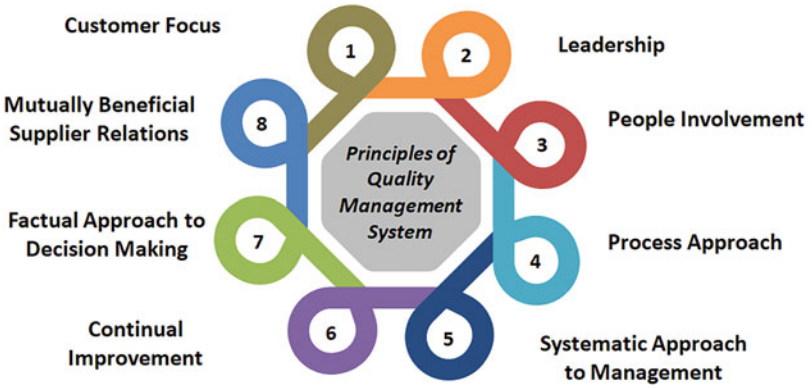


Fig. 4 Quality management system (QMS) principles

fulfill the requirements of customers and satisfy them"; Crosby vehemently propagated the concept of "conformance to customers' requirements," and Juran suggested "fitness for purpose of use, assessed by the users instead of industries, or the merchants." Therefore, the TQM has developed the integration of management viewpoints, quality principles, sets of SOPs, the use of statistical tools, quality control process, standardization, improvement mechanism, quality concept, staff participation, education and training, quality culture, etc. The eight principles of TQM are shown in Fig. 4. The mid-1980s and later periods witnessed the emergence of several important quality programs. Among them, ISO 9000 system and Six Sigma program came into practice in the year 1987. It is important to note here that the ISO system has been revised four times in 1994, 2000, 2008, and 2015. The Six Sigma quality scheme was widely imitated by GE in 1995 (Karthi and et.al. 2012).

Benefits of Quality Management (QM) and QM Tools and Methods

For the business growth of any organization, customer satisfaction and loyalty are extremely important. It is always crucial for industries to have loyal customers as business cannot thrive only on new customers but also requires repeated consumption from loyal customers. The QM safeguards improved quality goods and services for customer satisfaction, which eventually leads to customer loyalty. The quality is assessed through various indicators like performance, consistency, reliability, and durability. It is an important parameter vibe which an organization is compared with its competitors.

The QM tools ensure changes in the systems and processes, which finally results in improved and better-quality goods and services. The QM methods (say, TQM or Six Sigma) are used for delivering a high-quality product fulfilling product requirements, specifications, and customer satisfaction (Permana et al. 2021; Siva et al. 2016). The buyer would not buy and recommend the product if their previous buying experience is not good, in the event of a defective product or service. They would

come back to your organization if they are satisfied with their purchases. It is the responsibility of the organization to make sure that the buyer is satisfied with the product. It is the organization that has to understand what specifications of the product are and what the customer expectations are. It is imperative to gather the pertinent data to provide some insight and vision about requirements and demands. One of the sources for such information is the regular feedback from the customers that needs to be collected, monitored, and analyzed carefully.

The QM ensures high-quality products and services by eliminating defects and incorporating continuous changes and improvements in the system. It also ensures that the promised goods and services are delivered to the clients, for which various promotional activities can be carried out to make the public aware. The QM tools help an organization to design and create a product that the customer actually wants and desires. The QM ensures increased revenues and earnings, increased cash flow, higher productivity, timely disbursal of salary and perks to the staff, employees' well-being and satisfied employees, a healthy workplace, higher customer loyalty, etc. The removal of needless processes leading to waste of time and not helping productivity is always required. The QM enables employees to deliver more work in less time, the reduction of waste and inventory, staff to work closely with suppliers and to incorporate "Just-in-Time" philosophy, close harmony among employees, and a strong feeling of teamwork (Aycock 2003; Canel et al. 2000).

Need for Quality Management and Relevance in Global Trade

As per the detailed discussion in preceding sections of this chapter, one can inarguably and easily infer that quality is virtually or visibly crucial and important in every sphere of our lives, including global trade, and removing trade barriers. It would not be a stretch to conclude that all economies, and all their sectors, rely heavily on the existence of a quality culture. One can say that progress comes off the back of the continuous strive toward achieving good quality. All the countries need to be enabled to enjoy the advantages of globalization while effectively protecting themselves from its risks. The standards and their enforcement should not be considered as trade's new barriers but as a tool to facilitate global trade, ensuring adherence to laid-down standards, procedures, specifications, and regulations for products and services under global trade. For example, in developing countries, expensive certification procedures mean that agricultural smallholders and cooperatives that do not have access to technical assistance are at a serious disadvantage. Public institutions are increasingly unable to defend the interests of producers, especially small-scale ones. The result is that in many instances, small producers in developing countries get completely cut off from the process of standard setting and monitoring. Formerly, only tariffs were in principle recognized as restrictions to export/import and international trading. However, with the globalization of economies, the days when nations could afford to indulge in bilateral tariff-cutting negotiations have largely gone. Attention has shifted to so-called technical, or non-tariff, barriers to trade. A robust and strong national quality infrastructure (NQI) is essential in breaking down

technical barriers to trade. It is thus the key to the greater integration of the partner countries into the international trading system (Kher et al. 2010; Rab et al. 2021a; Rab et al. 2021b; Carvalho et al. 2021; Rab et al. 2022). The quality infrastructure (QI), its main pillars, and other elements are described separately in this section of the handbook in some chapters and other related literature. Readers are encouraged to go through the details of QI in these chapters.

Conclusion

The discussion presented in this chapter clearly reveals that quality infrastructure and quality management system of any country need to be strong, robust, effective, and sustainable for industrial, social, and economic growth. Practically, almost all the industries, organizations, academic institutions, business houses, hospitals, etc., have huge advantages in implementing quality system, accreditation, and conformity assessment schemes. The process, product, and service efficiencies can be significantly improved by imposing such schemes. The implementation of a QMS will aid the company in crucial areas like reducing the number of defective goods, enhancing internal communication, raising customer satisfaction, growing market share, and expanding globally. The winery's drive to continue its quest for quality improvement is driven by grasping these benefits. This report also illustrates the direct or indirect relationship between specific QM practices and other activities that leads to growth and innovation. The report is presented in a concise way, introducing quality subject and its terminologies; evolution of quality and historical perspectives; quality management system; and their applicability, importance, and significance in national and international trade. It is the endeavor of the authors to present a useful resource material at one place for all the stakeholders, including students, quality practitioners in calibration and testing laboratories, academicians and educators, accreditation and quality specialists, legal metrologists, regulators, administrators, and policymakers.

Abstract

The concept of accreditation evolved after the Second World War to standardize the products manufactured at different places by different manufacturing units. The accreditation was required to avoid the rejection, retesting, and recalibration and minimize the cost of the production, and accreditation was limited to the industrial goods and products. Initially, there was a problem in the measurement of the dimensions of the product produced by the different manufacturing units. Because of the difference in the dimension in the same product or similar products produced by the two or more than two units, there was rejection in one of the products. To avoid the reproduction due to difference in the products, the standardization was required so that products can be manufactured within the permissible limits. To obtain standardization accreditation is the most reliable tool, as there are various requirements which need to be fulfilled by the testing and calibration laboratories. By getting accreditation of the measurement

performed at different places of the globe, the measurement can be done within the permissible limits. In India the concept of accreditation was introduced in the early 1980s as it was expected in the future standardization will be the key for the success in the business not only at local level but at international level also. Initially, the growth of accreditation was very slow, as the National Accreditation Board for Testing and Calibration Laboratories (NABL) took around 11 years to accredit the first laboratory and accreditation was limited to the measurement at the production level in the manufacturing industries. Due to globalization the demand for accreditation was increased to export the products, and also to check the quality of imported products accredited laboratories were required. Over a period of time the accreditation was required in every field from manufacturing units to the food products, health products, etc. The growth of accreditation labs in India was remarkable after 2012. Almost in every field the National Accreditation Board for Testing and Calibration Laboratories (NABL) has accredited the laboratories, and many regulators have started recognizing the accredited laboratories for performing the testing and calibration in the required parameters. Today accreditation has entered everywhere; it seems that the laboratories of all fields get accreditation as it is the requirement of the regulators, ministries, various departments from the government and private sectors, and customers from our county as well as from aboard. Here, it has been discussed how the accreditation has impacted the general citizen of the country and how the accreditation entered in the life of the common men.

Accreditation · ILAC · APLAC · NABL · Weight and measures · Legal Metrology

Introduction

The term accreditation has great importance in today's scenario, and it was started during the Second World War. The need for accreditation was felt during the Second World War when the bullets produced at different manufacturing units were not fitted in the barrel of gun produced at different manufacturing units. The requirement of standardization in the field of measurement was felt at that time. The big challenge was that how to produce/manufacture standardized products to avoid the retesting and rejection. The term standardization comes into the existence. How measurements done by one organization can be similar or within the permissible limit so that it can be used by the other organization? What mechanism can be used to assure the measurements done by the organization? To assure the measurements done by the manufacturing unit, accreditation comes into the existence. The concept of accreditation was started first time in Australia, with the organization, namely, National Association of Testing Authorities (NATA) in 1947. Slowly the concept of accreditation evolved in other parts of the world.

The Indian government also felt the need of standardization in the measurement. To cater this need the National Coordination of Testing and Calibration Facilities (NCTCF), now the National Accreditation Board for Testing and Calibration Laboratories (NABL) (www.nabl-india.org-seen), India, was established with the objective to provide the government and industry with a scheme for third-party assessment of labs in 1982, and NCTCF was changed into National Accreditation Board for Testing and Calibration Laboratories (NABL) in the year 1993. In the year 1998 NABL was registered under the societies act, as an autonomous body under the Department of Science and Technology (DST). Presently NABL is a constituent board of Quality Council of India. NABL merged with Quality Council of India (QCI) (www.qcin.org-seen) on 04.01.2017. The Quality Council of India is an autonomous body under the Department for Promotion of Industry and Internal Trade (DPIIT), Ministry of Commerce and Industry, Government of India.

The growth of accreditation in India was very slow as NABL took 11 years to accredit the first laboratory. Initially the accreditation was limited to the manufacturing units, but as time passes, it becomes a requirement for everyone. The comparison of the present situation of accreditation with the early 1990 is completely different. Today the number of accredited labs in all the field is more than 7000. Accredited labs include calibration and testing as per the ISO/IEC 17025 (ISO/IEC 17025 2017) (general requirements for the competence of testing and calibration laboratories), medical testing laboratories as per ISO 15189 (ISO 15189 2012) (medical laboratories – requirements for quality and competence), proficiency testing providers laboratories as per ISO/IEC 17043 (ISO/IEC 17043) (conformity assessment-general requirements for proficiency testing), and reference material producers as per ISO 17034 (ISO 17034) (general requirements for the competence of reference material producers).

NABL is signatory to Mutual Recognition Arrangement (MRA) since 2000 as per ISO/IEC 17011 (ISO/IEC 17011 2017). In the year 2000 NABL was evaluated by Asia Pacific Laboratory Accreditation Cooperation (APLAC), now Asia Pacific Accreditation Cooperation (APAC) for testing and calibration laboratories as per ISO/IEC 17025. In year 2004 and 2008 NABL was re-evaluated and reaffirmed for testing and calibration laboratories. In the year 2012 NABL achieved MRA signatory status for the testing of medical laboratories and re-evaluated and reaffirmed for testing and calibration laboratories. During the APLAC evaluation in year 2016, MRA signatory status of proficiency testing providers (PTP) as per ISO/IEC 17043 and reference material producers (RMP) as per ISO 17034 was added with the previous scope of testing, calibration, and medical testing. Due to COVID-19 the APAC evaluation was conducted in 2021, whereas it was due in the year 2020. In the APAC evaluation 2021 NABL was re-valuated and reaffirmed for testing, calibration, medical testing, PTP and RMP.

It has been observed in the last decade the requirements of accreditation were felt in every sector of the country whether it is industry, food, agriculture, pharma, or chemicals and in the field of medical testing. From the industry point of view, the accreditation is very important because the testing done by the NABL accredited

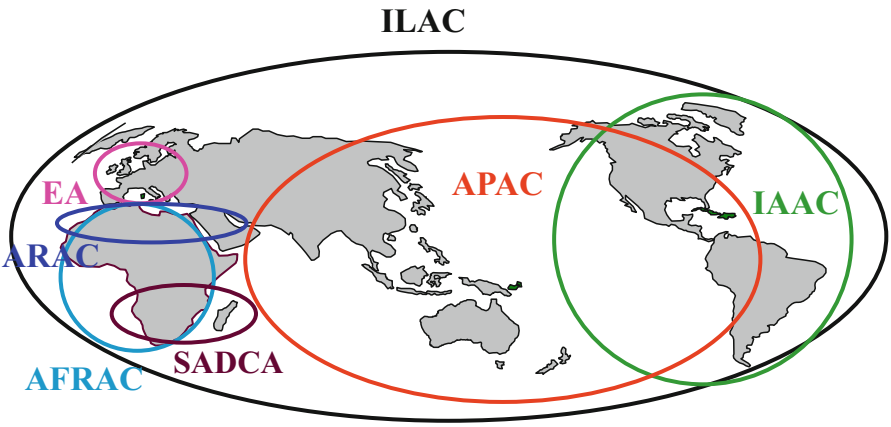

Fig. 1 International linkage of accreditation organizations

laboratory is accepted in the members country of APAC and International Laboratory Accreditation Cooperation (ILAC) and NABL is MRA signatory.

The status of NABL at the international level can be understood by Fig. 1.

EA	European Cooperation for Accreditation
APAC (www. https://www.apac-accreditation.org-seen)	Asia Pacific Accreditation Cooperation
ILAC (www.ilac.org-seen)	International Laboratory Accreditation Cooperation
IAAC	Inter-American Accreditation Cooperation
AFRAC	African Regional Accreditation Cooperation
ARAC	Arab Accreditation Cooperation
SADCA	Southern African Development Community Accreditation
Unaffiliated bodies	Peer-evaluated ABs who are not geographically located in one of the established regions

Here, it can be seen in the figure, the bigger circle is showing the ILAC region which is covering the whole globe. It shows that all the accreditation bodies which are members of the regional bodies are members of ILAC. NABL is MRA signatory in APAC and MRA members of ILAC also.

The accreditation can be understood with the definition "**Third party attestation related to a conformity assessment body conveying formal demonstration of its competence to carry out specific conformity assessment tasks (ISO/IEC 17000** 2004**)**" as per ISO/IEC 17011; here the accreditation body formally recognizing the conformity assessment body to perform specific task based on the assessment done by the assessors on behalf of the accreditation body and the technical competency of the conformity assessment body (CAB) is witnessed by the assessment team. Also, the management system of the laboratory is assessed based on the specific standard

for testing and calibration, medical testing, proficiency testing providers (PTP), and reference material producers (RMP).

The results which are produced by the accredited CABs are believed because the laboratory has quality management systems and various quality assurance activities to be confirmed by the laboratory, trained personnel, and traceable instruments. In a nutshell there is very stringent and rigorous process of accreditation followed by the accreditation body to assess the conformity assessment body for the specific scope of accreditation. The requirements of accreditation can be understood with the help of the parameters of accreditation in the testing calibration and medical testing.

The accreditation services provided by the NABL in the various types of testing are as follows:

In the field of testing, it includes chemical, biological, mechanical, electrical, electronics, fluid flow, forensic, non-destructive (NDT), photometry, radiological, and diagnostic radiology QA testing.

In the field of calibration, it includes mechanical, electro-technical, fluid flow, thermal, optical, medical devices, radiological, etc.

Similarly medical testing laboratories include clinical biochemistry, clinical pathology, cytogenetics, cytopathology, hematology and immuno-hematology, histopathology, microbiological and serology, and nuclear medicine (in vitro).

In the field of PTP, it includes testing, calibration, medical, and inspection, and RMP includes chemical composition, biological and clinical properties, physical properties, and engineering properties.

Now by considering the above scope of accreditation covered by NABL, it is evident that almost all the parameters covered and some of the parameters are directly affecting the common men. For example, food and agriculture product testing, drugs and pharmaceuticals products, water, environment and pollution, marine/aqua culture food products all are covered under scope of accreditation. Similarly, in the field of calibration, the calibration of mass, balance, and volume is required for the scientific purpose.

Most of the regulators require NABL accreditation for the purpose of approval. Some of the regulators are as follows:

- Ministry of Health and Family Welfare (Food Safety and Standards Authority of India (FSSAI))
- Ministry of Consumer Affairs (Weights and Measures)
- Ministry of Drinking Water and Sanitation
- Ministry of Commerce and Industry (Tea Board, Coffee Board, Spices Board, etc.)
- Ministry of Health and Family Welfare (Central Government Health Scheme (CGHS) and Govt. Hospital Laboratories)
- Ministry of Health and Family Welfare (Central Drugs Standard Control Organization)
- Ministry of Power (Bureau of Energy Efficiency (BEE))
- Ministry of Environment and Forests (Central Pollution Control Board (CPCB))
- Ministry of Consumer Affairs (Bureau of Indian Standards (BIS))

- Ministry of Commerce and Industry (Export Inspection Council (EIC))
- Ministry of Commerce and Industry (Agricultural and Processed Food Products Export Development Authority (APEDA), Marine Products Export Development Authority (MPEDA), Export Inspection Council (EIC), etc.)

Any laboratory requiring approval from the regulators to work with them requires NABL accreditation. There are some regulators which are performing integrated assessment for approving the laboratory, for example, FSSAI (https://fssai.gov.in-seen), tea board, AMPEDA, EIC, etc.

The requirement of accreditation is increasing day by day; almost in every field accreditation is required. In early 2000 there were very few laboratories accredited, and the demand of accreditation increased in the coming years. The accreditation is required by the govt. departments, regulators, and exporters.

The need of accreditation can be understood during the COVID-19. The reverse transcription–polymerase chain reaction (RTPCR) testing laboratories accredited by NABL have played a very big role, and still there are many states which are allowing to travel only after RTPCR negative report. Also, in the field of medical testing, the testing done by the accredited labs as per ISO 15189 is more reliable, and there in case of health insurance, the hospital which are having accredited pathology labs are given preference over the hospital which are having non-accredited laboratory.

Today, the international, national, or regional standards are available for each and every commodity which is used by the common men of our country. The common commodities can be food, water, air, soil, etc. which are directly impacting over the health of living things. For the safeguard of human beings, the testing is required in the field of air, water, and soil. The policies can be framed based on the testing results by the various types of the laboratories. Now the question which is always alive is the reliability of the test results produced by the laboratory. How the test results produced by the testing laboratory can be believed? And the best possible answer of this question is "**Accreditation**" as per ISO/IEC 17025, because the laboratory which has accreditation to perform specific task can be considered competent. Also, accreditation laboratory is proving their competence in every accreditation cycle based on the assessment conducted by the accreditation body.

The importance of accreditation is increasing day by day not only in the fields of manufacturing, production, research and development, and medical sciences but in the life of the common citizen of India, as there are many regulators in India which are taking care of quality in their respective fields.

The Legal Metrology Department under the Ministry of Consumer Affairs is taking care of weights and measures. By discussing the structure and working of Legal Metrology Department, the accreditation in the life of general citizens of India can be understood. Also, the Legal Metrology Department can be considered the fourth pillar of quality infrastructure. The term quality infrastructure is very important and can be understood with the help of Fig. 2.

The quality infrastructure of the country depends upon the four pillars, namely, National Physical Laboratory (NPL), New Delhi, which is custodian of physical standards of the country, and these physical standards are traceable to the SI unit by

Fig. 2 Quality infrastructure in India

means of intercomparison with other MNIs of the world. Second is the National Accreditation Board for Testing and Calibration (NABL) which is responsible for providing the accreditation to the testing, calibration, and medical testing laboratories in the country. The Bureau of Indian Standards (Bureau of Indian Standards Act 2016) (BIS) is responsible for developing various types of standards which can be referred for various purposes. The Legal Metrology can be considered the fourth pillar of the quality infrastructure because the weights and measure used for the commercial purposes are controlled by the Legal Metrology department only.

The Department of Legal Metrology takes care about the accurate quantity of weights and measure for the purpose of the various consumers/customers in the country. In fact, it is a direct implementation of quality infrastructure at ground level for the public across India that ensures accurate measurements of weight, length, and volume of the day-to-day commodity quantity purchased by a consumer from a trader. At present, few labs from government are unable to provide good services due to increase in population and variety of commodities with the time. Hence, the role of private labs to augment metrology service is also of paramount interest.

The prime function of the Legal Metrology Department is to ensure the quantity within the permissible limits. The Legal Metrology Department functions at center as well as state level. The Legal Metrology Department at center level is under the Ministry of Consumer Affairs, whereas at state level it is under the different ministries, differing from state to state. There are more than 100 secondary reference standard laboratories across the country, and these laboratories maintain the

Fig. 3 Brass Bullion weights used for trading purpose (https://dir.indiamart.com/impcat/brass-bullion-weight.html-seen)

Fig. 4 Weighing machine used for trading purpose (https://amtech-enterprises.business.site-seen)

traceability through RRSL laboratories; all five RRSL laboratories are NABL accredited and maintain their traceability through NPL-India.

The weights and measures which are commonly calibrated/verified/stamping by the Legal Metrology Department can be understood with the help of Figs. 3, 4, and 5.

Fig. 5 Brass conical measure used to measure the various liquids (https://www.indiamart.com/proddetail/brass-conical-measure-11082205288.html-seen)

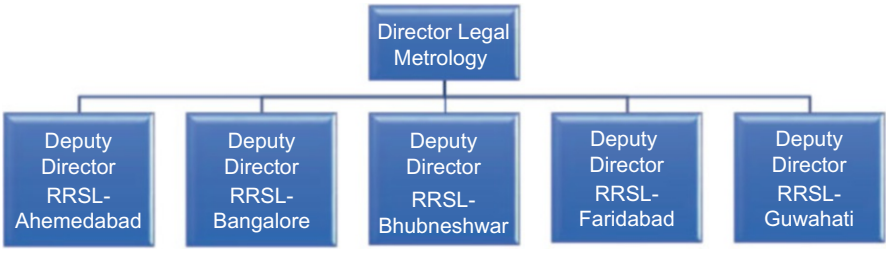

Fig. 6 Hierarchy of RRSL laboratories

There are many other measures, like measuring tape and steel scale, pressure gauges which are used on petrol pumps, etc.

The structure of Legal Metrology can be understood as below:

The Regional Reference Standard Laboratories (RRSL) under the Ministry of Consumer Affairs are under the control of the director of Legal Metrology, and the organization structure of the RRSL can be understood by Fig. 6.

The work of the Legal Metrology RRSL laboratories is to support the secondary reference laboratories of the state level. The traceability of the secondary standard reference laboratory of all the states is maintained through RRSL to the NPL.

The secondary standard reference laboratories are under the control of the controller of Legal Metrology of the particular state, and these labs are under the different ministries in the different states.

There are very few secondary reference laboratories accredited, and to improve the quality of work and their confidence, accreditation can be an effective tool. It has been discussed that all these labs must be under the ambit of accreditation. Also, it was observed that to develop the culture of accreditation among these labs, first recognition program can be initiated based on certain requirements like trained personnel, traceable instrument, and environmental and accommodation facilities of the laboratory. The joint program by NABL and the Legal Metrology Department has planned for the recognition of the secondary reference laboratories of various states. The recognition will be for 2 years and fee will be minimal.

The calibration/verification/stamping is done only by the state government labs under the Department of Legal Metrology, and it has been observed that the workload is very high; therefore initiative has been taken for Government Approved Test Centre (GATC) as per the GATC rule, 2013, from the private sector. The GATC rule is already established, and a Joint approval program can be initiated by NABL and the Legal Metrology Department. For executing the GATC program, the amendments in GATC rules are required so that the same can be executed smoothly. The amendments in the GATC rule can be discussed, and the policy document of Procedure for Approval from Legal Metrology Department for Government Approved Test Centre (GATC) for Calibration/Verification/Stamping can be discussed for executing the program jointly.

The requirements of GATC program were needed because there were many constraints in executing the calibration/verification/stamping of weights and measure across the country; therefore the Ministry of Consumer Affairs, Government of India, has issued a GATC act in 2013. The act was related to the approval of private laboratories for the execution of calibration/verification/stamping of weights and measure. The act was made for the private sector laboratories to perform calibration/verification/stamping of weights and measure because of the shortage of employees in the Legal Metrology Department at state as well as center government level. The state government was not able to verify the stamping of weights and measure with the required time period. Scientifically the weights and measure should be calibrated/verify/stamping within a year, but it was not possible. The reason of not executing the calibration/verification/stamping within the stipulated time period was not only due to shortage of manpower but due to nonavailability of infrastructure for executing the required functions. Therefore, the Indian government decided to approve the GATC (government-approved Test Centre) from the private sector. The rule was made in the year of 2013, but the Government of India was not able to execute this rule. Again, there was shortage of manpower for approving the GATC from the private sector. The GATC rules are well defined regarding the requirements of the laboratories in terms of personnel and the technical competence. As the Legal Metrology Department has constraints about the personnel who can execute the approval of GATC along with funds required for the execution of this scheme for the private sector laboratories. The Legal Metrology department has started discussion

with NABL for jointly executing GATC program, related to the training of personnel with respect to accreditation process, requirements of the accreditation body and measurement techniques in the field of weights and measures. The NBAL has conducted three training programs for the officers of Legal Metrology Departments from the center government and states along with union territories. The first training program was conducted in July 2017 for more than 50 officers of Legal Metrology, and the second training program was conducted in Sept 2018 where more than 50 officers were trained regarding the requirements of ISO/IEC 17025:2017 and techniques of mass metrology. A similar kind of training program was conducted for Legal Metrology Department officers in Feb 2019.

There were two programs agreed between Legal Metrology Department and NABL to upgrade quality of weight and measures:

NABL Legal Metrology Accreditation of Calibration Resources and Entities (NALM-ACRE) Recognition Program

There are many laboratories across the country in the Legal Metrology Department under the center government and the state government. In the states only very few laboratories are accredited, namely, one state level secondary reference laboratory of Kerala state is accredited, and recently one more laboratory from Bihar state got accreditation for the calibration of weights. The legal metrology departments of various states are interested to get the accreditation, but due to certain limitations it is not possible for them to go directly for the accreditation as per the international standard ISO/IEC 17025:2017. To overcome this situation NABL and Legal Metrology mutually decided to launch a recognition program so that in between recognition period or in the second cycle of the recognition, the laboratory may be accredited as per the international standard. There are more than 100 secondary reference standard laboratories in the various states which are providing the traceability to the district and working standard level laboratories. The objective of this program was to bring these laboratories under the ambit of accreditation. The accreditation as per ISO/IEC 17025 in the field of calibration for weights and measure was not possible due to the unavailability of funds with the states and NABL fee for the accreditation is around 2 lakhs per laboratory which includes the application fee, assessment fee, annual accreditation fee, etc. Also, the availability of manpower is not sufficient in most of the states; therefore it was decided that first the state level laboratories will be recognized and fee charges will be minimum. The parameters which can be considered for the recognition were:

(i) Qualification, experience, and competence of the personnel available with the laboratories
(ii) Training as per the ISO/IEC 17025:2017 and relevant standard of the calibration of weights and measures or any other training, for example, as per OIML standards, etc.
(iii) Availability of the instruments for calibration of the weights and measures

(iv) Environmental conditions of the laboratory
(v) Exposure to the measurement of uncertainty in the field of calibration of weights and measures
(vi) Any other requirement of NABL and Legal Metrology Department of center government

It was agreed the program will be launched jointly for the recognition of state level laboratory. The state level laboratory will send the application to NABL and fee will be minimal. Once the application will be accepted by the NABL and found that application is complete in all respect, the onsite visit will be arranged. The team for the onsite visit will include NABL representative and one member from the Legal metrology Department. The team will submit the report of onsite visit along with their recommendation. The report shall be reviewed by the accreditation committee. The accreditation committee consist of the experts of weights and measures and expert of Legal Metrology rules and regulations. Once the accreditation committee recommends the case, the approval shall be given by the CEO-NABL and Director Legal Metrology Department, Ministry of Consumer Affairs. The joint certificate of recognition by NABL and Legal Metrology Department shall be issued to the laboratory for the period of 2 years. To maintain the recognition the laboratory has to face the onsite surveillance visit. Also, after the recognition the laboratory may initiate for the accreditation of the laboratory based on the availability of funds and personnel in between the recognition cycle. In case a laboratory has successfully participated in the PT program of weights and measures, the laboratory may be considered for the accreditation based on the onsite visit for the management system as per the ISO/IEC 17025:2017, or in case laboratory has not participated successfully in PT program, then full-fledged assessment shall be conducted for the accreditation as per the ISO/IEC 17025:2017.

The NALM-ACRE program is under consideration, and hopefully it will be executed to upgrade the quality of the state level laboratories of the state government.

Government Approved Test Center (GATC) Program

The GATC program was already discussed, why this program is required, and it was decided that The GATC program will be in two phases. In phase-I only the government labs shall be considered for the GATC approval. The labs of Government organizations/semi-government/state government/autonomous body/public sector shall be considered, whereas in the later stage phase-II will be implemented and all the private labs will be considered for the GATC approval.

The instruments covered under the scope of GATC are as follows:

1. Water meter
2. Sphygmomanometer
3. Clinical thermometer

4. Automatic rail weighbridges
5. Tape measures
6. Non-automatic instrument of accuracy class-IIII/Class-III (up to 150 Kg)
7. Load cell
8. Beam scale
9. Counter machine
10. Weights of all categories

Here, it can be seen all the above instruments are very important for the daily use, especially weights, weighing balances, and volumetric vessels. The common citizen of the country cannot survive without accurate measurement of weights, volumetric vessels, and accurate performance of the weighing balances.

There were all the requirements given in the GATC act 2013, and all the responsibility and authorities were with Legal Metrology Department of Center Government, Ministry of Consumer Affairs. It has been realized by the government that the Legal Metrology Department cannot execute GATC program independently due to limitation of personnel and funds. To overcome this limitation and to execute this program, it was expected that NABL can be best option because in the last decade NABL has grown like anything and NABL has expertise in third party assessment. The personnel and expertise of NABL can be used for the execution of GATC program. After many meetings with chairman-NABL and higher officials of the Ministry of Consumer Affairs and Legal Metrology Department, it was decided that GATC program will be jointly executed. When joint execution of GATC program was agreed between NABL and Legal Metrology Department, Ministry of Consumer Affairs, it was observed that GATC rules need to be amended so that NABL may work jointly for the approval of GATC from the private sector.

Two meetings between Chairman-NABL, along with other officials of NABL, and higher officials of the Ministry of Consumer Affairs, along with the director and other officials of Legal Metrology Department, were held in the month of November 2020.

The amendments in the GATC act were suggested by the NABL to the Legal Metrology Department, Ministry of Consumer Affairs, and to decide the required amendments in the GATC act two more meetings between the NABL officers and Legal Metrology Department officers were held in the month of December 2020. After these meetings the amendments were finalized and agreed by the Legal Metrology Department, and modus operandi was decided between the NABL and Legal Metrology.

To improve the quality of weight and measures across the country, the Ministry of Consumer Affairs, Government of India, released the gazette notification for the approval of GATC from the private sector on 1 February 2021 (The Legal Metrology 2021), **the gazette notification was as follows**:

MINISTRY OF CONSUMER AFFAIRS, FOOD AND PUBLIC DISTRIBUTION

(Department of Consumer Affairs)

NOTIFICATION

New Delhi, 1st February, 2021

G.S.R. 95(E) (G.S.R 2021).—In exercise of the power conferred by sub-section (1) read with clause (n), (o) and (p) of sub-section (2) of section 52 of the Legal Metrology Act, 2009 (1 of 2010) (hereinafter referred to as the Act), The Central Government hereby makes the following rules further to amend the Legal Metrology (Government Approved Test Centre) Rules, 2013 (hereinafter referred to as the rules), namely: -

1.

(1) 1. Short title and commencement. — (1) These rules may be called the Legal Metrology (Government Approved Test Centre) Amendments Rules, 2021.

(2) They shall come into the force on the date of their publication in the Official Gazette.

2.

In the Legal Metrology (Government Approved Test Centre) Rules, 2013, in the rule 5, after sub-rule (16) the following sub-rule shall be inserted, namely: -

"(17) The National Accreditation Board for Testing and Calibration Laboratories ISO: IEC 17025:2017 accredited laboratories for calibration of weights and measures which are in the conformity with the conditions specified in sub-rule (3) of rule 5 shall be eligible to be notified as Government Approved Test Centre subject to compliance of the provisions of the Act and the rules made thereunder"

[F. No. WM-19(105)/2020]

ANUPAM MISHRA, Jt. Secy.

Note:

The principal rules were published in the Gazette of India, Extraordinary, Part II, Section 3, sub-section(i), *vide* G.S.R. number 593 (E). dated 5th September, 2013 and last amended *vide* notification number G.S.R. 94 (E). dated 20th January, 2016.

After the gazette notification, the Director, Legal Metrology Department, issued a notice on 04.08.2021 for "inviting application for Recognition/notification of NABL accredited testing/calibration laboratories for GATC purpose under legal Metrology." This notice was sent to all the NABL accredited testing/calibration laboratories accredited in the field of weights and measures and the companies engaged in the manufacturing of weights and measures, particularly the manufactures of weights, balances, volumetric vessels, measuring tapes, etc. All the concern laboratories are informed regarding the approval of GATC. The detailed information about the approval of GATC may be obtained from the legal Metrology unit, Department of

Consumer Affairs website https://consumeraffairs.nic.in/organisation-and-units/orders (https://consumeraffairs.nic.in/organisation-and-units/orders-seen) by the legal Metrology. In this notice the applications are invited by the interested parties/laboratories, which are willing to be the GATC.

In the continuation of this notice, the director of Legal Metrology, Ministry of Consumer Affairs, Government of India, New Delhi, issued an office memorandum on 06.08.2021 to all the Controllers of Legal Metrology of all states and union territories, and the subject of office memorandum was "Implementation of GATC." The matter of the memorandum was:

> "It is to inform that there is a provision of Government Approved Test Centre (GATC) in section 24(3) of Legal Metrology Act 2009. It has been implemented by the department. The application may be submitted through CEO, NABL. The details in this regard are available at the department website www.consumeraffairs.nic.in (www.consumeraffairs.nic.in-seen)"

The primary condition for getting GATC approval is NABL accreditation as per ISO/IEC 17025, which is mentioned in the Gazette notification published by the Legal Metrology Department, Ministry of Consumer Affairs. There are two steps which are required for GATC approval. i.e. Accreditation as per ISO/IEC 17025, and specific requirements of the Legal Metrology Department as per GATC Act 2013.

Here, it can be seen that the center government is very serious to upgrade the quality of weights and measure used for trade and commercial purpose. Due to shortage of personnel at center and state level, the work of Calibration/Verification / Stamping can be handed over to the private accredited laboratories.

As the notification has been already issued to all the states that NABL accredited laboratories shall be considered for the approval of GATC, application for GATC approval shall be sent to the NABL and NABL shall conduct the visit for the approval of GATC. There are certain requirements of the Legal Metrology Department which need to be fulfilled by the laboratory, and these requirements shall be verified by the joint team of NABL and Legal Metrology Department. The GATC approval shall be valid only till the validation of accreditation, and we can see now the importance of accreditation in the common citizen of our country. If we look 35–40 years back, the stones and other things were used to weigh the things, but slowly the stones were rooted out. The cast iron weights have taken over, but still there was a question of accuracy of the weight. To verify the mass of the weight within permissible limit, the Legal Metrology Department started calibration/verification/stamping of the weights used for the trade and commercial purpose.

Now the calibration/verification/stamping will be done by the GATC and primary condition to be the GATC is accreditation by NABL as per ISO/IEC 17025:2017 then only the laboratory can get GATC approval. The accreditation has entered in the life of common men of India. The weights which are used by the shopkeeper or any trader shall be verified by the NABL accredited laboratory.

In the case of secondary reference state level and working standard, laboratories in our country are more than 1400, and these laboratories are performing calibration/verification/stamping for the weights and measure. The question can be raised that

very few laboratories are accredited; how do these laboratories perform calibration/verification/stamping for weights and measure? The answer is very simple: the personnel working in these laboratories are well trained as per the requirements of the Legal Metrology Department. Also, all the Legal Metrology laboratories of our county are following the requirements of International Organization of Legal Metrology (OIML). In technical term all the state level laboratories of the country are working as the requirements of the International Organization of Legal Metrology (OIML), but still the government is very serious about the accreditation of these laboratories. The Regional Reference Standard Laboratories (RRSL) of the Legal Metrology and few state level laboratories are already accredited by NABL. As per the requirements of International Organization of Legal Metrology (OIML), all Regional Reference Standard Laboratories (RRSL) maintained their traceability particularly in the case of weights from National Physical Laboratory (NPL), New Delhi, India. The state level laboratories maintain their traceability from the Regional Reference Standard Laboratories (RRSL) and down the line state level laboratories provide traceability to the working standard laboratories at district level. It can be seen that most of the state level laboratories are not accredited, but they are getting traceability from the RRSL laboratories, and these laboratories are NABL accredited; in this way accreditation is impacting the working of state level laboratories.

In the last 40 years the impact of accreditation increased like anything in our country. The accreditation is required for so many things. It is required not only for scientific and research purpose but in daily life also. In the coming future, the impact of accreditation will definitely increase because most of the regulators in India require accreditation for the approval purpose. There are more than 4 lakh laboratories in our country which are engaged in testing, calibration, and medical testing, but the no. of accredited laboratories is around 7000. It can be seen that the 7000 accredited labs are significant, but still there is a huge opportunity in the field of accreditation. The day is not far away when calibration, testing, and medical testing of accredited laboratory will be accepted. The knowledge of common citizen is increasing day by day, and in the future the common citizen will ask for the accreditation for any type of testing and calibration, and in this context the Government of India felt the requirement of accreditation for the common citizen.

The GATC approval could be the revolutionary action by the Government of India. After the approval of GATC from the private sector, the calibration/verification/stamping may be possible for all the weights and measure available for the trade and commercial purpose in the country. The laboratories and manufactures of weights, weighing balances, volumetric vessels, steel scale, measuring tape, etc. will definitely come forward getting GATC approval. The GATC approval can only be obtained after the NABL accreditation. The government has understood the importance of the accreditation in the field of testing and calibration. The accreditation is the guarantee of competence of testing and calibration.

Many times, it has been seen due to poor quality of weights and measures there is a loss for the manufactures/producer and sometimes for the consumer of that weight and measure. A real time example of calibration of weight can be considered. A

sugar mill has sent the cast iron weights of 20 kg, for the calibration, and the results were surprising as one of the 20 kg weight was actually found 20.5 kg. When the management came to know about the actual value of the 20 kg weight, they were shocked and surprised because they have never thought that a single weight can have a difference of 500g. When the management of that sugar mill calculated the loss due to the use of that weight, it was in lakhs of rupees annually. After getting the unacceptable results of that weight, the weight was changed by the management, and calibration was done for the new weight. As the sugar mill has not got verification and stamping of that weight by the Legal Metrology Department due to the nonavailability of Legal Metrology Department in the sugar mill, in the present scenario the sugar mill was in the loss because whatever weight was weighed by that weight was 500 g plus for every 20 kg. The situation can be reversed; just imagine the weight of that weight were 19.5 kg, meaning 500g less as compared to the actual value. In this situation whatever weight measured with the help of that weight 500 g less was weighed for every 20 kg and consumer of sugar was getting less quantity. The situation is not healthy for the producer and for the consumer in either way. The objective of Legal Metrology is to ensure the quantity of weight and measure so that appropriate quantity should be given to the consumer and both manufacturer and consumer should not be at loss.

Another example of dimensional measurement can be taken. The measuring tape was purchased by the customer from the local market. The person who has purchased that measuring tape has taken the measurement for the door and given the order to the carpenter. The carpenter has made the doors based on the measurement given by that person. It was shocking to that person once he found the length of doors were approximately 2 inches short and were not fitting in the frame of the door. When investigation was done, it was found that the measuring tape was not proper. The initial measuring point was approx. 2 inches short. There was a manufacturing defect in that measuring tape. Because of the wrong measurement, that person suffers the loss of approximately 2 lakh rupees. The importance of correct measurement can be understood with the help of two examples discussed.

There are many processes and products which are used in daily life that required accurate measurement. The weights and measure are used daily in everybody's life; therefore the measurement of weights and measure should be accurate, or in other words it should be within the permissible limit so that the producer and consumer both should be in a win-win situation.

Reverse Transcription–Polymerase Chain Reaction (RT-PCR) Laboratories Accreditation

Another importance of accreditation was felt in the health sector specially for the medical testing laboratories. It can be seen that the previous situation the MRA is important for the testing and calibration laboratories as the results produced by the accredited laboratory in the field of testing and calibration are accepted in the member countries of APAC and ILAC. The retesting and re-calibration of the

exported item is not required if the exporting and importing countries are MAR signatory in APAC and ILAC. This situation was rarely faced in the field of medical testing. Because the medical tests performed on human beings and the results are frequently changed due to the complexity of environmental conditions and stability of the human samples. It has been observed that tests performed by one medical testing laboratory for some hospitals are not acceptable to the other hospital if the patient changes the hospital for his or her treatment. The repeatability and reproducibility are the core issue in the human samples for medical testing laboratories. There are various issues which affect the results of the testing. But during the pandemic of coronavirus disease of 2019 (COVID-19), everything has been changed from the technique of the assessment to the acceptability of the results of medical testing. The techniques of assessment changed due to the requirement of the accreditation not only at country level but at global level.

When the COVID-19 hits India in the month of March 2020 and the Government of India was forced to announce the country-wide lockdown, everything was closed except the essential services related to the health and food supply. NABL was also not able to conduct the assessment of the laboratories because there were no means of transportation to travel from one place to another place due to the strict lockdown. On the other hand, the government required more and more RTPCR testing laboratories for the testing of COVID-19 patient. The number of labs available for the RTPCR was less than 100, and to cater the need of COVID testing more and more RTPCR testing laboratories were required. As the matter was very serious and concerned with the human health, the Indian Council of Medical Research (ICMR) was in the search of RTPCR testing laboratories not only from the government sector but also from the private sector. To assure the quality of testing, what tool can be applied, the answer was again accreditation. ICMR (https://www.icmr.gov.in-seen) issues the order on 21.03.2020 in which the guideline laid down for COVID-19 testing in private laboratories in India, that NABL accredited laboratories for RTPCR testing shall be accepted. After this announcement many laboratories have applied for the accreditation, but there was a very serious constraint that during the lockdown NABL was not able to conduct the onsite assessment. The reason for not conducting the assessment were:

Non-availability of mode of transportation, air/train/car/bus, due to strict lockdown all over the country.

Non-availability of accommodation in the hotels, etc.

Non-availability of assessors due to the COVID-19; the assessors were avoiding the onsite assessment.

Most of the laboratories were in the red zone, and they want to apply for the NABL accreditation but not able to reach to the laboratories.

The requirement for the RTPCR testing was on peak, and only test results of NABL accredited laboratories were accepted by the ICMR; therefore every laboratory was in the need of accreditation.

Due to the unavoidable situation for the accreditation of RTPCR laboratories, NABL developed the program for the accreditation of RTPCR applicant laboratory

by means of online/remote assessment. The online/remote assessment was never done by NABL in any of the fields in the past 40 years. The concept of online/remote assessment can be understood by the definition of online/remote assessment "assessment of the physical location or virtual site of a conformity assessment body using electronic means"; here a virtual site is an online environment allowing persons to execute processes, e.g., in a cloud environment (ISO/IEC 17011:2017). It is evident that there was no physical visit of the assessors on the site of the applicant or renewal of the conformity assessment body. There is certain limitation during the online/remote assessment that good quality of Internet connection is required and sometimes it is very difficult to judge the observation of the witness of the test conducted for the competence of the conformity assessment body. The documents can be shown within some limitation, only one type of document can be shown to the assessment team, and in the online/remote assessment one assessor may witness one activity whereas in the physical visit one assessor may witness multiple activities. The quality of the assessment may be under doubt, and there was no past experience in conducting the online/remote assessment for any of the lab. Still NABL has opted the online/remote assessment for the RTPCR testing laboratories in the case of applicant as well as renewal of the RTPCR testing laboratories. The question raised was why did NABL opt for online/remote assessment whereas in the past there was no online/remote assessment conducted? The simple answer for this question can be the requirement of RTPCR testing laboratories to cater the need of testing in the pandemic of COVID-19. Now, another question may be raised why accreditation is required for the RTPCR testing? Why not non-accredited RTPCR testing laboratories are allowed to test the COVID-19 patient? It has been already discussed that in the case of medical testing as per ISO 15189:2012, the MRA signatory is not so much significant which in the case of testing and calibration laboratories as per ISO/IEC 17025, still because of the requirement of ICMR and the safety of the patient, accreditation is required for the acceptance of test results in the RTPCR testing by private laboratories. The accreditation makes sure about the operation of the laboratory with reference to the technical competence, use of traceable instruments, controlled environmental and accommodation conditions of the laboratory, and procedure of collection, transportation, and storage of the COVID-19 sample as per the guideline issued by ICMR. Accreditation makes sure that a specific laboratory is competent to perform the specific testing; therefore risk of wrong diagnosis and treatment is very less or it can be minimized. The requirement of accreditation for the private laboratories was not limited to the laboratories, but it was required to travel from one country to another country. In the recent past there are some states in India which have made RTPCR testing mandatory to enter in the state. Also, the states which have made RTPCR testing mandatory and someone wants to travel to that state, he or she can be allowed to board in the aircraft only after the negative RTPCR test report. In case of positive RTPCT test report, then the passenger will not be allowed to board in the aircraft. Similarly, the person with positive report will not be allowed to enter by road in the state. There are certain states which are conducting RTPCR tests when anyone wants to visit the state. The condition for the doctors,

administrative authorities, and state governments for accepting the result of RTPCR test is NABL accreditation.

Due to the requirement of accreditation for the acceptance of RTPCR test, the growth of accredited laboratories was remarkable, and presently there are more than 1700 laboratories. These laboratories were able to cater the testing need of the COVID-19 patent at the time of peak of COVID-19. There was a time when India was getting more than four lakhs COVID-19 patients and number of tests conducted were more than 15 lakhs to 20 lakh tests. Presently in India more than 16 lakhs RTPCR tests are conducted for COVID-19 patients. Today all the labs which are conducting RTPCR testing for the COVID-19 patients from the private sector are NABL accredited because only after the NABL accreditation the private RTPCR testing laboratory can be recognized and after the recognition the results can be accepted. NABL has done tremendous job during the time of pandemic by accrediting the RTPCR laboratories.

RTPCR testing is not only required in India for travelling from one state to another, but it is mandatory for travelling abroad. Most of the countries have banned the flights due to pandemic, and when flights were started, they required RTPCR test report, and this test report shall be an accreditation body which has MRA signatory status in APAC and ILAC. In international flights a person without negative RTPCR test will not be allowed to board. Here, it can be seen the importance of accreditation in the case of RTPCR testing not only in India but abroad also.

The overall scenario of the medical testing laboratories is that there are more than 80000 medical testing laboratories and the number of accredited laboratories in the field of pathology testing is around 1500. Also, in the case of medical treatment accreditation is not mandatory, and it can be seen that there are many labs which are still working without NABL accreditation but same is not true in the case of RTPCR testing. As the ICMR issued the order only NABL accredited laboratories testing shall be accepted, and the reason was only assurance of the results produced. For other types of the laboratories in the field of medical testing, a similar type of the guidelines may be issued by the other departments so that in the future slowly all labs may come under the ambit of accreditation.

Recognition of Food Testing Laboratories by Safety and Standards Authority of India (FSSAI)

Safety and Standards Authority of India (FSSAI) is responsible for maintaining the quality of food items manufactured, storage, sale, and import of food items for the human consumption. To regulate the food items for the human consumption, the food testing laboratories are required, and there are many laboratories which are engaged in the food testing. FSSAI has recognition scheme for the laboratories based on the certain requirements. The first requirement for the recognition of food testing laboratory is accreditation of the laboratory as per the ISO/IEC 17025:2017 or latest version of the standard and specific requirements/guideline of the NABL and second requirements of the FSSAI related to the qualification and experience of the

personnel in the field of food testing. Here, it can be seen that the laboratory willing to get recognition with FSSAI is required NABL accreditation. It was observed on many food items the mark of FSSAI. The mark of FSSAI on the human consumption food items whether manufactured in India or imported from any other country bearing the mark of FSSAI means that the food item is tested in the recognized laboratory and that the laboratory fulfilled the requirements for the accreditation as well as specific requirement of FSSAI. FSSAI has segregated the laboratories in various types, for example, level 1 laboratory, level 2 laboratory, referral food laboratory, R & D capabilities, training facilities, and other facilities. All these laboratories have specific requirements for the grading.

Recognition of Testing Laboratories by Agricultural and Processed Food Products Export Development Authority (https://www.apeda.gov.in-seen) (APEDA)

Agricultural and Processed Food Products Export Development Authority (APEDA) recognized laboratories for its registered importers. As the demand of Indian agricultural products is increasing day by day in the world, safety and quality of the agricultural product is required for the export purposes. The importing countries have certain requirements in the food products which are imported from India. There are certain international standards which need to be fulfilled by the product, and these food products need to be tested in the testing laboratories. APEDA has a scheme to recognize the food testing laboratories in the field of residual analysis of pesticides, heavy metals, drugs and antibiotics, aflatoxins and microbiological analysis, etc. There are certain requirements for the recognition of performing the testing for the agricultural products. It is stated in the requirement for the recognition that NABL accredited laboratory in the field of residual analysis of pesticides, heavy metals, drugs and antibiotics, aflatoxins and microbiological analysis etc. will be given preference if they follow latest version of ISO/IEC 17025.

Recognition of Testing Laboratories by the Bureau of Indian Standards (BIS)

The Bureau of Indian Standards (BIS), the National Standards Body of India, was established under The Bureau of Indian Standards Act, 1986, now revised to The Bureau of Indian Standards Act 2016. BIS has various conformity schemes for the protection of the interest of the consumers. ISI mark is one of the schemes to protect the interest of the consumers of various products produced by the Indian manufactures. BIS has recognition scheme for the manufactures from India and abroad. There are certain requirements, and accreditation of the laboratories is one of the requirements along with the compliance with various international and national standards of the product testing. Accreditation means the laboratory shall be accredited as per the ISO/IEC 17025:2017 and other requirements of the NABL along with required

product testing standards. BIS also declared in their requirement for the recognition that the accreditation body shall be a full MRA signatory member of ILAC (International Laboratory Accreditation Cooperation) and APAC (Asia Pacific Accreditation Cooperation). MRA signatory means that the accreditation body has been peer evaluated by APAC and eventually gets MRA status with ILAC.

Recognition of Testing Laboratories by Other Regulators

There are many other regulators, departments, and ministries which relay on the test results produced by the NABL accredited laboratories. The few examples are Central Pollution Control Board (CPCB) and State Pollution Control Board (SPCB) which accepts testing results of NABL accredited laboratories for the licensing of the various industries for operating in the particular region. The license is given by the Ministry of Environment, Forest and Climate Change (MoEF) to the various industries to operate in the particular region. Also, Central Pollution Control Board (CPCB) and State Pollution Control Board (SPCB) are endeavoring for getting NABL accreditation for their laboratories. Some of the laboratories of CPCB and SPCB are already accredited in the field of environmental testing.

The Ministry of Water recently started the program for the accreditation of water testing laboratories across the country. Slowly the water testing laboratories are applying for the accreditation in the field of water testing so that policies can be framed based on the results produced by these laboratories situated in the various states of the country.

Export Import Authority of India is also relaying on the NABL accredited laboratories. The EIC is giving recognition to the accredited laboratories only. Accreditation has entered almost in every department and ministry where testing is essential and decisions are taken on the test results produced by the laboratories, whether the laboratory is private or a part of the government organization or department.

Conclusion

It is evident that today accreditation has entered everywhere, from the science and technology to household items of the country. By looking back in the early 1980s, there was no concept of accreditation in the country, although weight and measure department was well established at the center as well as state level. In the 1970s RRSL laboratories were started in the various places in the country to support weights and measure of the country. India is a big country not only area wise but population wise also, and it was desperately required to assure the quality of weights and measures for the general use of the public. The calibration and testing done by the accredited laboratories is acceptable for the scientific, research, and development purpose and for commercial purpose verification and stamping of weight and measure done by the Legal Metrology Department is acceptable by the law. Today

Legal Metrology Department at center and state level is willing to get NABL accreditation for their laboratories. Also, as per the GATC rule 2013, private laboratories can be the part of calibration/verification and stamping. Legal Metrology Department, Ministry of Commerce, decided that only NABL accredited laboratories can apply for the GATC approval. Also, manufactures of the weight and measures may apply for the GATC approval. After the gazette notification many manufactures of the weights, weighing balance, measuring tape, volumetric vessels, etc. are willing to get the GATC approval.

If present scenario of country is considered in terms of accredited laboratories, there are more than 7500 accredited laboratories in the field of testing, calibration, medical testing, PTP and RMP. Out of these 7500 accredited laboratories, the no. of testing laboratories is more than 4000, and calibration laboratories are more than 1100, where medical testing laboratories are more than 1500. The accredited laboratories in the field of testing cover every parameter/product. For the common citizen's point of view, the common parameters can be food and agricultural products which consist of human food like milks and related products and other products produced in agriculture which are suitable for the human consumption, pharma products which consist of various types of medicines and other related products, and textiles which consist of various types of clothes and other products which are manufactured by the various textiles; even building material can be tested for the assurance of their quality, and the soil, water, and air are also tested for the suitability of their use for the establishment of manufacturing units in the particular area.

In the last 40 years, the importance of the accreditation has been increasing day by day. That day is not far away when common men will ask for the testing by the accredited laboratory. Today the common men are not aware of the benefit of the accreditation level. However, government and related departments are well aware of the benefit of the accreditation, and slowly the common men are getting awareness about the accreditation of the testing laboratories. The person or patient prefers the NABL accredited laboratory in the medical testing. Also, whenever any customer wants to purchase any product for the daily use, he prefers ISI mark product. As discussed the ISI mark is given by the BIS for the various types of products used by the customers.

In the future, the number of accredited laboratories will increase because there are many laboratories which are performing testing and calibration without accreditation. However, accreditation has already entered into the life of the common citizen of India.

Abstract

In the modern era, competition is more intense than ever before as modern business becomes more diversified, bigger, and improved. Therefore, it is crucial to confirm that an organization is providing customers with the best selection of products in order to maintain momentum and compete with its rivals. Companies can only guarantee the quality of deliveries by doing rigorous quality checks in advance. Strong national quality infrastructure with high standards is the only way to accomplish this goal. A strong national measurement system (NMS),

quality infrastructure (QI), and stricter metrological regulations and certification in trade and commerce are required due to the fast industrialization, growing demand for more precise measurements, updated technologies, and highly skilled workforce. Any nation that wants to engage in international trade and the exchange of services, especially developing nations like India, must have a strong QI. Through social, strategic, and industrial expansion, the QI is essential to the country's economic development. The upper organizations in India that are in charge of existing QI are CSIR-National Physical Laboratory (for scientific and industrial metrology), Bhabha Atomic Research Centre (for nuclear radiation metrology), Department of Legal Metrology (for legal metrology), Bureau of Indian Standards (for documentary standards and specifications), and National Accreditation Board for Testing and Calibration Laboratories (NABL) and National Accreditation Board Certification Bodies (NABCB) under Quality Council of India (for accreditation and certification). In this chapter, the role of quality measurements and relevant Indian infrastructure is briefly discussed. For establishing, implementing, and confirming the quality criteria for goods and services, a QI is an effective tool. For domestic markets to operate effectively as well as to have access and to be recognized on the global stage, high-quality infrastructure is essential. Along with promoting and preserving economic development, it is crucial for social and environmental harmony.

Introduction

After World War II, with the rise in demand for various consumer and industrial products, there arose the need to regulate the increase in world trade. Various organizations were formed in different parts of the world. Some countries came together to create the International Trade Organization (ITO) under the UN's Conference on Trade and Employment within the framework of the United Nations. However, they could not reach a common consensus and the talks for the creation of ITO broke down. Following this, around 23 countries met in Geneva in 1947 and agreed to regulate international trade by way of a general agreement. This was the onset of the General Agreement on Tariff and Trade (GATT). After eight rounds of talks and negotiations on trade-related issues, the World Trade Organization (WTO) was created in 1996 with its headquarters in Geneva with more than 95 percent of developing countries as its members. WTO's prime objective is to supervise and liberalize international trade and to negotiate and formalize trade agreements between member countries through their governments, with the aim of achieving free trade between the countries. Though every country wants to protect its animal life and safety, and in this garb sets some barriers to free trade. Technical rules, product standards, requirements for testing and calibration, and different inspection

and certification procedures between nations are examples of these trade barriers, also known as technical barriers to trade (TBT). The prime objective of WTO is to reduce these technical barriers to trade so that the regulations, standards, testing, and certification procedures do not create unnecessary hurdles in free trade (Overview of India's Quality Infrastructure 2018; Aswal 2020a, b; Rab et al. 2020, 2021a).

In the last quarter century, globalization of trade made it possible for the public to enjoy a vast range and quality of products manufactured in other countries. In order to have smoother international trade, it is essential for all products of the same category to conform to the same or similar standards. Thus, a product tested in one country and conforming to the standards of the importing country should not be required to be rechecked after importing. Rather, the result of testing in the exporting country should be acceptable to the importer in the other country. This is one of the objectives of WTO, which translates to "tested once, accepted everywhere." To control conformity assessment activities around member countries, a conference held in 1977 facilitated international trade by accepting accredited test and calibration results. This was formalized in 1996 as cooperation between 44 countries in Amsterdam and was known as International Laboratory Accreditation Cooperation (ILAC) (Hoekman and Kostecki 2009; Grochau et al. 2020; Patra and Mukhopadhayay 2019).

On a regional scale, the Asia Pacific Accreditation Cooperation (APAC) was initiated as cooperation in 1992 and was formally established as a regional forum in April 1995 with the signing of a memorandum of understanding (known as APLAC MOU) by 16 regional economies in the Asia Pacific region. Similarly, in the other parts of the world, such cooperations were established between member economies. The European Cooperation for Accreditation (EA), Inter-American Accreditation Cooperation (IAAC), South African Development Community in Accreditation (SADCA), African Accreditation Cooperation, and Arab Accreditation (ARAC) were later established in other regions. All these regional bodies and their member accreditation bodies operate through various bilateral and multilateral mutual recognition arrangements (MRAs). This helps in fulfilling the requirement "tested once, accepted everywhere" (Rab et al. 2021a, b; Czichos et al. 2011). section "Introduction" of this chapter provides background information and discusses the need for stronger infrastructure (QI). The development of measurement systems was then covered in section "Development of Measurement Systems" from both national and international perspectives. In section "Relevant Indian Infrastructure," a number of pertinent organizations connected to Indian QI are briefly described.

Development of Measurement Systems

Technological advancements after World War II created a need for a coherent system of units that can be used by one and all as different countries followed different systems of units earlier. The Treaty of the Metre (May 20, 1875), known as the Metre Convention as well, established an international conference for designing and

developing units for measurements. This conference is known as the General Conference on Weights and Measures (CGPM). The International Bureau of Weights and Measures (BIPM) was established at Sevŕes near Paris as an organization for custodians of International Standards. In order to facilitate the decisions in CGPM, an International Committee for Weights and Measures (CIPM) was established as an advisory body to CGPM. While CIPM is the body that runs the BIPM activities through its Directorate, CGPM is a diplomatic body to endorse any change in the international standards. On receiving representations from the International Union of Pure and Applied Physics (IUPAP), CGPM asked CIPM to study and come out with a practical system of units that can be adopted and followed by the whole world.

BIPM is the custodian of seven base units of the system called SI unit system which was adopted by the CGPM in 1960. In addition to these seven base units, there are several derived units that are byproducts of powers of the base units, with no factor other than 1. These derived units are known to represent the derived quantities and are expressed in terms of the base units. Dimensionally too, they are expressed in terms of the dimensions of the base units. All the measurable physical quantities can now be expressed in terms of base or derived units (Rab et al. 2020, 2021a; Rab and Yadav 2022; Stock et al. 2019).

The global metrological hierarchal structure is somewhat like as given in Fig. 1. The standards maintained at BIPM derive their reference value directly from SI units. From this, the national standards of various countries, maintained at their

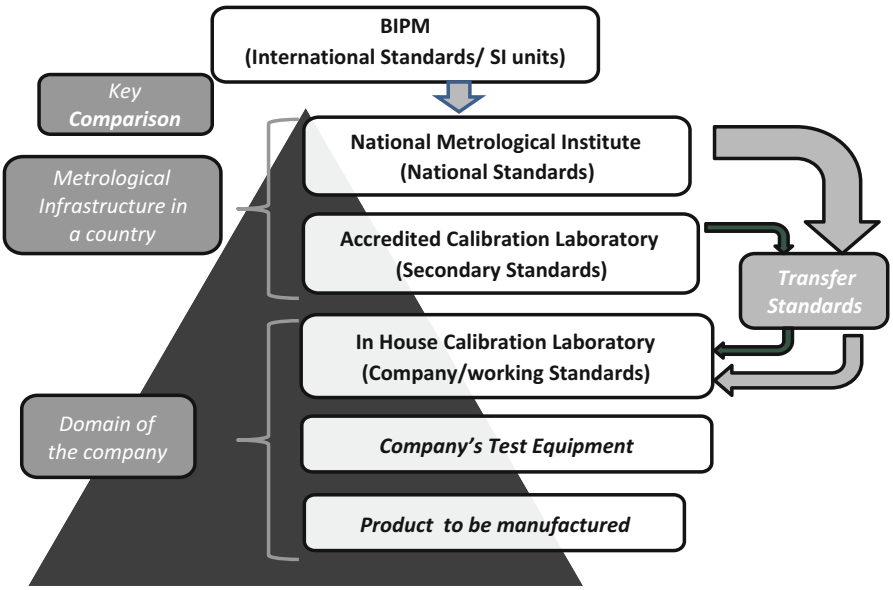

Fig. 1 Traceability transfer from SI units (BIPM) to working level

respective National Metrological Institutes, derive their reference values through comparison, called "key comparison." These national standards, at various levels of accuracy and uncertainty, form the backbone of any nation's traceability structure. NMIs are usually also the custodian of the primary standards unless otherwise mandated by the government. Other standards (secondary standards) draw their reference value and uncertainty from the national standards maintained at NMIs. From these secondary standards, various working standards or shop floor instruments are calibrated in accredited laboratories. In this fashion, the traceability from the SI units maintained at BIPM is transferred to the working level. It is always ensured that the chain of traceability is an unbroken one.

The key comparisons among all permanent members of CGPM are organized by Consultative Committees (CCs) on behalf of CIPM, under the framework of CIPM MRA. Inked in 1999, this MRA is for National Measurement Standards and for Calibration and Measurement Certificates issued by NMIs. This MRA is also a step toward giving an open, transparent, and comparable environment for agreements by concerned governments for fair trade within economies and nations where the calibration results produced in one country are acceptable to another. It is also a way to reduce or demolish trade barriers.

The National Measurement System

The post-World War II period witnessed the application of physical measurements over a vast range of applications in daily life and industry. With the advancement in technology, especially electronic measurements, and information technology, these physical measurements proliferated at a rate like never before. This also resulted in a massive expansion in the measurement-related budgets in every country, as such measurements were essential for public health, safety, and the environment. Major users of such measurements were government and private entities alike. Public welfare programs like a supply of safe drinking water or measurement of air pollution consumed a lot of public money. It necessitated the need for making the right policies and regulations to control the wasteful expenditure related to the measurement system. "If the direct cost of making measurements is large, the indirect cost of making poor measurements must be huge." A nation's measurement requirements are diverse just because the implementation of various economic and social schemes is dealt with by many different regulations, both at the national and sub-national levels. The economic ecosystem provided by industries, traders, consumers, etc. must thrive along with the social ecosystem (Gupta et al. 2020; Yadav and Aswal 2020; Fanton 2019). Such diverse requirements are difficult to weave into a single pattern. Effective policy comes from effective decisions and planning based on the right data. The data is used to create and make policies for the nation's social and daily life (Rab et al. 2022). Such a national measurement system structure can be defined to have five elements:

(i) Conceptual system: where measurement quantities and units are defined.
(ii) Technical infrastructure: to implement the defined quantities and units and to provide techniques for implementation.
(iii) Realization of measurement capabilities: to realize the measurement quantities.
(iv) Enforcement network: to disseminate and enforce the regulations, decisions, and policies.
(v) End use measurement: to support the different levels of system.

Such a national measurement system provides a coherent system that ensures that consistent measurements are made throughout the country. This provides a qualitative basis and quantitative data for taking effective decisions in policy making. Good data for taking effective decision-making not only requires measurement in the laboratory but also requires all other activities to support the measurement for good data. In any country, there are many activities that ensure the production of good data in the laboratory. The measurement infrastructure supports not only the market economy but also social infrastructure. This also requires technical infrastructure to support both economic and social infrastructure at various levels. This is known as "infra-technology," which includes measurement and test methods, applicable regulations and standards, implementation systems, and relevant training. Such "infra-technology" includes regulations, standards, metrology, standardization, accreditation/certification and training, etc.

Thus, a national measurement system must include:

(a) Setting national policy.
(b) Introducing metrology within that policy.
(c) Framing regulations.
(d) Provision for infrastructure for metrology.
(e) Engagement of other national and international bodies.

These five activities are mostly fall in the governmental role. Other roles are:

(a) Developing and maintaining documented standards.
(b) Appropriate metrological controls.
(c) Verification of regulated equipment/instruments.
(d) In-service checks of regulated equipment/instrument.
(e) Inspection and control of packaged materials.
(f) Market surveillance.

These six activities are the role of legal metrology system of the country.

Apart from above, the following roles, played by many governmental and private institutions, also contribute to making of national measurement infrastructure of a country:

(a) Maintaining national standards of measurements and dissemination of units.
(b) Maintaining and disseminating certified reference materials (CRMs).

(c) Technical advice.
(d) Type approval and controls.
(e) Calibration.
(f) Testing.
(g) Training.

These roles fall into the domain of the NMI, standard developing organizations, accreditation bodies, assessment and certification bodies, and training institutes. The government, legal metrology, and other bodies listed above must work in the most coherent manner to thrive the challenges faced by the country for economic, social, and technological requirements.

Relevant Indian Infrastructure

An emerging economy initially requires a trade measuring system with proper legislation for its transition. After that, additional legal metrology controls for global traceability and regulatory measurements can be implemented. A complete metrology system, complete with a thorough traceability infrastructure and national metrological controls, will exist in a developed economy. This section provides details on the quality infrastructure in India, including the current systems for metrology, standardization, accreditation, technical rules, conformity assessment, and support activities. The CSIR-National Physical Laboratory (CSIR-NPL) is the keeper of national measuring standards within the Indian Quality Improvement system; the Department of Legal Metrology makes rules and regulations and enforces metrology for trade and commerce; and the Bureau of Indian Standards (BIS) deals with documentary standards of goods and services, and accreditation bodies operate under the auspices of the Quality Council of India (QCI) in India, according to the country's QI system. Other nations also have their own NQIs, which may or may not be similar systems with numerous acting bodies and agencies operating at various levels (Aswal 2020b, c; Rab et al. 2021a; Mandal et al. 2021). Figure 2 provides an illustration of the general picture of the structures of any NQI. An NQI for conformity assessment is required by each of the government departments/regulators listed in Table 1 in order to implement various schemes, related to manufacturing, food, energy, health, environment, electronics, export, etc.

Legal Framework

Legal Metrology Act, 2009 (replacing the earlier Standards of Weights and Measures Act, 1976), provides for the "establishment and enforcement of standards of weights and measures, regulate trade and commerce in weights, measures and other goods which are sold or distributed by weight, measure or number and for matters connected therewith or incidental thereto." This Act replaces the earlier Act and provides for standard weights and measures, the establishment of an institution for

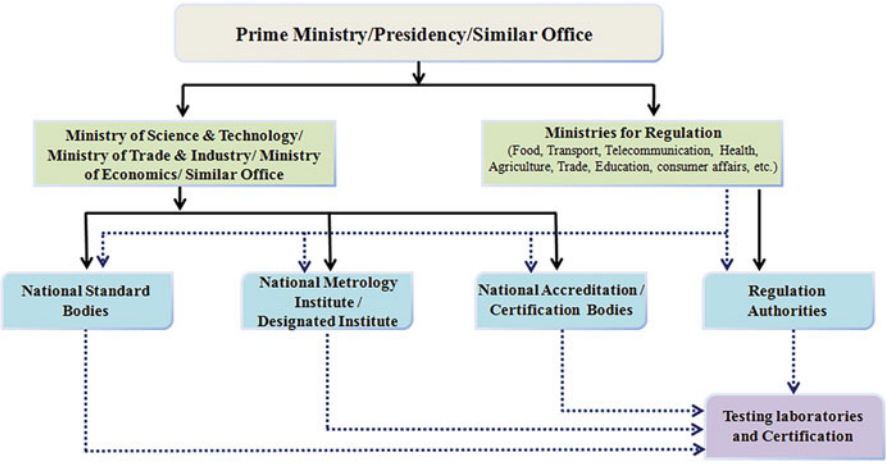

Fig. 2 Linkages of organizational relationships of the national quality infrastructure; continuous lines indicate oversight relationships, and dot-line relationships indicate coordination

controlling legal metrology rules framed under the Act, and provision for verification and approval of weights of measures and offenses and penalties thereon. Thus, this Act and the rules formed there under (Legal Metrology Rules 2011) are the backbones of the legal framework in India. This Act established that "every unit of weight or measure shall be in accordance with the metric system based on the international system of units. The base unit of (i) length shall be the meter; (ii) mass shall be the kilogram; (iii) time shall be the second; (iv) electric current shall be the ampere; (v) thermodynamic temperature shall be the kelvin; (vi) luminous intensity shall be the candela; and (vii) amount of substance shall be the mole." The Act further established that "the reference standards, secondary standards, and working standards of weights and measures shall be such as may be prescribed."

The Act provides clarity on the units further to be operated in the country. It provides the following: (i) the base units of weights and measures specified as above shall be the standard units of weights and measures; (ii) the base unit of numeration (an international form of Indian numerals) specified in shall be the standard unit of enumeration; (iii) for the purpose of deriving the value of base, derived, and other units, the central government shall prepare or cause to be prepared objects or equipment in such manner as may be prescribed; and (iv) the physical characteristics, configuration, constructional details, materials, equipment, performance, tolerances, period of reverification, methods, or procedures of tests shall be such as may be prescribed. These prescriptions are further elaborated in the Legal Metrology (General) Rules 2011 framed under the Act.

Legal Metrology (General) Rules, 2011, rules provide for, amongst other things, that calibration to the various measuring instruments shall be traceable to "National Measurement Standards." It also provides that for any transaction (in trade,

Table 1 Partial list of various bodies in India as a part of countries' conformity assessment

Name of organization/body	Status and control	Scope and subject area	References
Automotive research Association of India (ARAI)	Research Institute of the Automotive Industry with the Ministry of Heavy Industries and Public Enterprises, Govt. of India	Lay down the automotive industry standards and published safety standards	Automotive Research Association of India (ARAI) (2022)
Standardisation testing and quality certification (STQC)	Ministry of Electronics and Information Technology, government of India	Provides quality assurance services in the area of electronics and IT through countrywide network of laboratories and centers. The services include testing, calibration, IT, and e-governance, training, and certification to public and private organizations	Standardisation Testing and Quality Certification (STQC) (2022)
Telecom regulatory Authority of India (TRAI)	Jurisdiction of Department of Telecommunications, Ministry of Communications, government of India	Regulator of the telecommunications sector in India. The goal of the organization is to foster the conditions necessary for the country's telecommunications sector	TRAI, Telecom Regulatory Authority of India (2022)
Bureau of Energy Efficiency (BEE)	Agency of the Government of India, under the Ministry of Power	Provides energy performance standards for appliances' energy conservation building code Regulatory authority for mandatory energy labeling for eight types of appliances, notified by the central government	Bureau of Energy Efficiency (BEE) (2022)
Securities and exchange Board of India (SEBI)	Ministry of Finance, government of India	It is the regulatory body for securities and commodity market in India. It monitors and regulates the Indian capital and securities market while ensuring	Securities and Exchange Board of India (SEBI) (2022)

University Grants Commission (UGC)	Statutory body, under Ministry of Human Resource Development	Determining and maintaining standards of teaching, examination, and research in universities, framing regulations on minimum standards of education, monitoring developments in the field of collegiate and university education, disbursing grants to the universities and colleges, serving as a vital link between the union and state governments and institutions of higher learning, and advising the central and state governments on the measures necessary for the improvement of university education	University Grants Commission (2022)

commerce, etc.), "the product is required to conform to the specifications laid down by the International Organization of Legal Metrology about the matters aforesaid."

The legal metrology framework in India operates as a federal structure. This Act further established the administrative framework to control the proliferation of the weights and measures in India. In the center, the Department of Legal Metrology is established under the Department of Consumer Affairs, Ministry of Consumer Affairs, Food and Public Distribution, Government of India. This is the centralized

department to control the legal metrology framework requirements centrally. For the purpose of disseminating traceability for standards covered by weights and measures, there are currently five Regional Reference Standards Laboratories (RRSL) in operation. In the states, the Controllers of Legal Metrology are the premier officer to enforce Legal Metrology Act at the ground level. Additional Controller, Joint Controller, Deputy Controller, Assistant Controller, Inspectors, and other employees of the state exercise the powers and discharge the duties conferred or imposed on them by or under this Act in relation to intrastate trade and commerce. This framework is further strengthened by the functioning of more than 100 secondary standards laboratories and 1100 working standards laboratories for the dissemination of metrological traceability. These state authorities have been authorized to "inspect any weight or measure or other goods in relation to which any trade and commerce has taken place or is intended to take place and in respect of which an offense punishable under this Act appears to have been or is likely to be, committed are either kept or concealed in any premises or are in the course of transportation" (Rodrigues Filho and Gonçalves 2015; Velkar 2018; Pasaribu and Sirait 2020).

National Metrology Institute

The CSIR-National Physical Laboratory (CSIR-NPL) located in New Delhi is the National Metrology Institute (NMI) of India, engaged in keeping the National Physical Standards of the country, except for the radiation standards, which are kept by the Bhabha Atomic Research Centre (BARC). NPL functions as a premier laboratory under the Council of Scientific and Industrial Research (CSIR), Government of India. Established in 1947, one of its main functions is to "establish, maintain, and improve continuously by research, for the benefit of the nation, National Standards of Measurements and to realize the Units based on International System (Under the subordinate Legislations of Weights and Measures Act, 1956, reissued in 1988 under the 1976 Act)."

CSIR-NPL is a signatory to the International Bureau of Weights and Measures (BIPM) Mutual Recognition Arrangement (MRA). The National Physical Laboratory has the responsibility of realizing the units of physical measurements based on the international system (SI units) under the subordinate legislations of the Weights and Measures Act, 1956 (reissued under the Legal Metrology Act, 2009). NPL also has the statutory obligation to realize, establish, maintain, reproduce, and update the national standards of measurement and calibration facilities for different parameters.

The laboratory is maintaining at present six out of seven SI base units (except mol). However, some of the related activities related to mol are also being followed. The derived units for physical measurement for force, pressure, vacuum, luminous flux, sound pressure, ultrasonic power and pressure, and the units for electrical and electronic parameters, viz., dc voltage, resistance, current and power, ac voltage, current and power, low-frequency voltage, impedance and power, high-frequency voltage, power, impedance, attenuation and noise, microwave power, and frequency. Impedance, attenuation, and noise are also maintained by CSIR-NPL.

The national standards of physical measurement at CSIR-NPL are traceable to international standards. The laboratory periodically carries out an intercomparison of national standards with the corresponding standards maintained by National Metrology Institutes (NMIs) of other countries under the consultative committees of the International Committee of Weights and Measures (CIPM) and the member nations of the Asia Pacific Metrology Programme (APMP). The major implication of this exercise of establishing equivalence of national standards on measurement at CSIR-NPL with those of other NMIs is that calibration certificates issued by NPL would have global acceptability.

Certified reference materials (CRMs): CRMs are required and used to ensure high-quality measurement as well as to maintain the traceability of analytical measurements to national/international measurement system (SI unit) in order to fulfill the mandatory requirement of quality systems (as per ISO/IEC 17025 standard). The use of appropriate reference materials provides traceability to the measurement in the chemical field, where formal traceability to SI units is not possible. Two types of materials are recognized by ISO Committee on Reference Material (ISO REMCO), (i) certified reference materials (CRMs) and (ii) reference materials (RMs). Certified reference material (CRM) is used whenever the calibration cannot be strictly made in SI units and the traceability could not be established. The CRM should be provided by NMIs or a competent supplier, usually an accredited RMP (recognized material producer). The RMP is accredited according to ISO 17034, produces CRM as per ISO Guide 35, and issues certificates according to ISO Guide 31. Many laboratory-accredited bodies have accredited RMPs as per ISO 17034. The values given to CRM are considered to have metrological traceability.

In India, many RMPs have come up in the recent past, mainly due to development in the field of metrology, and also due to the requirement for the CRMs. The accreditation for the RMP's capability is assessed by National Board for Testing and Calibration Laboratories (NABL), which is APAC (Asia Pacific Accreditation Cooperation) MRA partner. The RMPs are capable of producing the CRMs on a continuous basis, although the values of the CRM are certified by CSIR-NPL. CSIR-NPL is engaged in coordinating an interlaboratory program on planning, preparation, and dissemination of certified Indian reference materials named as Bharatiya Nirdeshak Dravyas (BNDs). Many CRMs for petroleum and petroleum products, pharmaceutical materials, metals and alloys, building materials, etc. are now being made locally, and the values of these CRMs are provided by CSIR-NPL (Rab et al. 2020; Yadav et al. 2021; Mande et al. 2021; Garg et al. 2021; Gupta 2009).

Bureau of Indian Standards (BIS)

The Indian Standards Institution (ISI), as it was formerly known, was founded in 1947 with the aim of fostering the peaceful growth of standardization work in India. The Bureau of Indian Standards (BIS), the national standards body of India, has been actively involved in activities related to international standardization and has represented India's interests at various times as these standards have been developed.

BIS is a founding member of the International Organization for Standardization (ISO) and has been actively taking part in ISO and International Electrotechnical Commission (IEC) operations.

The BIS formulates Indian standards through technical committees, which are constituted of sectional committees, subcommittees, and expert panels established to address particular groups of topics. These committees and panels are represented by industries, consumers, regulators, policy makers, and people from academia. As a matter of policy, BIS's efforts to develop standards have been as consistent as practicable with the pertinent directives established by the International Organization for Standardization (ISO).

The bureau's primary duties include developing, recognizing, and promoting Indian standards, More than 21,500 standards are developed by BIS, covering crucial economic sectors that aid the sector in raising the caliber of its goods and services. The BIS has identified 15 divisions that are crucial to Indian business. Each division has a separate division council to oversee and supervise the work for the preparation of the Indian standard. To ensure compliance with the international standards, the standards are periodically reviewed and revised in accordance with technological advancement (Bantu et al. 2020; Miguel et al. 2021).

Quality Council of India (QCI)

It is the National Body for Accreditation registered as a society and functions under the aegis of the Department of Promotion of Industry and Internal Trade under the Ministry of Commence, Government of India. It functions with the support of the Government of India and the Indian industry represented by the three premier industry associations, (i) Associated Chambers of Commerce and Industry of India (ASSOCHAM), (ii) Confederation of Indian Industry (CII), and (iii) Federation of Indian Chambers of Commerce and Industry (FICCI). QCI is also a signatory to IAF (International Accreditation Forum) and ILAC (International Laboratory Accreditation Cooperation) MRAs. QCI with its accreditation boards, namely, National Accreditation Board for Certification Bodies (NABCB), National Accreditation Board for Education and Training (NABET), National Accreditation Board for Testing and Calibration Laboratories (NABL), National Accreditation Board for Hospitals & Healthcare Providers (NABH), and National Accreditation Board for Quality Promotion (NBQP), is engaged in accreditation activity of various proliferated institutes, laboratories, and hospital services. These five accreditation boards engage in accreditation programs and work under the umbrella of QCI (Fig. 3). Each board functions independently and only in its specific field of competence.

In addition to the above, there are scores of bodies engaged in the field of measurement and have established state-of-the-art laboratories. These are India's premier institutions for research and development. In the field of electrical measurements, Central Power Research Institutes (CPRIs) are engaged in the field of testing as well as research in the field electrical power sector. In addition, the Electrical Research and Development Association (ERDA) is also engaged in the field of

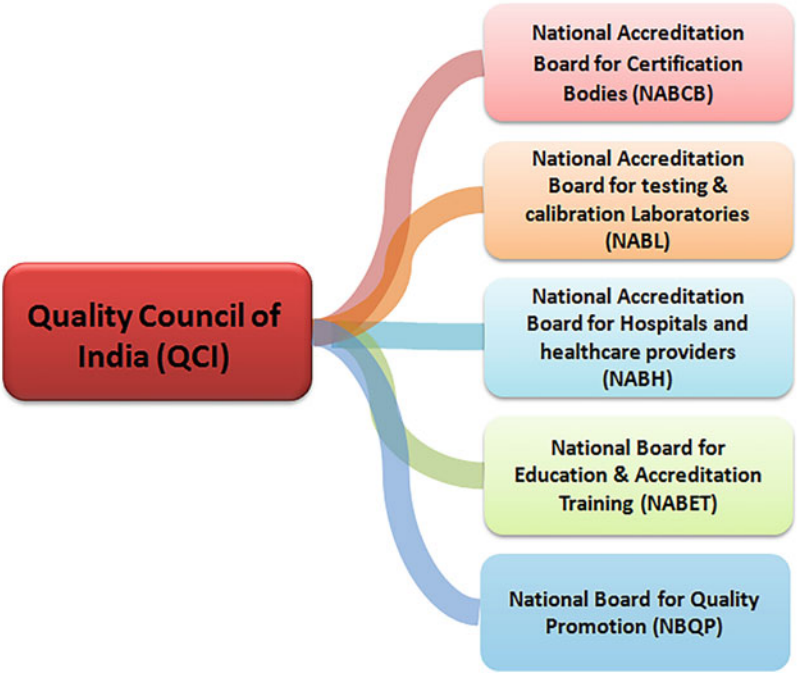

Fig. 3 Structure of quality council of India

research and testing. Another governmental organization, i.e., Electronics Research and Testing Laboratories (ERTLs), has a number of testing laboratories engaged in testing in the field of electronics. This also provides help in product development to the manufacturers.

In addition to the above, there are several organizations engaged in the research and development and testing of mechanical, metallurgical, civil, analytical chemistry, and other fields. These organizations have trained staff, state-of-the-art facilities, and a well-developed management structure to control the transfer of metrological traceability to the shop floor level.

Bhabha Atomic Research Centre (BARC)

The major nuclear research institution in India is the Bhabha Atomic Research Centre (BARC). It was established as Atomic Energy Establishment, Trombay (AEET), in January 1954 as a multidisciplinary research program crucial to India's nuclear program by Dr. Homi Jehangir Bhabha. It operates under the Department of Atomic Energy (DAE), Government of India. After Homi Bhabha passed away in 1966, AEET was renamed Bhabha Atomic Research Centre (BARC).

BARC's primary goal is to maintain and secure nuclear energy activities. It deals with all facets of atomic energy, from computerized modeling and simulation to theoretical reactor technology, novel reactor fuel material development, risk analysis, evaluation, etc. Under the authority of the Legal Metrology Act and in accordance with the CIPM MRA, CSIR-NPL had advised BIPM to designate BARC as the nation's Designated Institute (DI) status for ionizing radiation in 2003. BARC is now responsible for the establishment, maintenance, and dissemination of ionizing radiation in India. The organization has taken part in 52 intercomparison exercises and is currently moving forward with the appropriate steps to apply for the approval and registration of CMCs in ionizing radiation in close collaboration with CSIR-NPL.

Agricultural and Processed Food Products Export Development Authority (APEDA)

In accordance with the Agricultural and Processed Food Products Export Development Authority Act, which was approved by the Parliament in December 1985, the Government of India formed the Agricultural and Processed Food Products Export Development Authority (APEDA). Along with improving infrastructure and quality, APEDA has been actively involved in market development to boost the export of agricultural products. APEDA's plan scheme, the "Agriculture Export Promotion Scheme," aims to promote agricultural exports by offering financial support to registered exporters through the scheme's sub-components of market development, infrastructure development, quality development, and transportation assistance. It operates with 13 virtual offices and five regional offices in Mumbai, Bengaluru, Hyderabad, Kolkata, and Guwahati. APEDA connects the Indian exporters to the international market and offers comprehensive export services. It also offers referral services and makes suggestions for the appropriate joint venture partners.

Central Pollution Control Board (CPCB)

The Central Pollution Control Board (CPCB) of India is a department of the Indian government in charge of monitoring the quality of the air and water as well as any other pollution-related concerns. It is a legally recognized organization that is under the purview of India's Ministry of Environment, Forests, and Climate Change. Founded in 1974 under the Water (Prevention and Control of Pollution Act), it was later given duties and authority under the Air (Prevention and Control of Pollution) Act, which was passed in 1981. With seven zonal offices and five laboratories, the CPCB's headquarters are located in New Delhi. Given the complexity of environmental monitoring, experts from the metrology institute, academia, and industry must cooperate to enhance the measurement of hazardous emissions to protect human health and quantify climate-influencing factors. A nationwide certification program is being developed in India by CSIR-NPL in collaboration with the CPCB and the Ministry of Environment and Climate Change.

Conclusion and Way Forward

There is a growing awareness of quality infrastructure's significance to the economy and to society at large on a global scale. Better quality infrastructure is a requirement for free and equitable trade on a national and international level since it forms the basis of technical rules, documented standards, and legal metrology. Concepts like safety, security, efficiency, reliability, and precision are of utmost importance when creating systems that offer assurances of product quality in any institution, business, or organization. In order to smoothen market transactions, the consumers must have the confidence that purchased goods are of right quantity and quality, and for this accurate and commonly accepted measurements are essential. Importantly, precise and globally recognized measurements provide market access for the export of goods like food and commodities.

A brief description of the necessity for measurement and the national quality infrastructure is presented. The nations with well-established and reliable national quality infrastructure gain from a wide range of factors, such as increased participation in international trade, economic growth, and wealth. Advanced innovations, technologies, and product development are made possible through the knowledge gained and measurements made via standards and measuring procedures, which benefits both consumer protection and domestic commercial activity. A well-established, high-quality infrastructure is a need in any nation because it creates a win-win situation for all the stakeholders involved.

Abstract

Globalization and Industrial Revolutions have not only nourished new opportunities and challenges but also caused unnecessary disruption and polarization within and between countries and society. In this case, the economic competition is fiercer than ever before in the modern world. As a result, for barrier-free import and export, a firm must guarantee that it provides consumers with a high-quality product selection to remain up with its competitors. Companies can ensure the

quality of deliveries by completing rigorous quality checks ahead of time, and it can only be accomplished with a robust national *Quality Infrastructure (QI)*. Most of the nations have their own QI system, which supports government policy goals in industrial development, federal trade rules and control, food safety, efficient use of natural and human resources, health, the environment and climate change, etc. Several countries having highly strong QI have their industrial and economic growth healthy. On the other hand, some countries lack the infrastructure required to satisfy quality standards, posing concerns and challenges in today's competitive world. As a result, the QI plays a critical role in social, strategic, and industrial progress of any country. This chapter provides an overview of the institutional framework of QI with National and International perspectives. The study also describes the *Strengths, Weaknesses, Opportunities and Threats (SWOT)* analysis of the QI. Further, the *Global Quality Infrastructure Index (GQII)* has been updated with the inclusion of current data up to Dec 31, 2021, and summarized for the member states (63 countries) of the *International Bureau of Weights and Measure (BIPM)*. Hopefully, this study would benefit government agencies, industry, academia, and various organizations as a reference bank for future decisions and policymaking connected to robust QI.

Introduction

The current Covid-19 pandemic is a watershed moment in world economic policy, and it has caused a number of recessions and has impacted worldwide trade. Unlike industrialized countries, which have been using significant financial resources to limit the damage to their economy, countries in the world do not have these resources – at least not to the same extent. As a result, focusing on long-term economic development has become even more critical for these countries' national economies. Aside from financial assistance, there are slew of long-term technical options for keeping the economy afloat during this downturn. These options include QI initiatives that would assist firms, and other economic stakeholders ensure the quality of their products and processes, allowing them to become more competitive. Quality has become increasingly linked to health, cleanliness, safety, resilience, and sustainability due to the ongoing global Covid-19 outbreak (Aswal 2020a, b; Naidoo and Fisher 2020; Iyke 2020; Aizawa 2019).

In an economy, a quality policy assures that the institutions responsible for metrology, standards, accreditation, and certification are well-established, vigorous, and operate together cohesively and in synergy. Such intuitions are firmly connected and constitute a network in a particular economy at the national level, i.e., *National Quality Infrastructure (NQI)*. The NQI is also linked to various international institutions and organizations, forming an *"International Quality Infrastructure" (IQI)*

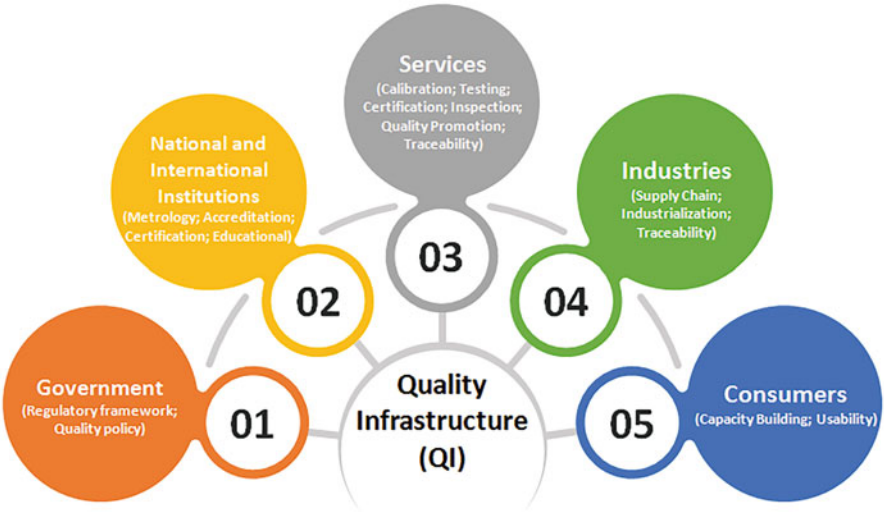

Fig. 1 Basic Quality Infrastructure Framework

network (Rab et al. 2021a, b; Harmes-Liedtke and Di Matteo 2011, 2019). Figure 1 exhibits the main linkages of government to the consumer in a QI system. In order to correlate the QI with well-being and quality of life, a global quality Infrastructure index (GQII) has been introduced (Rab et al. 2021b) including the data up to the end of the year 2020. In the updated version herein, we have used the data up to December 2021. The index uses publicly available sources from official websites of different constituents of IQI. The index is used to rank the global status of various countries in terms of QI. The indicator also shows how QI relates to other developmental indicators including economic performance, GDP per capita, competitiveness, economic complexity, export performance, etc.

The linkages between appropriate national institutes and international institutes in the case of NQI are formed depending on national requirements. The *World Bank* and other donor organizations aid many countries in developing NQIs to promote industrial development, removing trade and entrepreneurial barriers, and facilitate global technical cooperation (Tippmann 2013; UNIDO 2019; Clemens and Kremer 2016). Some of the significant organizations/agencies directly or indirectly connected with QI are summarized in Table 1.

As witnessed in Table 1, there are many organizations working for the IQI, for understanding the harmonization, uniform and barrier-free trade. It is interesting to grasp, examine, and analyze the functions of the QIs to further strengthen them. A SWOT analysis of the QI system is also performed to understand the different aspects of QI, like what are the strengths and weaknesses of the QI system and how these can be utilized into opportunities to make the QI system strong and robust. Further in the implementation, the anticipated threats are identified and highlighted. With the help of the updated QI data in GQII, this chapter also provides a comprehensive overview of the QI of 63 BIPM member states.

Table 1 A list of major organizations/institutes/groups related to QI

Name of the organization	Description
United Nations (UN)	The *United Nations (UN)* is an intergovernmental organization whose mission is to promote international peace and security, foster cordial relations among nations, foster international collaboration, and serve as a focal point for harmonizing nations' actions. The UN was established in 1945 and is currently headquartered in New York City on the international territory; and has offices in Geneva, Nairobi, Vienna, and The Hague, with a current total membership of 193 countries (United Nations 2020)
World Trade Organization (WTO)	The *World Trade Organization (WTO)* is an international organization that regulates and supports international trade. The organization is used by governments to establish, update, and enforce international trade rules. It began operations on January 1, 1995, due to the 1994 *Marrakesh Agreement*, which replaced the 1948-established *General Agreement on Tariffs and Trade (GATT)*. The WTO is headquartered in Geneva, Switzerland, and has 164 member countries (World Trade Organization 2019)
United Nations Industrial Development Organization (UNIDO)	The *United Nations Industrial Development Organization (UNIDO)* is a UN specialized organization that helps countries to improve their economies and industries. The *UN General Assembly* founded UNIDO in 1966, and it is located at the UN Office in Vienna, Austria, with 170 member states (United Nations Industrial Development Organization 2020)
The World Health Organization (WHO)	The *World Health Organization (WHO)* is a UN specialized organization which deals with international public health. The WHO was established in 1948 and is headquartered in Geneva, Switzerland. The WHO has six regional offices and 150 field offices worldwide, currently with 194 members (World Health Organization 2020)
International Organization for Standardization (ISO)	The *International Organization for Standardization (ISO)* is a global standard-setting organization composed of various national standards bodies' representatives. The ISO was founded in 1947 and is headquartered in Geneva, Switzerland, with 167 national standards bodies (International Organization for Standardization 2019)
International Electrotechnical Commission (IEC)	The International Electrotechnical Commission (IEC) is a non-profit organization that develops and publishes the international standards for all electrical, electronic, and related technologies, commonly known as "electrotechnology." The IEC was founded in 1906 and is headquartered in Geneva, Switzerland. There are currently 88 countries that are members of the IEC (2020)

(continued)

Table 1 (continued)

Name of the organization	Description
International Telecommunication Union (ITU)	The International Telecommunication Union (ITU) is a UN-specialized organization in charge of all information and communication technologies issues. It was founded as The International Telegraph Union in 1865, making it the oldest UN agency (The International Telecommunication Union (ITU) 2019). The ITU is a multinational organization with 193 member countries based in Geneva, Switzerland
ASTM International	*ASTM International*, formerly known as the *American Society for Testing and Materials*, founded in 1902, is an international standards organization that develops and publishes voluntary technical standards through consensus for a wide range of materials, products, systems, and services (ASTM International 2021)
The International Atomic Energy Agency (IAEA)	The *International Atomic Energy Agency (IAEA)* is the international organization for nuclear-related research and technological cooperation. The IAEA was founded in 1957 and is currently headquartered in Vienna, Austria, with 173 member states (International Atomic Energy Agency 2021)
International Accreditation Forum (IAF)	The *International Accreditation Forum, Inc. (IAF)* is a global organization of Conformity Assessment Accreditation Bodies and other organizations involved in conformity assessment in the sectors of management systems, products, services, personnel, and other such of the conformity assessment program. The IAF was established in 1993 due to the inaugural meeting of "Organisations that Accredit Quality System Registrars and Certification Programs" in Houston, Texas, on January 28, 1993 (The International Accreditation Forum (IAF) 2020)
International Laboratory Accreditation Cooperation (ILAC)	The *International Laboratory Accreditation Cooperation (ILAC)* first began as a conference held in Copenhagen, Denmark, on October 24–28, 1977, to foster international cooperation to facilitate trade by promoting the acceptance of accredited test and calibration results. The ILAC was founded later on in 1996 as a formal collaboration with a charter to create a network of mutual recognition agreements among accreditation agencies. In calibration, testing, medical testing, inspection, proficiency testing providers, and reference material manufacturer's certification, ILAC manages the international arrangements (International Laboratory Accreditation Cooperation 2021)
World Meteorological Organization (WMO)	The *World Meteorological Organization (WMO)* is a United Nations specialized organization that promotes worldwide collaboration in atmospheric science, climatology, hydrology, and geophysics. The WMO comprises 193 countries and territories, allows the "free and unlimited" exchange of data, information, and

(continued)

Table 1 (continued)

Name of the organization	Description
	research among its members' meteorological and hydrological organizations. The WMO is headquartered in Geneva, Switzerland, and it is governed by the World Meteorological Congress, which meets every 4 years to define policies and goals (The World Meteorological Organization 2020)
International Bureau of Weights and Measures (BIPM)	The *International Bureau of Weights and Measures (BIPM)* is an office formed under the Metre Convention and consultation with The International Committee for Weights and Measures (CIPM) that allows member states to collaborate on measurement science and standards. The BIPM was established on May 20, 1875. Following the signing of the Metre Convention, a treaty among 17 Member States that has since grown to 63 (International Bureau of Weights and Measures 2019)
National Metrology Institutes (NMIs)	Each country has a single *National Metrology Institute (NMI)*, which is responsible for maintaining national measurement standards and distributing the International System of Units. Most of the countries have their own NMI, which is internationally recognized and part of a worldwide framework that ensures comparable measuring standards and capabilities. The directors of the state institutes for metrology from all 48 member countries of the *Metre Convention* were invited to sign the *Mutual Recognition Agreement (MRA)* on the mutual recognition of national measurement standards and calibration and measurement certificates at the 21st *General Conference of Weights and Measures (CGPM)*, held in Paris under the auspices of the BIPM. The phrase *"National Metrology Institute"* was established worldwide in the MRA, and signed by 38 countries represented at the CGPM. The acronym NMI is used all across the world for such an institute (Rab et al. 2021a; Kind and Lübbig 2003)
International Organization of Legal Metrology (OIML)	The *International Organization of Legal Metrology (OIML)* is an intergovernmental organization founded in 1955 to assist economies in establishing effective legal metrology infrastructures that are mutually compatible and internationally recognized in all areas where governments are responsible, such as trade facilitation, mutual confidence, and harmonization of consumer protection levels around the world (International Organization of Legal Metrology 2020)
Group of 20	The G20 consists of 19 countries as well as the European Union. With almost 80% of global GDP, 75% of international trade, and 60% of the world's population, the group plays a key role in ensuring global economic growth through the development in QI (Bradford 2016)

Significance of Sustainable Development Goals (SDGs) and G20 in QI

Protecting the environment, ensuring dignified lifestyles for all people, and achieving inclusive economic growth and prosperity are all related to QI. The UNIDO is assisting QI constituents in several countries across the world. It has helped to create and strengthen numerous QI-related institutes by supplying cutting-edge equipment and building technical skills. The 2030 Agenda for Sustainable Development, which was launched in 2015, is a beacon around which all countries, businesses, and civil society can unite with the common goals of decreasing poverty and establishing a more sustainable and equitable world. The SDGs are a blueprint for a more prosperous and sustainable future for everyone. The SDGs address global issues such as poverty, inequality, climate change, environmental degradation, peace, and justice (THE 17 GOALS; UNIDO).

The QI also helps countries to achieve the SDGs in the most efficient way possible. International commerce is regarded as a source of wealth and poverty reduction, and it improves the efficiency of domestic markets and promotes access to global markets. It is accomplished through quality assurance, standard compliance, and addressing consumer demands at home and overseas. The QI assists in meeting market demands, and it can address social and environmental issues while attempting to avoid excessive trade obstacles. The UNIDO is now developing a QI Scorecard for Sustainable Development, which will make the link between SDGs and QI even more visible and measurable (UNIDO 2019).

The pandemic's economic impact is exacerbated by supply chain disruptions that have put the manufacturing industry on hold and declining commodity prices. This has roiled financial markets, tightened liquidity conditions in many nations, resulted in extraordinary capital outflows from poor countries, and put pressure on foreign exchange markets, with some countries facing dollar shortages. Local currency weakness limits the government's ability to implement fiscal stimulus on the scale required to stabilize the economy and address the health and humanitarian crises.

To deal with such a financial crisis, The G20 was established in 1999 with the goal of discussing policies that would lead to global financial stability. It is a global strategic platform that brings together the world's leading industrialized and emerging economies. The G20 includes Australia, Argentina, Brazil, China, Canada, France, India, Germany, Indonesia, Italy, Japan, Korea, Mexico, Saudi Arabia, Russia, South Africa, the United Kingdom, the United States, Turkey, and the European Union. The G20 has a critical role in ensuring global economic growth and prosperity in the future (Cooper and Thakur 2013; Kirton 2016).

The *G20 Hangzhou Summit* in September 2016 defined *Quality Infrastructure Investment (QII)* as an investment "which aims to ensure economic efficiency in view of life-cycle cost, safety, resilience against natural hazards, job creation, capacity building, and transfer of expertise and know-how on mutually agreed terms and conditions while addressing social and environmental impacts and aligning with economic and development strategies" (The G20 or Group of Twenty 2021; The 2016 G20 Hangzhou Summit 2016).

Fig. 2 The G20 Principles for Promoting Quality Infrastructure Investment

At the G20 Finance Ministers' and Central Bank Governors' Meeting in Fukuoka, Japan (8–9 June 2019), the leaders reaffirmed the need for QI by embracing the Principles for QII. "Maximizing the positive impact of infrastructure to achieve sustainable growth and development while preserving the sustainability of public finances, raising economic efficiency in view of life-cycle cost, integrating environmental and social considerations, including women's economic empowerment, building resilience against natural hazards and other risks, and strengthening infrastructure governance" were among the recommendations in their communiqué (Yoshino et al. 2019; Langston and Crowley 2022; Jaramillo et al. 2021). The G20 Principles for Promoting QI Investment are exhibited in Fig. 2.

Similarly, there are other groups of countries such as the G7, BRICS, APEC, African Union, European Union, and other collaborations for national developments. For example, Canada, France, Germany, Italy, Japan, the United Kingdom, and the United States are members of the Group of Seven (G7), an intergovernmental political forum. By 2020, the collective group will control a little more than half of the global net wealth. The majority of the members are international leaders in politics, economics, social issues, legal issues, environmental issues, military, religious, cultural, and diplomatic connections.

Quality Infrastructure and Its Baselines

QI studies have been carried out in order to better understand and compare economic developments and performance. As previously stated metrology, standardization, accreditation, and certification are the four fundamental foundations or bases of any country's QI. Through calibration, testing, certification, verification, and inspection, these pillars ensure conformity assessment. The national quality policy of a country

ensures that metrology, standards, accreditation, and certification agencies are well-established, robust, and collaborate. Such institutions are interconnected and form a QI network for any country (Aswal 2020a, b).

Figure 3 shows these major bodies associated with the QI system, for example, in Indian NQI, CSIR-NPL is responsible for scientific and industrial metrology (NMI); *Bhabha Atomic Research Centre (BARC)* is responsible for nuclear radiation metrology as a *Designated Institute (DI)*; the Legal Metrology Department is responsible for legal metrology; *Bureau of Indian Standards (BIS)* is working for documentary standards and product specifications, and *Quality Council of India (QCI)* is

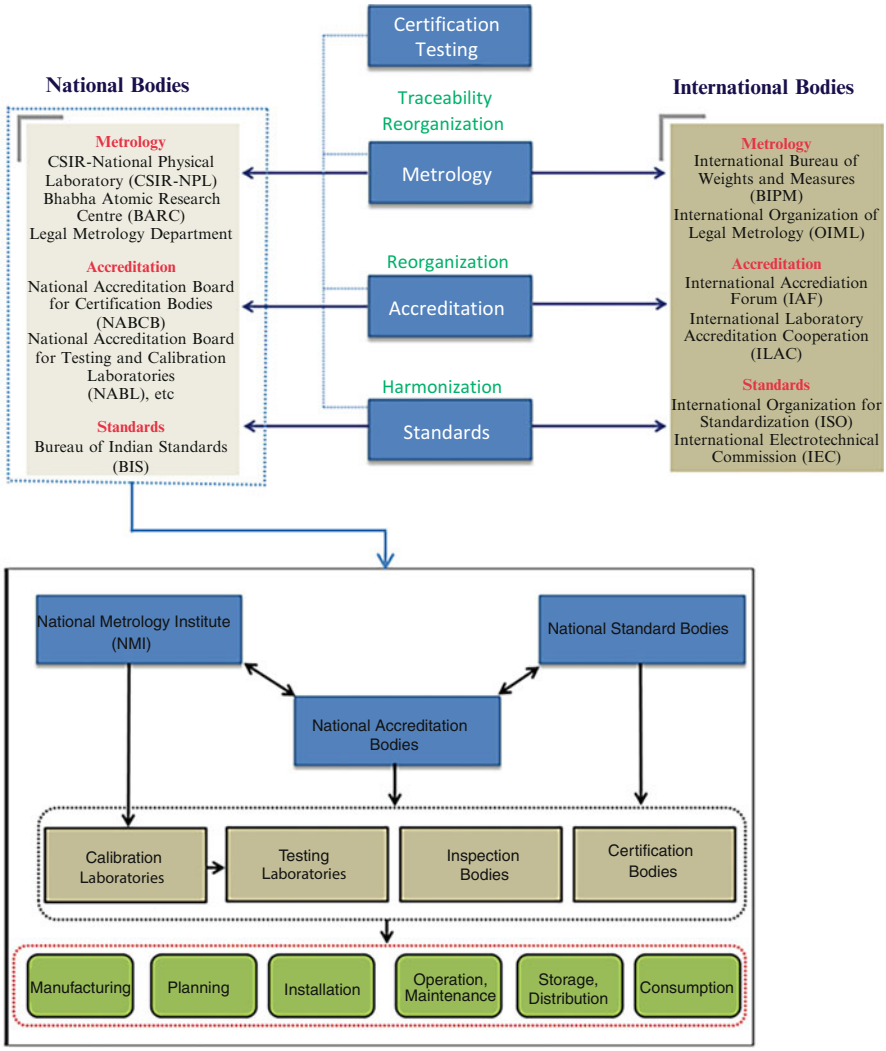

Fig. 3 National and international bodies associated in the QI system; a case of country India

responsible for accreditation and certification (Rab et al. 2021a, b). There are few more institutions or bodies like Agricultural and Processed Food Products Export Development Authority (APEDA), Food Safety and Standards Authority of India (FSSAI), Express Industry Council of India (EICI), Engineering Export Promotional Council of India (EEPCI), Projects Export Council of India (PECI), Manufacturers' Association for Information Technology (MAIT), Organisation of Plastic Processors of India (OPPI), National Association of Software and Service Companies (NASSCOM), National Green Tribunal (NGT), Indian Stainless Steel Development Association (ISSDA), Federation of Indian Export Organisation (FIEO), Central Drugs Standard Control Organisation (CDSCO), Atomic Energy Research Board (AERB), Telecom Regulatory Authority of India (TRAI), etc. apart from several other financial and insurance regulators, which are directly and indirectly connected with Indian NQI.

The major four constituents of the QI system are briefly described in the subsequent section.

Metrology

One of the central pillars of the QI system is metrology. The beginning of modern metrology, which is based on the metric system, may be traced back to France's adoption of the metric system in the 1790s. Following that, the definitions of the SI unit system were developed under the authority of CGPM and supervision of CIPM, as part of an international standards body having its working office known as BIPM in France (International Bureau of Weights and Measures 2019).

Metrology is essential for almost all walks of human life. It is critical for environmental conservation, ensuring dignified and quality lives, and creating inclusive economic growth and prosperity. It is necessary for trade, scientific comparison, innovation and developing technologies, technical cooperation, and simply basic information exchange. Building good metrological traceability leads to better QI, which is a step toward establishing the right policy framework conditions and the rule of law, which are essential for a prosperous economy (Rab et al. 2020; Yadav and Aswal 2020; Zafer et al. 2019).

However, it has been observed that not all countries have the same metrological capabilities. On the other hand, some countries have comprehensive and robust metrology programs, while others either do not have or do not have appropriate QIs. One of the parameters for evaluating such capabilities is documented as CMCs, which have the highest credibility and reliability. After a rigorous process as per CIPM MRA, these CMCs of the NMIs are published on *Key Comparison Database (KCDB)* of BIPM (Rab et al. 2022a, b). The NMIs participate in the key comparisons to evaluate if their measurement standards and procedures are comparable. *Consultative Committees (CCs)* or *Regional Metrology Organizations (RMOs)* conduct such comparisons, referred to as Key or Supplementary Comparisons. As a result, the participation in frequent and the number of comparisons results in better reliability, compatibility of measuring standards, and confidence in the measurement standards.

For the regulatory framework, each country requires a measurement system as well as proper legislations. Legal metrology ensures fair commerce through accurate measurements by transferring the benefits of metrology to ordinary residents of the country through suitable legal enforcement. As a result, legal metrology is an important aspect of the technical regulation system, and such legal legislations are framed to fulfill the country-specific requirements and by and large agree to the WTO's Agreement on Technical Barriers to Trade (TBT Agreement) criteria.

Accreditation

The accreditation is basically started in laboratory services after World War II and was coordinated by the *ILAC*. The accreditation through *Certification Bodies (CBs)* came into existence much later and is being managed by the *International Accreditation Forum (IAF)*. The ILAC and IAF, two international accreditation organizations, are in the process of merging. The key mechanism for cross-border recognition of conformity assessment services is accreditation. The global and regional accreditation co-operations control the acknowledgment of the technical competence and impartiality of *NABs*. The NABs sign the ILAC MRA and the IAF *Multilateral Recognition Agreement (MLA)* for this purpose. The signatories agree to recognize accreditations and conformity assessment.

In most nations, there is only one *Accreditation Body (AB).* On the other hand, some have multiple ABs, like several ABs competing in India in various accreditation areas. In some exceptional cases, bi-national and regional ABs are also present. The *Joint Accreditation System for Australia and New Zealand (JAS-ANZ)*, for example, is in the existence as CB for accreditation for both countries. Furthermore, not all countries or economies have a governing agency for certification. The critical need for developing a NAB is sometimes lacking in smaller and less developed countries. Some of these economies have created *National Accreditation Focal Points (NAFPs)*. These competent bodies operate as information sources in nations that do not have accrediting bodies. These accredited bodies in various areas could lead to the diffusion of their country's competency, authority, and credibility (Cross-Frontier Accreditation 2021; GQII 2021).

Standardization and Certification

As part of the *Technical Barriers to Trade (TBT)* agreement, the *WTO* encourages adopting international standards as best practices. It demands involvement in standardization initiatives, including participation by developing nations. The *ISO* develops international standards in a variety of fields, except for electrics and electronics, which are handled by the *IEC*, and telecommunications, which are regulated by the *ITU* (Rab et al. 2021a, b; World Bank 2019; QI4D 2022).

SWOT Analysis

The SWOT analysis describes the strengths, weaknesses, opportunities, and threats based on the information acquired from the networks studied for QI. The SWOT analysis of QI is examined focusing on a better understanding of the restrictions that countries confront throughout the investment cycle and the inefficiencies that undercut the value-added proposition. Table 2 describes the SWOT analysis of QI.

Table 2 SWOT analysis of QI

Strength	Weakness	Opportunity	Threat
• Reduction of barriers to trade • The cornerstone for the development of the economy and society • Safety of industrial production sites • Facilitation of digitalization and innovation • Protection of consumers from unsafe products • Clean environment and climate change • Sustainable energy • Improving public health	• Lack of coordination between the central bodies of QI (Metrology, Accreditation, Standards, and Conformity assessments) • Lack of adequate government support to the QI bodies • Comparatively frequent interventions of government organizations • Regulations should be for organization booster but not for hindrances • The duality strategy is setting high requirements for exports while lowering them for domestic consumers • Because the private sector is weekly organized, the government is more likely to intervene in the market. In this regard, technical laws are frequently preferred, whereas industry self-regulation is weaker	• Development and harmonization of metrology, standards, accreditation, conformity assessment, and market surveillance • Innovation in standardization of products, processes, and organizational arrangements • Strengthen the corporation between various countries and advanced development of metrological infrastructure • Funds for research and development are scarce, so QI bodies rely frequently on the finances arranged by themselves or depend on international developmental funding • National country-specific standards formation in line with international standards	• Parity exists between the developed and underdeveloped countries, which reflect the less QI in underdeveloped countries • Conflict may arise between technological, innovations, and legal framework • Maintenance of infrastructure and facilities • Funding issues with the developing and underdeveloped countries • Export restrictions • Import dependency • The higher price of domestic products, due to inclusion of cost for metrology, standards, and accreditation

As discussed earlier, the goal of a SWOT analysis is to identify the strengths and weaknesses of the QI, as well as opportunities and threats in various areas of the QI system. The pillars of QI (Metrology, Accreditation, Standardization, and Certification) play a key role in improving technology development and industrialization, affordable healthcare and safety, clean environment and climate change, sustainable energy, international trade facilitation, and the creation of a level playing field in society, according to a SWOT analysis. The analysis also indicates the need of more synchronization and synergy between all the pillars of QI keeping metrology as the focal theme for enhancing the growth of the economy and quality of life.

Updated GQII and Its Significance

The GQII formula includes the primary major component of the QI system. The authors have defined critical metrics for each component to measure the country's QI development state. The GQII formation was extensively explored and reported in our previous publication (Rab et al. 2021b). The present studies provide the GQII metrics on QI and its components for BIPM member states in an updated version. This allows us to evaluate and rank the progress of a country's various QI elements. On January 19, 2021, the Republic of Estonia also became the permanent member state of BIPM (2021). Thus, the GQII ranking has been calculated for all the 63 states compared to the 62 countries in the previous edition. The GQII follows the equation as:

$$GQII_i = (C_1 + C_2 + C_3 + C_4 + C_5 + C_6) \times \frac{100}{6} \tag{1}$$

where C_1, C_2, C_3, C_4, C_5, C_6 are defined as follows:

$$C_1 = \frac{CMC_i/P_i}{(CMC/P)_{max}}; C_2 = \frac{K\&SC_i}{K\&SC_{max}}; C_3 = \frac{ISO_i/P_i}{(ISO/P)_{max}}; C_4 = \frac{TC_{si}}{TC_{max}};$$
$$C_5 = \frac{E_{Edui}\%}{E_{max}}; C_6 = \frac{M_{ITCi}}{M_{max}}$$

$i = Country_1, Country_2, Country_3, \ldots Country_n$

P_i = Country population

CMC_i = Total number of calibartion and measurement capabilities

$K\&SC_i$ = Total number of key and supplementry comparisons

ISO_i = Total number of vaild ISO Standards issued (9001, 14001, 22000, 13485, and 27001)

TC_{si} = Total number of technical committees participations according to ISO

E_{Edui} % = % expenditure of GDP on Education

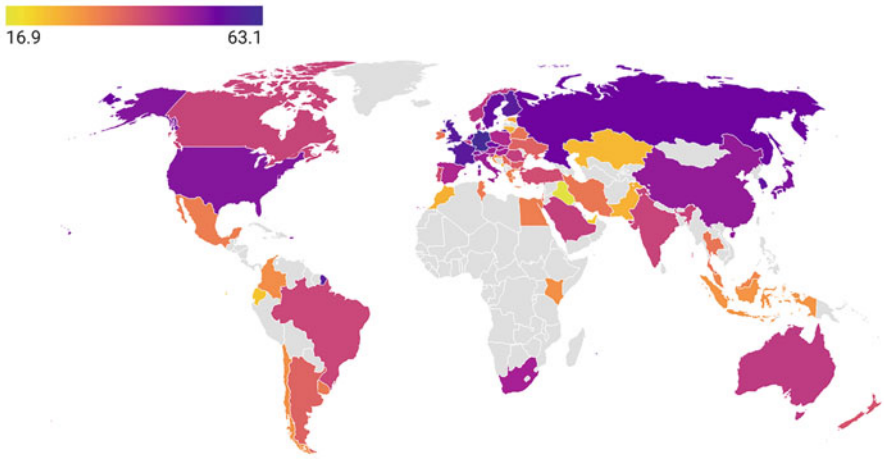

Fig. 4 BIPM member states visualization with GQII (**The world map is only intended to be used as a visual aid and does not indicate any view on the legal position of any country or territory or the delimitation frontiers or boundaries, has been expressed*)

Membership (M_{ITCi}) = Number of memberships of international QI system (WTO, IAF, ILAC, CIPM, OIML, ISO, IEC, ITU)

Figure 4 depicts the current situation of QI from a geographical standpoint. The figure demonstrates that European countries have rather well-developed QIs. In addition, several African countries have limited quality assurance agencies and are attempting to improve their scientific and industrial metrological capabilities.

Figure 5 shows the comparison of nations' GQII rankings with their GDP per capita rankings. The GDP per capita is used as a global metric for determining a country's wealth (GDP). GDP per capita, in its most basic form, shows how much economic production value can be given to each person of a country. It also aids in comprehending how the economy grows in tandem with the population. These QI indicator correlations are critical for determining the role of a country's competitiveness and economic development. As per GQII ranking, a country with a well-developed QI is economically affluent, whereas a poorly developed QI is economically disadvantaged. The ranking clearly shows that higher CMCs, participation in more key comparisons (BIPM 2020) and technical committees' more ISO certifications (The ISO Survey) and higher economic investment in education (World Bank 2020) certainly contribute to a higher GQII score for a country. Only openly available data in metrology, standards, certification, and education have been considered for this indicator. Accreditation data is not included in the methodology since it is either unavailable or provided in a very complex and variable manner from country to country. The ranking and GQII score of each country is shown in the appendix (Table A).

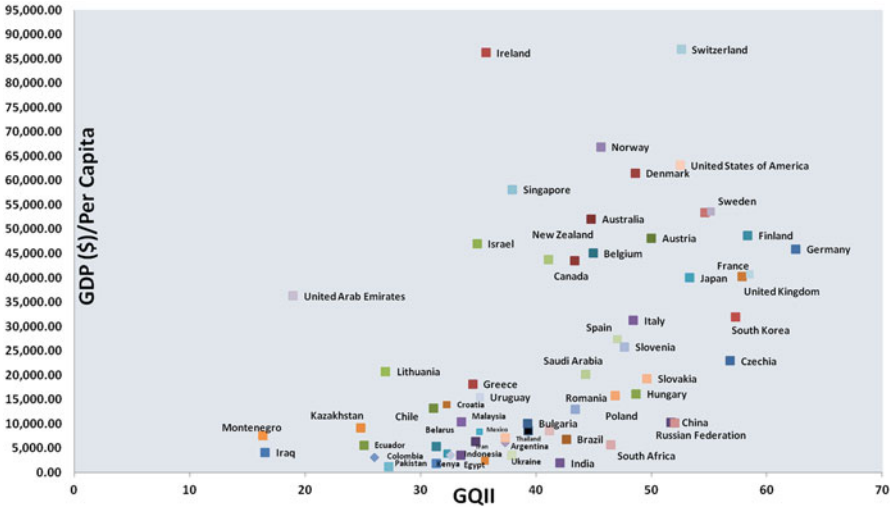

Fig. 5 GDP ($) per capita with GQII

Discussion and Way Forward

The transition to a more sustainable and inclusive economy is one of the current generation's most pressing issues. Climate change, biodiversity loss, and pollution are all becoming increasingly worrisome. These environmental crises are intertwined with the world's numerous development challenges. During the COVID-19 epidemic, digitalization increased substantially. The pace of digital change will continue to pick up. Innovation and the massive volumes of data generated can enable governments to progress considerably on their development agendas. The concentration of power among digital behemoths, on the other hand, produces dependencies that stifle competition.

Meanwhile, new difficulties such as privacy, security, and accountability arise. As each country adopts and improves its NQI, it is also responsible for meeting technology needs, minimizing superfluous technical trade barriers, and addressing environmental, health, and safety concerns. The process of developing an internationally recognized NQI takes time, and policymakers must decide which sort of NQI is most suited to their country's future engagement with the global economy. Indeed, authorities are grappling with transforming the systems they inherited and restructuring the conformity assessment infrastructure in a timely and cost-effective manner.

Germany (1st), France (2nd), and Finland (3rd) are the top three countries in this edition of the GQII ranking. In the case of India, the GQII ranking this year is 29 out of 63 BIPM member states studied, with a GQII score of 43.2. It is also discovered that the development of the individual components of the QI has a high level of coherence. A country with high metrology values is likely to be advanced in other areas as well. The main issue was that accreditation data was processed in very diverse ways from country to country, making it difficult to compare. The GQII would be an excellent monitoring tool for international development programs focusing on QI.

Conclusion

A good QI is the first step toward a stable political environment and the rule of law. It also leads to high-quality goods, which is essential for a healthy economy. As a result, it is critical to research and comprehend the function of QI in any country's development. Further, during and after the COVID-19 pandemic, QI work would be exceedingly more critical to guarantee that products and services, particularly in the medical and food sectors, meet the established criteria. Governments' attempts to provide essential medical items and assure food safety and security in the most efficient, effective, and sustainable manner require advanced QI services and mutual recognition agreements among trading partners. In the middle- and low-income countries, there is increasing potential to assist QI development. It is unavoidable for development partners to promote awareness about the relevance of QI in assisting nations in attaining sustainable growth and development and ensuring that QI systems are aligned with the demands of the private sector and regulatory bodies across trading partners. It is also critical to guarantee that development partners work and coordinate to ensure that our client countries receive the best possible assistance based on available resources, competencies, and capabilities.

This chapter provides a concise review of the QI. The IQI bodies have been studied to strengthen NQI. In addition, a SWOT analysis was performed to understand the QI better. The second edition of GQII has been reported as a measure of QI in various countries based on data from the various QI components. The quality of life in 63 BIPM member nations has been studied. According to the findings of the GQII studies, most countries with high GDP also have high QI or vice versa. Stakeholders and policymakers should find this insightful study to be highly useful as a reference source.

Appendix

Table A GQII ranking of BIPM member states

Country	GQII score	Rank
Germany	63.06	1
France	57.97	2
Finland	57.78	3
United Kingdom	57.69	4
Korea	56.14	5
Sweden	55.24	6
Russian Federation	54.57	7
Netherlands	54.50	8
Czechia	54.37	9
Japan	53.10	10
Switzerland	52.54	11
United States of America	52.54	12
China	51.05	13
Italy	49.67	14
Austria	49.57	15
Slovakia	49.44	16
Denmark	49.43	17
Hungary	48.55	18
South Africa	48.29	19
Slovenia	48.28	20
Spain	47.42	21
Poland	47.22	22
Belgium	45.16	23
Norway	44.95	24
Australia	44.73	25
Romania	44.03	26
Saudi Arabia	43.86	27
India	43.23	28
Canada	43.08	29
Brazil	42.93	30
Portugal	41.83	31
Turkey	41.50	32
New Zealand	40.52	33
Bulgaria	39.39	34

(continued)

Table A (continued)

Country	GQII score	Rank
Ukraine	38.42	35
Argentina	38.29	36
Singapore	37.13	37
Serbia	37.01	38
Israel	36.11	39
Belarus	35.73	40
Thailand	35.43	41
Ireland	35.43	42
Iran	35.14	43
Uruguay	34.90	44
Tunisia	34.49	45
Mexico	34.16	46
Egypt	33.99	47
Greece	33.74	48
Malaysia	32.78	49
Colombia	31.78	50
Kenya	31.49	51
Chile	31.48	52
Croatia	30.98	53
Indonesia	30.87	54
Estonia	28.04	55
Pakistan	26.53	56
Lithuania	26.53	57
Morocco	26.17	58
Montenegro	25.97	59
Kazakhstan	25.24	60
Ecuador	23.51	61
United Arab Emirates	22.98	62
Iraq	16.94	63

Abstract

On 20 May 2019, *Le Système internationale d'unités* (SI) or the International System of Units underwent a historic change to become defined in terms of assigned values of constants of nature. This chapter provides a brief historical overview of units and describes the changes that occurred in the redefinition. We dedicate this chapter to the memory of Prof. Ian Mills, OBE, FRS (1930–2022), who played a significant role in the redefinition.

SI · Units · Redefinition · Measurement standards

Introduction

Le Système internationale d'unités (SI), or International System of Units, came into being in 1960, through the action of the *Conference général des poids et mesures* (CGPM) or General Conference on Weights and Measures (https://www.bipm.org/en/measurement-units; https://www.bipm.org/en/committees/cg/cgpm). It was firmly based on the metric system, whose roots were in the French Revolution of the late eighteenth century (Adler 2003; Quinn 2017) and followed in the tradition set by the international *Convention du Mètre* (the Treaty of the Meter) of 1875, which established the metric system as the official system of measurement units for the world, or at least for those 17 countries who were signatories of the original treaty (https://bipm.org/en/metre-convention). That treaty established the *Bureau International des Poids et Mesures* (BIPM) or International Bureau of Weights and Measures (http://bipm.org/en/home), which became the guardian not only of the spirit of the metric system and of its evolution and growth, but also, as we will see below, of the artifacts that formed the basis for that system of units.

On 20 May 2019, the 144th anniversary of the signing of the original *Convention du Mètre,* the SI underwent what we consider to be the most revolutionary change in the metric system since its inception during the French Revolution. Approved by the CGPM on 16 November 2018 in Versailles (Stock et al. 2019), the result of this revolutionary reform is that today all of the seven base units of the SI (the meter, kilogram, second, ampere, kelvin, mole, and candela), are defined by the adoption of fixed values of seven "constants of nature." As a result, all of the derived units of the SI, which are derived from the base units, are in turn defined by those constants of nature. The International System of Units is now free of those artifacts on which the original metric system was based. In principle, scientists on Earth could communicate to hypothetical scientists on any other planets what we mean by "kilogram," "meter," "second," and so forth, assuming, as seems likely, that the laws of physics and the natural constants are uniform throughout the universe.

Here, we present an abbreviated and incomplete historical review of the units for time and length, as an example of how such units have changed over time, and as an example of how constants of nature can be, and have been, used to define a unit. Then, we present a similar review of the unit of mass, describing the more recent changes in the definition of this unit – why a change was needed and how it was accomplished. We briefly describe the situation with the other base units of the SI.

A Brief History of Time (with Our Apologies to the Late, Great Stephen Hawking (Hawking 1988))

For a long while, and beginning at an indefinite time, the unit of time, the second, has been $1/(24 \times 60 \times 60)$ of a day, an understanding arising from choosing to have 24 h in a day, 60 min in an hour, and 60 s in a minute. But, what is a "day"? In modern times, until the middle of the twentieth century, this was understood to be the "mean solar day." The solar day, the time between successive passages of the sun across the meridian, varies throughout the year, because of factors like the inclination of the earth's axis of rotation relative to the plane of its orbit around the sun and the eccentricity of that orbit. This deviation is as much as 30 s from the mean (https://en.wikipedia.org/wiki/Solar_time). How to determine the mean value, averaged over a year, was never specified by the governing metrological bodies established by the *Convention du Mètre* and was left to the astronomers. The understanding and observation that the mean solar day was in some sense an artifact that was susceptible to change over time (friction due to the tides, changes in ocean currents, and other effects can change the length of a day) led to a redefinition of the second. In 1960, the CGPM defined the second as a fraction of the tropical year 1900. While this provided a stable definition, it was still essentially an artifact, and not one to which one could easily refer.

Meanwhile, the use of transitions between energy levels of atoms or molecules was being discussed as a possible new approach to the definition of the unit of time (Rabi 1945). The idea of using atoms as frequency standards dates back to Maxwell in 1873 (Maxwell 1873) and Thomson (Lord Kelvin) and Tait in 1879 (Thomson and Tait 1879). The history of much of the early development of such atomic clocks is reviewed by Ramsey (Ramsey 1983). The first "atomic" clock operated at a National Metrology Institute (NMI) was the 1949 molecular ammonia clock at the US National Bureau of Standards (see Fig. 1), and the first NMI cesium atomic clock was operated at the U.K. National Physical Laboratory in 1955 (see Fig. 2). With such atomic clocks providing superior performance and convenience compared to the astronomical definitions of the second, in 1967/1968 the CGPM redefined the second as *"the duration of 9192631770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the caesium 133 atom."* This is equivalent to defining the hyperfine frequency of ^{133}Cs and as such represents an example of defining a unit of measure by defining a constant of nature, a definite improvement over the mean solar day, which is not guaranteed to be stable over time.

The definition of the SI second in terms of ^{133}Cs is the current (2023) definition. It is not likely to remain so for very much longer. The hyperfine frequency, which is a natural constant, is not a "fundamental" constant. There can be, and in fact are, other transitions in other atoms that are superior. For example, Al^+ with 9×10^{-19} relative uncertainty (Brewer et al. 2019) and Sr with 2×10^{-18} relative uncertainty (Nicholson et al. 2015) (more recently, a resolution of 8×10^{-21} relative uncertainty has been achieved (Bothwell et al. 2022)), and today the redefinition of the SI second, in

Fig. 1 Dr. Harold Lyons (right), inventor of the ammonia absorption cell atomic clock, observes, while Dr. Edward U Condon, the director of the National Bureau of Standards, examines a model of the ammonia molecule (1949) (http://ethw.org/Milestones:First_Atomic_Clock,_1948). (Credit: NIST, USA Digital Archives)

terms of some ion or atom with an appropriate transition at an optical frequency, is under active consideration.

That the current and future definitions of the SI second are not in terms of fundamental constants of nature leaves open the possibility that the discovery of better transitions will continue to lead to future redefinitions of the second. The story of length, below, is an example of a unit, the meter, being defined in terms of a "fundamental" constant, so that no future redefinition of length should ever be needed.

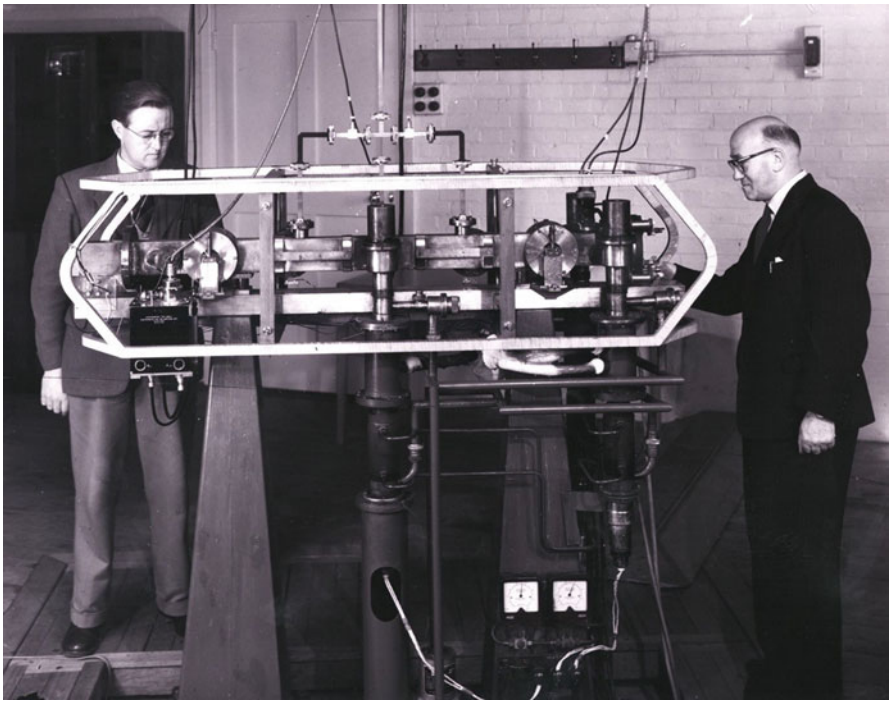

Fig. 2 Jack Parry (left) and Louis Essen (right) with the NPL cesium atomic clock in 1955 (https://en.wikipedia.org/wiki/Atomic_clock). (Credit: NPL)

A Short History of Length

In order to appreciate the need for, and the beauty of, defining a unit by fixing the value of a fundamental constant of nature, we review some of the history of units for length. This history includes various ways of defining the unit of length and illustrates the appeal of these various ways. According to the usual folklore, which is probably more or less accurate, the first standards of length were based on the dimensions of the human body (see Fig. 3). A yard was the distance from one's nose to the end of an extended hand. A foot was the length of a foot. A fathom was the length of one's arm-span – the distance between outstretched hands, a hand was the distance across the palm of that body part, and the cubit was the length from the elbow to the fingertip.

The advantages of such a measuring system are obvious: One always has the standards of measurement "at hand" so to speak, a tremendous convenience. The disadvantages are equally obvious – the variability of the measurement standard from one user to another could be annoying (as in commerce) or disastrous (as in engineering) (https://usma.org/unit-mixups).

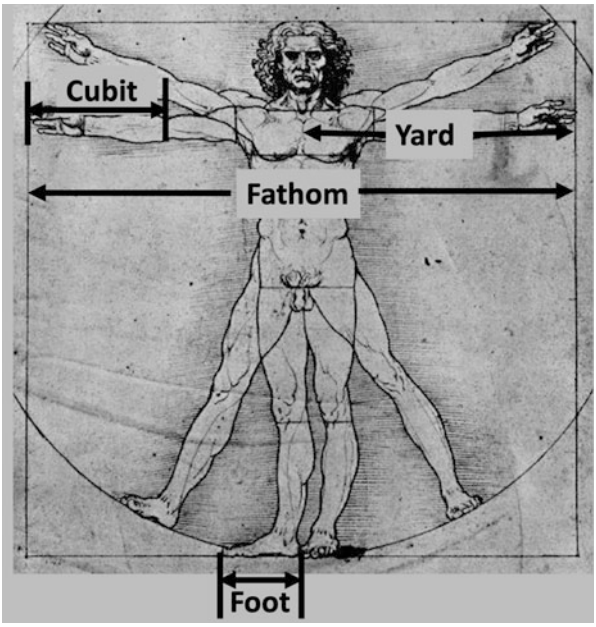

Fig. 3 A few standard lengths referred to the dimensions of the human body (the Vitruvian Man, drawing by Leonardo da Vinci, dated to c. 1490). (Image: Public domain)

The approaches used to deal with the variability of length standards seem at times to have been remarkably modern. One oft-recounted definition of the "foot" as a standard of length was the average of the foot length of 16 randomly chosen men (see Fig. 4) (https://en.wikipedia.org/wiki/Foot(unit)):

> Stand at the door of a church on a Sunday and bid 16 men to stop, tall ones and small ones, as they happen to pass out when the service is finished; then make them put their left feet one behind the other, and the length thus obtained shall be a right and lawful rood to measure and survey the land with, and the 16^{th} part of it shall be the right and lawful foot.

The beauty and modernity of this definition lies in the recognition that random choice and averaging is likely to produce a more consistent result than a single realization of the definition using one's body.

More commonly, at least according to legend, the unit of length was based on the body of a particular person, typically the monarch. In ancient Egypt, the royal cubit was based on the bodily dimensions of the Pharaoh (https://www.bksv.com/en/knowledge/blog/perspectives/egyptian-cubit). The Pharaoh was not readily available for repeated measurements in the field, for the construction of pyramids, for example, so another rather modern approach was used – the creation of an artifact standard that represented the royal cubit, an artifact in stone, as shown in Fig. 5.

Another way to establish a consistent standard of length foreshadowed modern practice in a different way. The inch (1 ft = 12 in) was at one time defined to be the

Fig. 4 Foot length of 16 randomly chosen men. (Woodcut published in the book Geometrei by Jakob Kobel, Frankfurt, c. 1535) (Image: Public domain)

Fig. 5 A replica of the Royal Cubit of Amentop I, from the National Institute of Standards and Technology (NIST) digital archives (https://www.bksv.com/en/knowledge/blog/perspectives/egyptian-cubit). (Credit: NIST, USA Digital Archives)

length of three barleycorns (see Fig. 6) (https://en.wikipedia.org/wiki/Barleycorn (unit)).

The hope for such a definition was that nature itself would guarantee the consistency of the unit – an aspirational "natural constant." Unfortunately, whether due to variations in cultivation conditions, temperature, rainfall, or the like, the length of barleycorns was not reliably constant. (Interestingly, the barleycorn as a unit of length lives on as the difference between successive shoe sizes in some English-speaking countries (https://en.wikipedia.org/wiki/Shoesize).)

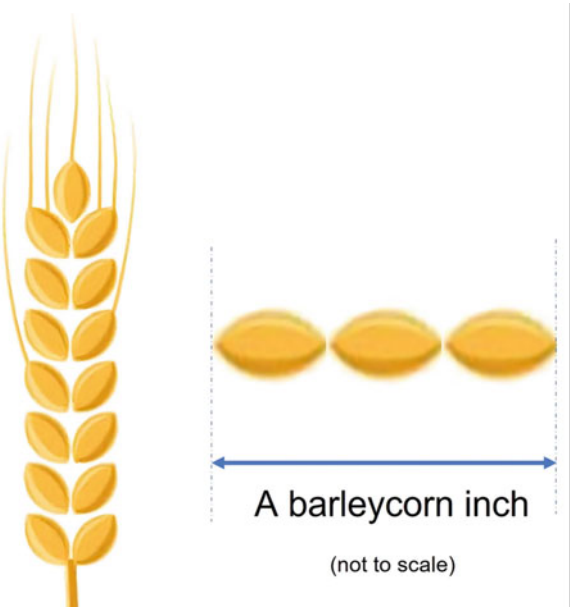

Fig. 6 Inch defined as the length of three barleycorns (https://workingbyhand.wordpress.com/2022/04/18/a-note-on-inches-and-feet)

Such seemingly modern approaches to length standards notwithstanding, it was the ancient approach of an artifact standard that became widespread. Figure 7 shows one such artifact, (literally) fixed in stone at the city hall of the German town of Regensburg, presenting what appears to be a rather generous realization of the fathom. Such artifacts provided clear, reliable, and, at least for the requirements of the day, stable standards of measurement. However, if one were to go to another town, one would typically find another such artifact, with no guarantee that the standard of length would be the same there as it was in Regensburg.

The French Revolution, whose beginning is often associated with the storming of The Bastille in 1789, engendered a spirit of reform that extended to the system of measurement units. The resulting Metric System of units was characterized not only by having the multiples and subdivisions of units by factors of 10, but by definitions of those units that would, at least in principle, be available "for all time, for all people." A commemorative medal containing that sentiment is shown in Fig. 8.

The allegorical creature using dividers to measure the earth evokes the new unit for length, the meter, and its definition, being one ten-millionth (10^{-7}) of the length of the meridian from the earth's pole to the equator (as the dividers are indeed placed), passing through Paris.

The meter was to be the measure of all things (Adler 2003). Not only was the meter and its multiples and submultiples to be the measure of all lengths, areas, and volumes, but it was also to form the basis for the new unit of mass, as we shall see below.

Fig. 7 Artifact imbedded in a wall. (Credit: David Newell; Reproduced by permission)

Fig. 8 Commemorative medal for the Metric System (http://monnaiesanciennes.free.fr/imageselsen104/MED-000576002dc.jpg). (Credit: *Direction Générale des Entreprises*, France)

In order to realize the definition of the new unit of length, two parties, led by astronomers Delambre (who went north from Paris) and Méchain (who went south), surveyed the meridian, measuring the length between Dunkirk and Barcelona, which by appropriate extrapolation gave the measure of the pole-to-equator meridian in the units of the Ancien Régime (or at least some version of it, since nonuniformity of such units was a major motivation for the metric reform).

Measuring the earth had been difficult, taking 7 years and involving many adventures and misadventures. It was not a task likely to be repeated very often. So, to preserve that hard-won measure of all things, an artifact was made, in the same spirit as the stone royal cubit of ancient Egypt. A platinum rod, end-to-end 1 m, was deposited in the Archives of France in 1799 (https://en.wikipedia.org/wiki/Metre). This "meter of the archives" is pictured in Fig. 9, and it became the defining artifact for the meter for France, and ultimately for an increasing number of countries that, in the following years, adopted the metric system.

In 1875, 17 countries met in Paris and adopted, as an international treaty, the *Convention du Mètre.* This treaty established the metric system as the measurement standard for those countries and created the International Bureau of Weights and Measures (*Bureau International des Poids et Mésure*s – the BIPM) as the repository of new artifacts of length and mass yet to be manufactured. The new International Prototype of the Meter was a "line standard" for which the distance between two scratches engraved into a Pt-Ir alloy bar (a distance made as close as possible to the length of the Meter of the Archives) became the standard of length for all those in the world who adopted the metric system (see Fig. 10).

The latter part of the nineteenth century, when the new meter bars were made, experienced a revolution in length metrology. Physicists in France and elsewhere had established that light was a wave phenomenon. Scientists like Babinet in 1827 and Maxwell in 1859 had earlier suggested that the wavelength of light would be a more suitable standard of length than either an artifact or the dimensions of the planet (p. 154 of Ref. (Quinn 2017)). Albert Michelson, the inventor of his eponymous interferometer was the first, with Benoît, to compare the wavelength of light to the

Fig. 9 The meter standard made of Platinum by Lenoir (1799) with its case; Photo Courtesy: National Archives of France (AE/I/23/10) & UNESCO Memory of the World Register, 2005

Fig. 10 Line standard meter. (Credit: NIST, USA Museum Collection)

International Prototype of the meter, in 1892 and 1893 (p. 154 of Ref. (Quinn 2017)). Subsequent improvements by Benoît with Fabry and Perot established optical measurement of length with an uncertainty, a few 100 nanometers, similar to the uncertainty in realizing the meter from the primary meter bar itself, with the definition of the meter being the distance between two engraved lines in a metal surface (p. 155 of Ref. (Quinn 2017)).

The ease with which length could be measured using optical interferometry meant that, soon, people were using the wavelength of light as a *de facto* standard. In fact, the wavelength (in air!) of the red light from a cadmium lamp, which had been used in the Michelson experiments and those that followed, was defined to be a certain number of angstroms, thus establishing a practical length scale that was independent of the length scale determined by the international prototype of the meter. (Today, the angstrom is exactly 10^{-10} m, but in the early part of the twentieth century, it represented a separate length scale to be used for spectroscopy (https://en.wikipedia.org/wiki/Angstrom).)

By the middle of the twentieth century, it was clear that the definition of the meter needed to be changed to reflect the widespread use of interferometry to measure length. There was much discussion about the best choice of a reference wavelength. While the red cadmium line had been in common use for some time, the spread of wavelengths due to the isotopic mixture was of concern. Eventually, the orange line emitted by ^{86}Kr was chosen, and in 1960 the General Conference on Weights and Measures adopted a new definition of the meter which defined the wavelength in vacuum of that spectral emission (see Fig. 11). This definition of the meter realized a dream expressed by, among others, Maxwell, who in the nineteenth century wrote: "...the most universal standard of length...would be the wavelength in vacuum of a

Fig. 11 Krypton lamp used for the realization of the meter as defined in 1960 by the CGPM (https://www.nobelprize.org/uploads/2018/06/advanced-physicsprize2005.pdf). (Credit: NIST, USA Museum Collection)

particular kind of light. . .” (Maxwell 1873). That same conference adopted the *Système International d’Unités* (the SI) as the official system of units, with the meter, kilogram, second, ampere, (degree) kelvin, and candela as its six base units. It was an auspicious year indeed, being also the year when the first laser was demonstrated.

The development of the laser foreshadowed the next, and we expect, the last change in the definition of the meter. Rapid developments in laser technology soon took laser light from the spectrally broad, pulsed output of the first flashlamp-pumped ruby laser to the spectrally narrow output of continuous-wave helium-neon lasers stabilized to absorption lines in a gas of molecular iodine. By the early 1980s, the wavelength of the I_2-stabilized He-Ne laser (See Fig. 12) had become the *de facto* standard of length, just as the wavelength of light from a cadmium lamp had become the *de facto* length standard earlier in the century. Metrologists were once again using a length standard that was not the SI standard, but which represented a

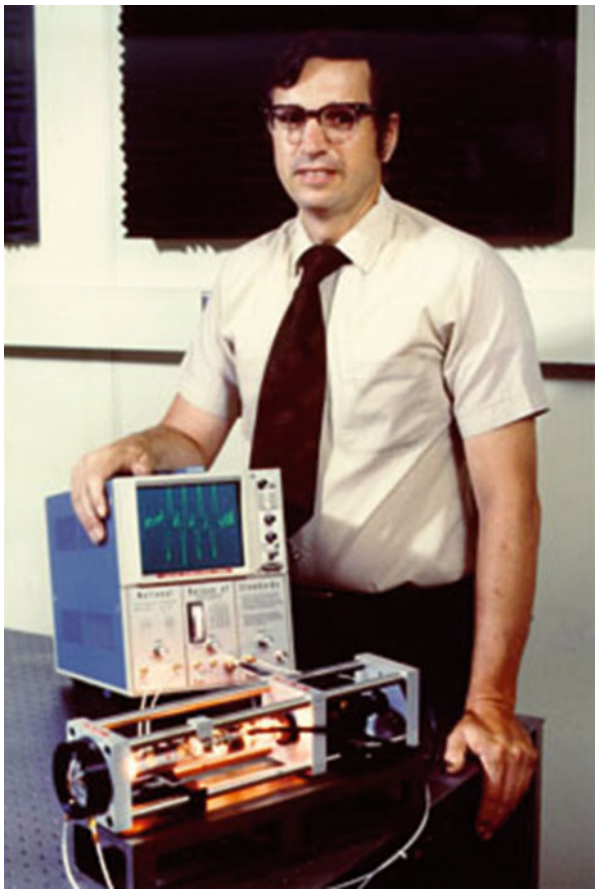

Fig. 12 An I_2-stabilized He-Ne laser (https://www.nist.gov/image-25845) with the spectrum of iodine absorption to which the laser is locked. Dr. Howard Layer is seen in the picture circa 1980 at NIST. (Credit: NIST, USA)

technology that had surpassed the capabilities of the official SI length standard. This same situation has recurred several times in the history of metrology.

The time had come again to redefine the meter. The obvious choice, following historical precedent, would have been to define the wavelength of some laser stabilized to some molecular or atomic transition, with the I_2-stablized He-Ne laser as the obvious candidate. Fortunately, the metrology community did not make the obvious choice, but rather a bold and beautiful choice, one that set the stage for a vast reform of the SI, accomplished in just the past few years. That beautiful choice was to define the speed of light.

This new definition of the meter, indeed this new approach to defining the meter, depended in large part on the development of another new technology – the measurement of the frequency of optical radiation. By means of frequency chains, whereby harmonics of microwave frequencies were used to lock the frequency of far-infrared lasers and those lasers were used to lock the frequencies of shorter

wavelength lasers, it was possible to determine the frequency of visible light with an accuracy at least as good as the accuracy with which optical wavelengths could be compared. Because of the universal relation: $c = f\lambda$, if one measures the frequency f of light, and if one defines the speed of light c, then the wavelength λ is known to the same accuracy as that to which the frequency is measured. The new definition of the meter, adopted by the CGPM in 1983, is that the meter is the distance traveled by light in a certain time, effectively fixing, exactly, the speed of light.

One of the beautiful features of this new definition is that future improvements in technology are automatically incorporated into the existing definition. In the past, the technology of optical interferometry made the International Prototype Meter obsolete. Then, the technology of lasers made the Krypton lamp obsolete. Now, improvements in lasers and improvements in the ability to measure optical frequencies will not necessitate any change in the new definition of the meter. In fact, such improvements have happened and were recognized in part by the award of the 2005 Nobel prize in Physics to John L. Hall and Theodor W. Hänsch (https://www.nobelprize.org/uploads/2018/06/advanced-physicsprize2005.pdf).

While the krypton definition of the meter had the advantage of being based on a constant of nature, that constant, being particular to a certain atomic species, was not, as it turned out, the best choice. Now, the definition of the meter is based on a fundamental or universal constant of nature, the speed of light. This reference to a fundamental constant is the heart of the beauty and the strength of the current definition of the meter. That achievement of 1983 has now, as of 2019, been brought to four other units of the SI. The most revolutionary of the changes of 2019 to the SI units is the change in the definition of the kilogram.

A Light History of Mass

As with standards of length, standards of mass have a long history. Figure 13 shows a set of weights or masses used in ancient Babylonia. Such sets of artifact weights or mass-standards were common throughout the ancient world and were often used to

Fig. 13 Artifact mass standards of ancient Babylonia (https://www.wikiwand.com/en/Ancient_Mesopotamian_units_of_measurement#Media/File:Mesopotamian_weights_made_from_haematite.JPG). (Credit: Geni; Reproduced under CC BY-SA 4.0)

verify the weight of precious metals of the sort that might be used in coinage. The problem with mass artifacts, as with the even more prolific length artifacts, was that they varied from place to place. At least in some cases, the standard of mass varied according to what sort of material was being weighed. In prerevolutionary France, for example, the livre (pound) used to measure the weight of bread was different from that used to measure the weight of metals (Adler 2003).

As with standards of length, the French revolutionaries determined to eliminate the inconsistency of mass standards by referring the new unit of mass, named the kilogram, to the newly minted standard of length, the meter. The kilogram was to be the mass of one cubic decimeter (a cube with 10 cm on each edge or one litre) of water. Originally, the water was to be at its freezing temperature, 0 °C, but the fact that water has a density maximum at 4 °C motivated the definition to be changed accordingly.

The kilogram definition had some obvious advantages. Being based on the new meter as the standard of length, it was consistent with the revolutionary ideal that the meter should be the measure of all things. Water was readily available, and at 4 °C, the density extremum, temperature variations were minimally perturbative. Nevertheless, it did not turn out to be very easy to realize the definition at the level of accuracy with which one could compare masses using a balance. So, as with the unit of length, whose definition based on the size of the earth was difficult to realize, the unit of mass was enshrined as an artifact. The Kilogram of the Archives, a platinum cylinder made to have the mass of one litre of water, as well as could be determined, was deposited in the Archives of France in 1799, just as the Meter of the Archives was. Figure 14 shows one of the authors of this chapter holding the 1799 Kilogram of the Archives, on a visit to that unheated institution in December of 2019.

The 1875 *Convention du Mètre* mandated the creation of a new standard of mass, to become the International Prototype of the Kilogram (IPK). Made of platinum-iridium, the IPK was chosen from among a number of nearly identical copies as the one whose mass was closest to the mass of the Kilogram of the Archives, insuring consistency of the definition upon the adoption of the new standard. The IPK itself, stored under three glass enclosures, open to the atmosphere, is shown in Fig. 15 and has only been taken out for comparison to the working standards a few times since its creation. The working standards have been used from time to time to compare against the national standards distributed to the signatories of the *Convention du Mètre.* All of these kilograms were made at the same time and in the same way so that they are nominally identical except for slight differences in mass, differences that were measured at the time.

While various copies of Pt-Ir kilograms can be compared to one another with a precision on the order of a microgram (a part in 10^9), differences between copies vary over time by tens of micrograms. Figure 16 shows the time variation of a subset of kilogram copies relative to the IPK. Variation of tens of micrograms (parts in 10^8) is typical, and variations of more than a hundred micrograms sometimes occur.

This situation, where time variations of various standard kilograms, all nominally identical, can be many times the precision with which kilograms can be compared, is clearly intolerable. Because the various copies are nominally identical, it is

Fig. 14 William D Phillips holding the case containing the 1799 Kilogram of the Archives, at the Archives of France, in December of 2019

impossible to assert that the IPK, the standard of mass in the SI, is not changing. In fact, an examination of Fig. 16 would lead one to conclude that the IPK is probably changing by tens of micrograms. On the other hand, the "mass" of the IPK cannot change, because, by definition, it is always 1 kg. Presumably the masses of the various Pt-Ir kilograms vary because surface or other contaminants change over time, and change differently in the different copies. Because there is no mass standard that can be guaranteed to be more stable than the IPK and its copies, there is in practice no way of knowing which of the kilograms is changing by how much or in what direction.

Standardized cleaning techniques were established in an attempt to address the apparent change in mass with time, but different (nominally identical) kilogram copies responded differently to such cleaning, compounding the uncertainty about what is meant by a kilogram. (See Fig. 17.1 on p. 343 of Ref. (Quinn 2012), and also (Davis 2003).)

It became clear that the kilogram needed to be redefined, and that redefinition should, by preference, be in the same spirit as the redefinition of the meter. That is, the kilogram should be defined by choosing a fixed value of some constant of nature. To see what that constant might be, consider the equation $E = mc^2$. The meaning of this equation is that E is the energy of an object of mass m at rest. Now consider the equation $E = \hbar\omega$, where $\hbar$ is the reduced Planck constant. The meaning of this

Fig. 15 The international prototype kilogram and its six official copies in a safe at the BIPM (Davis 2003). (© BIPM and IOP Publishing Ltd. Reproduced by permission of IOP Publishing. All rights reserved)

equation is that E is the energy of a single photon of light having frequency ω. If we combine these two equations, we find $E = mc^2 = \hbar\omega$, so that $m = \hbar\omega/c^2$.

The apparent meaning of this final equation is that if an object were to emit a single photon of frequency ω, its mass would change by m. Since we have fixed c in defining the SI meter, and since we have (see above) long ago fixed the frequency of the cesium hyperfine interval in defining the SI second, if we now fix the value of the Planck constant h, we have, at least in principle, a way to define the kilogram via the change in mass of an object that emits a photon of known frequency. In practice the process of thus "weighing" a photon is not currently good enough to form the basis of realizing the new definition of the kilogram better than several parts in 10^7 (Rainville et al. 2005). Fortunately, two other methods exist that allow a sufficiently good realization of the kilogram definition based on choosing a fixed value for h: the

Kibble balance and the X-ray crystal density (XRCD) method (Taylor and Mohr 1999; Mills et al. 2005, 2011; Possolo et al. 2018; Wood and Bettin 2019).

Kibble Balance Method to Realize the Kilogram

In 1975, Bryan Kibble of the UK National Physical Laboratory introduced the idea behind what we now call the Kibble balance or the Watt balance (Kibble 1975). It was originally seen as a way to realize the definition of the SI ampere, or, equivalently, to determine the relationship between a legal, national, definition of the ampere and the SI ampere. The SI definition was: *The ampere is that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross-section, and placed 1 m apart in vacuum, would produce between these conductors a force equal to* 2×10^{-7} *newton per meter of length.*

Note that this definition is equivalent to fixing the vacuum magnetic permeability as $\mu_0 = 4\pi \times 10^{-7}$ N/A^2. So the SI definition of the ampere, which predated the official establishment of the SI, had already adopted the practice of defining a base unit in a way that fixed the value of a natural constant before this was done for the SI second and well before the recent (May 2019) reform of the SI where all the base units are so defined.

The "legal" or "national" definition of the ampere, mentioned above, existed because of the difficulty in realizing the SI definition. Originally (before the discovery of the Josephson effect and the integer quantum Hall effect), the legal definition of the ampere was that current which would produce a voltage drop of one "legal volt" across a resistance of one "legal ohm." The legal volt was set by assigning a voltage to the average of an ensemble of standard cells (electrochemical voltage

sources), and the legal ohm was set by assigning a resistance to the average of an ensemble of wire-wound resistors. Each major national metrology institute would have its own set of standard cells and resistors. The values assigned to these standard cells and resistors were as close as possible to their SI values.

With the advent of the Josephson and quantum Hall effects, the legal volt and ohm were replaced by fixing the (legal) values of $2e/h$ and h/e^2 in units of hertz per (legal) volt and (legal) ohms. In 1990, the international metrology community agreed upon fixed values for these constants, chosen according to the best known SI values, but they were not in fact the SI values. This eliminated the time variation of legal electrical units and differences from one nation to another. As we will see below, the measurement of current, voltage, and resistance in this way is crucial to the realization of the kilogram with the new definition using the Kibble balance.

Consider now the realization of the SI ampere. One cannot directly realize a definition involving infinitely long wires, so in practice one makes coils, determines their dimensions and locations, and measures the force between the coils when they are energized with current measured in legal/national units. The measurement of the force along with the relevant dimensions gives the current in SI units, and thus one determines the ratio of the legal and SI amperes. A severe problem is that the measurement of dimensions of the current-carrying coils is difficult (one must know the location of every part of every wire). It is this difficulty that Kibble's method addresses.

A schematic diagram of the apparatus is in Fig. 17. The measurement is done in two phases. In one, called the weighing mode, a current I is passed through the coil

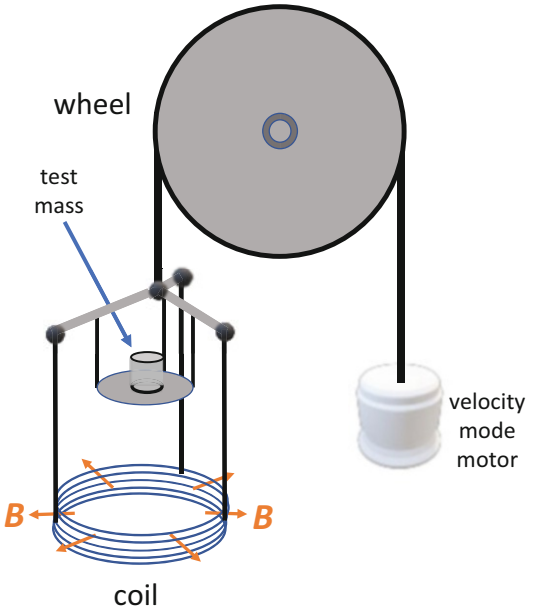

Fig. 17 Schematic diagram of a Kibble balance. (Image: Public domain)

that is suspended from a wheel that is free to turn. The coil is in a radial magnetic flux density B produced by a permanent magnet, and the current is adjusted to provide an upward Lorentz force that balances the force of gravity mg on the test mass. The local acceleration of gravity g is separately measured. The electrical force is ideally IBL, where L is the length of the wire in the coil, so that

$$mg = IBL \tag{1}$$

The product BL depends on the details of the coil winding and the strength of the magnetic field, both of which are difficult to determine accurately. To address this, there is a second phase of the measurement called the velocity mode in which the coil is slowly driven up and down with a velocity v by the velocity mode motor. This produces a potential difference V between the ends of the coil according to Faraday's law, given by

$$V = vBL \tag{2}$$

Elimination of the troublesome product BL between Eqs. (1) and (2) yields

$$m = \frac{IV}{vg} \tag{3}$$

This equation can be written as $mgv = IV$, equating mechanical and electrical power in watts, which is why the Kibble balance was previously known as the watt balance. Moreover, the two-phase nature of the measurement eliminates both mechanical and electrical energy losses. However, Eq. (3) as a way to realize a new definition of the kilogram lacks any reference to the Planck constant, which we say above is the heart of the definition. The Planck constant comes in because of the way that current and voltage are measured using the Josephson effect and the quantum Hall effect. Voltages are measured relative to the Josephson constant $2e/h$ while currents are measured in terms of the voltage across a resistor measured relative to the von Klitzing constant h/e^2. The units of V are proportional to $h/(2e)$ (volts/hertz) while the units of resistance are proportional to h/e^2 (ohms). The current I, measured as voltage divided by resistance is proportional to $(h/2e)/(h/e^2)$, so the unit of mass is proportional to $(h/2e)^2/(h/e^2) = h/4$, that is, m is proportional to h (among other things), but is independent of e.

This explains how fixing the value of h allows a realization of the new definition of the kilogram. The actual process is, naturally, rather complex (Olsen et al. 1980, 1989; Kibble et al. 1983; Robinson and Schlamminger 2016; Thomas et al. 2017; Wood et al. 2017; Ahmedov et al. 2018; Li et al. 2019; Schlamminger and Haddad 2019; Kim et al. 2020; Fang et al. 2020). It is, in fact, far more complex than the realization of the old definition, which simply involved comparing masses to the mass of the IPK. Figure 18 shows a Kibble balance apparatus at the National Institute

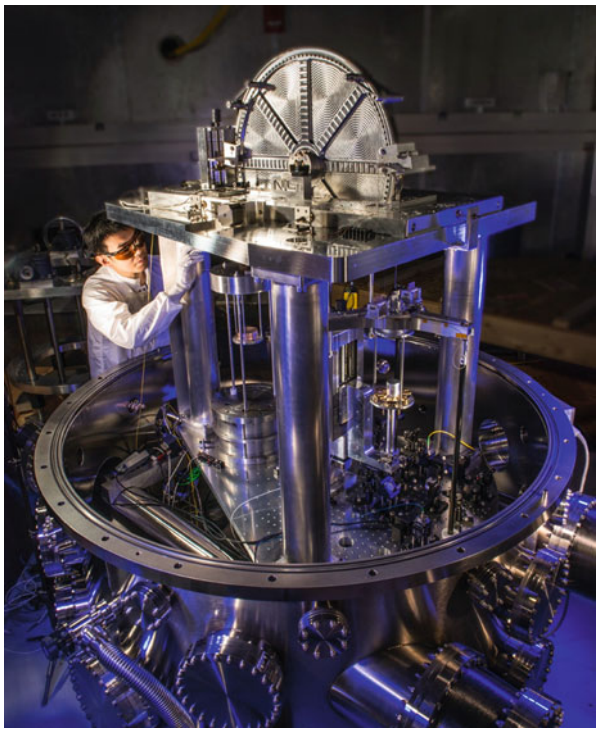

Fig. 18 A Kibble balance at the National Institute of Standards and Technology. The wheel at the top of the image can rotate, allowing the vertical translation of a suspended coil. It also acts as a balance to determine the electromagnetic force on that coil. (Credit: NIST, USA Digital Archives)

of Standards and Technology that is capable of realizing the new definition of the kilogram to parts in 10^8.

Before the redefinition, the relation between the Planck constant and the mass used in the Kibble balance meant that when a known mass was used, the experiment provided a value for the Planck constant. After the redefinition, the roles of the mass and the Planck constant were reversed so that a known value for the Planck constant meant that the Kibble balance experiment was a measurement of the mass.

Silicon Sphere Method to Realize the Kilogram

The basic idea of this method, enabled by fixing the value of h, is to determine, by some means, the mass in kilograms of a single atom of silicon, and also to determine the number of silicon atoms in a crystal of silicon, yielding the mass of that sample of silicon.

This approach to realizing the kilogram has its origins in the Avogadro project (Azuma et al. 2015; Newell et al. 2018). The original goal of that project was to determine the Avogadro constant by measuring the number of atoms in a known mass (known in terms of the IPK) of ^{28}Si. That number, along with the molar mass of

^{28}Si (determined by well-established mass comparison techniques) and the atomic mass unit in kilograms gives N_A, the Avogadro constant. The heart of the Avogadro project is the X-Ray Crystal Density (XRCD) method, which involves making a nearly perfect silicon sphere from a nearly perfect crystal of nearly isotopically pure ^{28}Si, and measuring the dimensions of that sphere, as well as measuring the lattice constant of that perfect crystal (see Figs.19 and 20) (Azuma et al. 2015; Deslattes 1969; https://newscientist.com/article/dn14229-roundest-objects-in-the-world-created/).

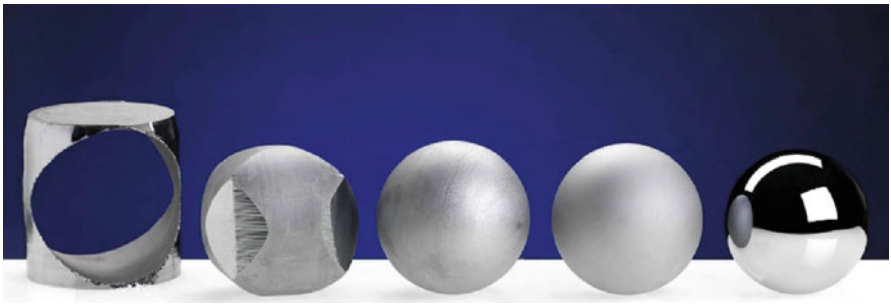

Fig. 19 Steps in the process of manufacturing a near-perfect silicon sphere, from single-crystal boule to finished, polished sphere (Meeβ et al. 2021). The creation of a near-perfect silicon sphere begins with the growing of a suitably large perfect crystal of isotopically pure (enriched) ^{28}Si, using the crystal growth techniques developed over many years by the semiconductor industry for producing silicon chips from large wafers of single-crystal silicon. The grown crystal is then fabricated into a nearly perfect sphere through a process of sequential cutting, polishing, and measuring. The measurement process is performed interferometrically, and the final sphere is round to within some tens of nm with a surface roughness better than a nm. The deviation from sphericity reflects the underlying crystal structure. (Credit: Rudolf Meeß et al. 2021 Meas. Sci. Technol. 32 074004; CC-BY IOP Open Publishing)

Fig. 20 A finished silicon sphere (https://newscientist.com/article/dn14229-roundest-objects-in-the-world-created/). (Credit: CSIRO)

Before the redefinition, the measurement of N_A also provided a value for h, because there is a relation $N_A h = C$, where C is an accurately known combination of constants, including the Rydberg constant and the fine-structure constant, so that measuring either h or N_A effectively determines the other (see Sec. 5 in Mohr 2008a).

With the establishment of the techniques of the Avogadro project, it became possible to invert the goal of the project and imagine a definition of the kilogram based on fixing the value of N_A, although this was not the approach finally taken. Fixing the value of the Planck constant h also allows the redefinition of the kilogram using the XRCD methods of the Avogadro project because the mass in kilograms of a silicon atom is well known once the value of h is fixed.

There are two ways in which the Si mass can be determined. First: with h fixed, the electron mass in kilograms is known from the Rydberg constant and the fine-structure-constant with an uncertainty of parts in 10^{10} (Tiesinga et al. 2021). The ratio of the electron mass to the mass of ^{12}C is determined with an uncertainty of parts in 10^{11} by comparing the electron spin flip frequency of hydrogen-like $^{12}C^{5+}$ to the cyclotron frequency of $^{12}C^{5+}$ in the same magnetic field (Köhler et al. 2015). The ratio of ^{12}C and ^{28}Si masses is known to parts in 10^{11} (Huang et al. 2021; Wang et al. 2021). This chain of measurements gives the mass in kilograms of a silicon atom with an uncertainty of parts in 10^{10}, much better than the parts in 10^8 uncertainty of measurements on the silicon sphere.

Second: With h and c fixed, the recoil velocity $\hbar\omega/mc$ of a Rb (or a similar species like Cs) atom receiving the momentum of an optical photon of frequency ω gives the mass of an Rb atom in kilograms. This velocity measurement, using atom interferometric determination of the Doppler shift associated with the recoil velocity, gives the mass in kilograms of Rb to parts in 10^{10} (Weiss et al. 1993; Browaeys et al. 2005; Cladé et al. 2019; Yu et al. 2019; Morel et al. 2020). With the known ratios of atom masses good to parts in 10^{11} (Huang et al. 2021; Wang et al. 2021), the silicon mass is known to parts in 10^{10} and can be used directly with the XRCD measurements to determine the mass of a silicon sphere.

While it is tempting to think of the silicon sphere as simply another example of an artifact kilogram, it is not that at all. The artifact IPK is a unique object, and independent of a comparison to that object one would not be able to fabricate a replica. With a fixed value assigned to h, one can use the process described to make a kilogram of silicon, without reference to any artifact mass standard.

One of the appealing aspects of the new definition of the kilogram is that it only specifies the value of h, not the technique by which, given that value of h, one would realize the definition. There is no priority given to either the Kibble balance or the silicon sphere method of realizing the kilogram. Only when both methods were in sufficient agreement was the final decision made to adopt the new definition. As of this writing (late 2023) the performances of both methods are similar (a few parts in 10^8) and improvements are expected in both. The new definition puts an end to the unknown and unknowable changes in the standard of mass that had plagued mass metrology since the inception of the IPK.

The Current Story of the Ampere

As mentioned above, the old definition of the ampere, involving the forces between current-carrying wires, has been difficult to implement with high accuracy, which led to the institution of a different, non-SI set of electrical units, the "legal" electrical units. Early in the twentieth century, these legal units were different in each major National Metrology Institute and involved ensembles of electrochemical standard cells to represent the legal standard of voltage and ensembles of wire-wound resistors to represent the legal standard of resistance. Given such legal standards for the ohm and volt, one could realize a legal ampere as the current which produced a voltage of a legal volt fixed across a legal ohm. In 1990, the worldwide metrology community adopted conventional, fixed values of the Josephson constant $2e/h$ and the von Klitzing constant h/e^2 as defining constants for legal electrical metrology (Taylor and Witt 1989). That system existed in parallel to the SI electrical units based on the mechanical definition of the ampere, with the SI values of $2e/h$ and h/e^2 continuing to be measured quantities while the legal values of those constants remained fixed.

With the SI value of h being fixed in order to redefine the kilogram, it is natural to also fix the SI value of the elementary charge e. This defines the ampere, a coulomb/second, as being the current of a certain number of electrons per second, that number being the inverse of the electron charge in coulombs. While in principle one could count electrons, the technology for doing that is at the moment insufficient for the required accuracy and precision for realizing the SI ampere. Instead, one does exactly what was done for the legal ampere, except that now the fixed and exact values of $2e/h$ and h/e^2 are SI values and one realizes the SI ampere. This means that one no longer needs the old "legal" system of electrical units because one has exact SI values of the Josephson and von Klitzing constants. At various times after the 20 May 2019 adoption of the reformed SI, various countries switched their legal electrical metrology from the old 1990 values to the new SI values, so that there is no longer any distinction between the SI and legal electrical units.

In every case of changing the SI definition of a unit of measure, the new definition was chosen to be within the uncertainty of the old definition. That is, with a definition based on fixing the value of a constant of nature like h or e, that fixed value is within the uncertainty of the best measurement of that constant before the change in definition. In this way, the transition from one definition to another is seamless and invisible to even the most demanding metrologist. This is not the case for the system of legal electrical units. Because electrical measurements had advanced significantly between 1990, when the legal values of $2e/h$ and h/e^2 were chosen, and 2018, when the SI values of those constants were chosen, there was an abrupt jump in the legal electrical units when each country made its legal units consistent with the SI. Those jumps amounted to about 1.1×10^{-7} for the Josephson constant and 1.8×10^{-8} for the von Klitzing constant.

As noted in section "Kibble Balance Method to Realize the Kilogram," before the redefinition, the definition of the ampere in terms of parallel conductors had the consequence that the vacuum magnetic permeability μ_0 was exact. Moreover, the

vacuum electric permittivity, $\epsilon_0 = 1/(c^2\mu_0)$, was also exact. Since the redefinition, neither of these constants is exact, but rather determined by experiment through their relation to the fine-structure constant α, which is given by

$$\alpha = \frac{e^2}{4\pi\varepsilon_0\hbar c}$$

The fine-structure constant is the dimensionless constant that characterizes the strength of electromagnetic interactions. It is accurately known (parts in 10^{10}), and being dimensionless, it cannot be affected by any redefinition of units. Before the redefinition $e^2/\hbar$ was determined by the value of α, because both ϵ_0 and c were exact. After the redefinition, since both e and $\hbar$ are exact, the value of ϵ_0 is determined by the value of α. Before the redefinition, even though the ratio $e^2/\hbar$ was precisely determined, values of e and $\hbar$ were less precise individually.

The Rest of the Base Units: The Kelvin, Mole, and Candela

Here we briefly summarize the effect of the redefinition of the SI on the rest of the seven base units of the SI – the kelvin, mole, and candela. Resources for additional information include Ref (Moldover et al. 2016; Guttler et al. 2019; Sperling and Kűuck 2019). For more details about these units, the reader is referred to chapters of this volume on temperature (Chap. 11, "Quantum Definition of New Kelvin and Way Forward"), mole (Chap. 13, "The Mole and the New System of Units (SI)"), and candela (Chap. 12, "Realization of Candela"), which deal with them.

In the past, the kelvin, the SI unit of thermodynamic temperature, was 1/273.16 of the temperature of the triple point of water. In principle, ideal gas thermometers could be used, along with this definition, to measure temperatures in units of the kelvin. Moreover, based on this definition, the value of the molar gas constant R could be determined by measuring acoustic resonant frequencies of a gas, such as argon or helium, in a cavity. The frequencies depend on the speed of sound in the gas, which in turn is related to R. The Boltzmann constant k is related by $k = R/N_A$, where the Avogadro constant N_A was more accurately known than either k or R. As a result, the value of the Boltzmann constant was best determined by the frequency measurements of R.

In the new SI, this relationship is turned around, and the kelvin is defined by fixing the value of the Boltzmann constant as $k = 1.380649 \times 10^{-23}$ J/K. This, together with the exactly defined value of N_A, yields an exact value for $R = kN_A$. As with all of the unit redefinitions, the fixed value of k was chosen to be the best measured value before the redefinition. One of the effects of the redefinition is that the triple point of water is no longer, by definition, 273.16 K. Operationally, it is the same kinds of measurements using acoustic gas thermometers that may be used to realize the kelvin under the redefined SI. However, the spirit of the new definition is significantly different. The kelvin now has a distinctly microscopic, atomic flavor, in contrast to the macroscopic nature of the old definition. In principle, with the value

of k fixed, one could determine the temperature of an atomic gas by measuring the velocity distribution of the constituent atoms, and hence their mean kinetic energy. At present, such measurements are not the best way to determine temperature, but one can imagine that the new definition will encourage the further development and improvement of such measurements, which would cement both the spirit and practice of considering temperature as a microscopic property (Darquié et al. 2013).

The old definition of the mole was that a mole is the amount of substance having as many elementary entities as there are ^{12}C atoms in 12 g of ^{12}C. That number of entities is N_A, the Avogadro constant. In the old SI, the value of N_A was measured using the techniques described above for the silicon sphere method of realizing the kilogram. In the new SI, the mole is redefined by fixing the value of the Avogadro constant. One of the implications of this redefinition is that a mole of ^{12}C is no longer, by definition, exactly 12 g of ^{12}C, but instead is a measured quantity. It is worth noting that this change in the definition uncouples the mole from the kilogram. Without this uncoupling, there would be two different definitions of the kilogram which would be an inconsistency in the SI.

While the mole and kelvin have new definitions in the revised SI, and these definitions have a different, more microscopic and quantum, spirit than did the old definitions, for the immediate future the experimental methods involving these units will remain essentially the same.

The definition of the unit of luminous intensity, the candela, is unchanged by the redefinition of the SI, but it is now expressed in a manner that fixes the value of a constant of nature. The previous definition was that *"The candela is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency* 540×10^{12} *hertz and that has a radiant intensity in that direction of 1/683 watt per steradian."* The current, and completely equivalent definition is: *"The luminous efficacy of monochromatic radiation of frequency* 540×10^{12} *Hz,* K_{cd}*, is* 683 *lm/W."* Luminous efficacy describes how bright light appears to the human eye. While it is not in principle a "constant of nature" in the way that the speed of light is, it has been found to be reasonably constant across the range of demographic groups and so is useful for comparing the effectiveness of various light sources.

Conclusion

On 16 November 2018, in Versailles, France, a group of 60 countries comprising the CGPM made history with a unanimous vote, agreeing to redefine the SI in a profound way to take effect on 20 May 2019. The festive event celebrated scientists' fulfillment of the long-standing dream of a measurement system based entirely on unchanging fundamental properties of nature. The spirit of the day can be seen in Fig. 21, where five of many authors of papers that contributed to the change are seen toasting the successful vote.

The redefinition by the assignment of fixed values to a set of defining constants completely specifies the measurement system in a simple way. In fact, quoting from the SI Brochure, the document that provides the official basis for the SI, the complete

Fig. 21 Celebration of the redefinition of the SI at Versailles: l. to r., Ian Mills, OBE, FRS, former President of the *Comité Consultatif des Unités*, to whom this chapter is dedicated; Terry Quinn, CBE, FRS, Emeritus Director of the BIPM; Barry Taylor, NIST; Peter Mohr, NIST, one of the authors of this chapter; and Edwin Williams, NIST. (Credit: NIST, USA)

definition of the SI system of units is given by the brief listing of constants, exactly as shown here (https://www.bipm.org/en/publications/si-brochure):

"The International System of Units, the SI, is the system of units in which

- **The unperturbed ground state hyperfine transition frequency of the cesium 133 atom, $\Delta\nu_{Cs}$, is 9 192 631 770 Hz.**
- **The speed of light in vacuum, c, is 299 792 458 m/s.**
- **The Planck constant, h, is 6.626 070 15 $\times$ 10^{-34} J s.**
- **The elementary charge, e, is 1.602 176 634 $\times$ 10^{-19} C.**
- **The Boltzmann constant, k, is 1.380 649 $\times$ 10^{-23} J/K.**
- **The Avogadro constant, N_A, is 6.022 140 76 $\times$ 10^{23} mol^{-1}.**
- **The luminous efficacy of monochromatic radiation of frequency 540 $\times$ 10^{12} Hz, K_{cd}, is 683 lm/W.**

where the hertz, joule, coulomb, lumen, and watt, with unit symbols Hz, J, C, lm, and W, respectively, are related to the units second, meter, kilogram, ampere, kelvin, mole, and candela, with unit symbols s, m, kg, A, K, mol, and cd, respectively, according to Hz = s^{-1}, J = kg m^2 s^{-2}, C = A s, lm = cd m^2 m^{-2} = cd sr, and W = kg m^2 s^{-3}."

There it is, the definition of the SI in one sentence. Of course, additional information is needed to implement the definitions, as described in the preceding sections. However, as technology evolves, enabling more precise measurements, there will be no need to change the definitions, with the exception of the particular frequency used to define time, as mentioned in section "A Brief History of Time

(with Our Apologies to the Late, Great Stephen Hawking (Hawking 1988))." But the form of the definition will not need to change.

Numerical values for the constants *h, e, k,* and N_A in the list are based on the results of measurements up to the time of the 107th meeting of the *Comité international des poids et mesures* (CIPM) or the International Committee for Weights and Measures, which met in June 2018 and recommended the redefinition of the SI to the CGPM for consideration at its meeting in November, 2018. The CIPM had earlier requested that the Committee on Data for Science and Technology (CODATA) Task Group on Fundamental Constants carry out a survey and least-squares adjustment to determine the best current values for consideration at their meeting (Newell et al. 2018; Mohr et al. 2018). The other three constants in the list were not changed by the redefinition, although the wordings of the corresponding definitions were modified.

As is evident in the list of values of the SI defining constants, the definitions apply to combinations of the traditional base units of the earlier SI. For example, the definition of c relates the combination of units m/s to a physical phenomenon, namely, the invariant speed of light in vacuum, and the definition of h determines the combination kg m^2/s or J/Hz. The constants have been chosen to determine combinations of units so that all of the traditional base units are defined (Mohr 2008b). As a result, it is no longer necessary to single out base units, as was previously the case because they were defined individually. Here we summarize some features of the redefinition.

- For the kilogram, variations of the mass of an artifact are eliminated, along with the possible associated drift of the definition of the kilogram. Also, the artifact kilogram no longer has the mass of exactly 1 kg.
- Accurate electrical measurements in terms of the Josephson effect and the quantum Hall effect are now directly based on SI units because h and e are exactly defined in the SI. The constants μ_0 and ϵ_0 are no longer exact, although very precise, and still satisfy the relation $\mu_0\epsilon_0 c^2 = 1$.
- The new definition of the mole specifies the exact number of entities in a mole, rather than indirectly specifying it as the number of entities in 12 g of ^{12}C. Now, the molar mass of ^{12}C is not exactly 12 g.
- The Boltzmann constant is exactly defined and is no longer based on the triple point of water, which is affected by the purity and isotopic composition of the water being used as the standard. The triple point of water is no longer exactly 273.16 K.
- Besides the fact that four important fundamental constants have become exact, other physical constants are also either exact or have substantially reduced uncertainties. Important among these are energy-equivalence relations between the joule, volt, hertz, and kelvin, all of which are now exact.

To conclude, we note that the idea of using fundamental constants in equations of physics to define measurement scales has a long history. Many scientists considered finding a suitable set of constants, such as the set c, $\hbar$, e, and m_e, for example. People who contributed in this pursuit include Gauss, Maxwell, Stoney, Planck, Fleming,

Hartree, and others (Tomilin 1998). However, in general, it was found to be more practical to use artifacts to define measurement standards. It is only relatively recently that technology has progressed to the point that it has become a practical reality to apply the laws of physics using fixed values of the constants to define a complete measurement system. The turning point came in 2018 when it was decided that the last artifact, the International Prototype of the Kilogram, could be replaced by mass determinations based on the Kibble balance and silicon spheres to redefine the SI.

Abstract

The new definition of the kilogram was implemented on May 20, 2019. The kilogram is now defined by fixing the value of the Planck constant. In principle, national metrology institutes can realize the kilogram from the Planck constant individually to establish their primary mass standards. The Planck constant is related to a mass of 1 kg by the X-ray crystal density method. This method can be therefore used to realize the kilogram by the new definition. As an example of such realization using this method, the realization experiment at the National Metrology Institute of Japan is introduced. For this realization, the volume of a 1 kg ^{28}Si-enriched sphere is measured by optical interferometry. The

Introduction

Humans have been trying to understand this world by developing diverse measurement technologies. For seamless sharing of measurement results around the world, the international measurement scale is provided by the International System of Units (SI) (BIPM 2019), and the most advanced technologies in each era have been used to define units in the SI to establish more reliable measurement scales. The SI is not eternal and continues to evolve with the development of science and technology. The kilogram is at the core of the SI, and its definition was also fundamentally revised taking advantage of state-of-the-art technologies in 2019 (Stock et al. 2019, Kuramoto et al. 2020, Kuramoto 2021, 2022).

The origin of the kilogram dates back to the end of the eighteenth century. The original concept was based on the mass of 1 dm^3 of water and was materialized in a cylinder of platinum in 1799. Platinum was chosen to make the cylinder chemically stable and resistant to rust. In 1889, this artifact was replaced by a cylinder made of an alloy of 90 % platinum and 10 % iridium prepared by a state-of-the-art metallurgical technology at the time. This alloy is harder and less likely to wear than pure platinum. This new artefact is known as the international prototype of the kilogram, and the kilogram was defined as the mass of this artifact (Fig. 1), which was stored at the Bureau International des Poids et Mesures (BIPM, France). Its copies were distributed to the signatories of the Meter Convention and were used as their national prototypes, leading to the worldwide unification of the mass scale.

By definition, the mass of the international prototype of the kilogram was exactly 1 kg without any uncertainty associated. In practice, however, the mass of this – and in fact any – artefact cannot be perfectly stable. One hundred years after its manufacture, the long-term stability of the mass of the international prototype of the kilogram was estimated to be several tens of micrograms (Girard 1994, Kuramoto 2021), and its inevitable instability casts a shadow on the accuracy of the international mass scale.

To overcome this issue, the Planck constant was proposed as the new basis of the kilogram because, to the best of our present knowledge, it is invariant in time and space. The unit of the Planck constant is J s, which is equal to kg m^2 s^{-1}. The meter has been defined by fixing the numerical value of the speed of light since 1983, and the second has been defined by fixing the numerical value of the cesium frequency since 1967 (BIPM 2019). Consequently, assigning a fixed numerical value to the Planck constant has the effect of redefining the kilogram. Moreover, the Planck

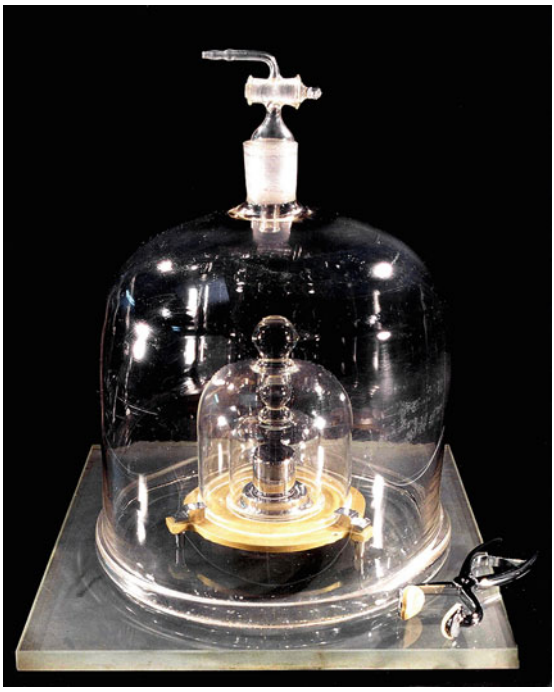

Fig. 1 International prototype of the kilogram enclosed by three bell jars: This cylindrical weight made of a platinum–iridium alloy is kept at the Bureau International des Poids et Mesures (BIPM) in Sèrves, France. The diameter and height are both approximately 39 mm. (Photograph courtesy of the BIPM)

constant can be practically related to a mass of 1 kg by two different methods. One is the X-ray crystal density (XRCD) method (Kuramoto et al. 2020), which counts the number of silicon atoms in a 1 kg single-crystal silicon sphere. The mass of the sphere is then determined from the mass of a silicon atom and the number of atoms. Because the atomic mass can be derived using the Planck constant with the help of other physical constants, this method relates the sphere mass to the Planck constant. The second method is to use the Kibble balance (Robinson and Schlamminger 2016), in which the gravitational force acting on a 1 kg weight is balanced with the electromagnetic force. The electromagnetic force is measured using quantum electrical standards based on the Planck constant. Thus, the mass of the weight is related to the Planck constant by measuring the gravitational acceleration.

In the 2010s, the time was ripe to redefine the kilogram. The two methods were improved by worldwide cooperation between national metrology institutes (NMIs) (Kuramoto 2021), leading to measurements of the Planck constant h based on the mass of the international prototype of the kilogram with uncertainties superior to the long-term stability of the artefact itself. In 2017, the h value for the new definition of the kilogram was determined by the Task Group on Fundamental Constants of the Committee on Data for Science and Technology (CODATA TGFC) from the eight values of h measured using the two methods (Newell et al. 2018). The eight data values used by the task group are summarized in Table 1 and Fig. 2. IAC-11, IAC-15, IAC-17, and NMIJ-17 were measured by the XRCD method (Azuma et al. 2015, Bartl et al. 2017, Kuramoto et al. 2017b). NIST-15, NIST-17, NRC-17,

[a] Data name given in the CODATA 2017 Special Adjustment of the Fundamental Constants (Newell et al. 2018)

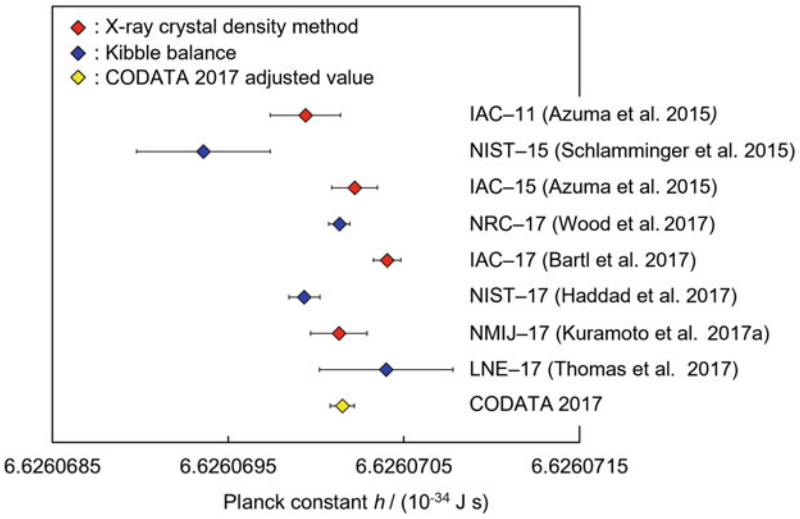

Fig. 2 Eight key data values used to determine the CODATA 2017 adjusted value of the Planck constant (Kuramoto 2021). The numerical value of the CODATA 2017 adjusted value is used in the new definition of the kilogram. A complete list of input data in the CODATA 2017 adjustment is provided by Newell et al. (2018) and Mohr et al. (2018)

and LNE-17 were measured using the Kibble balances (Schlamminger et al. 2015, Haddad et al. 2017, Wood et al. 2017, Thomas et al. 2017). The h value determined by the task group is known as the CODATA 2017 adjusted value and is $6.626\ 070\ 150(69) \times 10^{-34}$ J s, with a relative standard uncertainty of 1.0×10^{-8}. At present, the kilogram is defined by fixing the value of h to $6.626\ 070\ 15 \times 10^{-34}$ J s. This new definition came into effect on May 20, 2019.

In principle, it is now therefore possible for NMIs to realize the kilogram individually from the Planck constant to establish their primary mass standards. However, as of May 2022, all NMIs disseminate mass standards not from their own individual realization experiments but from the consensus value of the kilogram to avoid any possible international inconsistency among mass measurements (Davidson and Stock 2021). The consensus value is an agreed common basis to ensure the international equivalence of mass standards. As of May 2022, the consensus value is 1 kg – 2 μg with a standard uncertainty of 20 μg. The mass of the international prototype of the kilogram is not exactly 1 kg but 1 kg – 2 μg on the basis of the consensus value. NMIs still use their national prototypes of the kilogram as primary mass standards, and the relationships between the national prototypes and the international prototype are known. The masses of the national prototypes are therefore traceable to the Planck constant through the consensus value. The consensus value will be updated after each international comparison of the realizations of the kilogram by NMIs organized by the Consultative Committee for Mass and Related Quantities (CCM) scheduled to take place every 2 years. After the consistency of the realization results from a sufficient number of individual realization experiments is achieved, NMIs can provide mass standards directly traceable to their own realization experiments. Criteria for the transition from the internationally coordinated dissemination with the consensus value to the dissemination from the realizations by NMIs are described by CCM (2019).

The National Metrology Institute of Japan (NMIJ) is the NMI of Japan. After the use of individual realization experiment for the dissemination of mass standards becomes viable, NMIJ will use the XRCD method to establish the national mass standard. The XRCD method can realize the kilogram with a relative uncertainty of a few parts in 10^8. In this method, the kilogram at a nominal mass of 1 kg is realized using a single-crystal silicon sphere (Stock et al. 2018, Davidson and Stock 2021, Kuramoto et al. 2020, 2021). As an example of the realizations using this method, the realization experiment at NMIJ is introduced.

X-Ray Crystal Density Method

The new definition defines only the value of h and does not imply any method for its practical realization (Stock et al. 2019, Kuramoto 2021, 2022). We can realize the kilogram using any method – including the XRCD method and the Kibble balance – that relates the Planck constant to the mass. In the XRCD method, the number N of Si atoms in a 1 kg Si sphere is counted by measuring its volume V_s and lattice constant a (Kuramoto et al. 2020, 2021). Figure 3 shows an example of 1 kg Si spheres used for the realization, manufactured from a silicon crystal highly enriched

Fig. 3 1 kg ^{28}Si-enriched spheres manufactured from the AVO28 crystal. Left, AVO28-S5c; right, AVO28-S8c. (Photograph courtesy of AIST)

with the ^{28}Si isotope produced by the International Avogadro Coordination (IAC) project (Andreas et al. 2011a). The number N is given by

$$N = 8\, V_{\mathrm{s}}/a^3, \tag{1}$$

where 8 is the number of atoms per unit cell of crystalline silicon. The mass of the sphere m_{s} is therefore expressed by

$$m_{\mathrm{s}} = N\, m(\mathrm{Si}), \tag{2}$$

where m(Si) is the mass of a single Si atom. The new definition of the kilogram is based on the Planck constant h, and the mass of a single electron m(e) is given from the Planck constant h by

$$m(\mathrm{e}) = \frac{2hR_\infty}{c\alpha^2}. \tag{3}$$

where c is the speed of light in vacuum, α is the fine-structure constant, and R_∞ is the Rydberg constant (Cladé et al. 2016). The mass of a single Si atom m(Si) is related to m(e) by

$$\frac{A_{\mathrm{r}}(\mathrm{Si})}{A_{\mathrm{r}}(\mathrm{e})} = \frac{m(\mathrm{Si})}{m(\mathrm{e})}, \tag{4}$$

where A_{r}(e) and A_{r}(Si) are the relative atomic masses of electron and Si, respectively. Silicon has three stable isotopes, ^{28}Si, ^{29}Si and ^{30}Si. The value of A_{r}(Si) can therefore

be determined by measuring the isotopic amount-of-substance fraction of each isotope. The relationship between $m(\mathrm{Si})$ and h is given from (3) and (4) by.

$$m(\mathrm{Si}) = \frac{2A_\mathrm{r}(\mathrm{Si})}{A_\mathrm{r}(\mathrm{e})} \frac{R_\infty h}{\alpha^2 c}. \tag{5}$$

By combining Eqs. (1), (2), and (5), we can express the sphere mass m_s in terms of h using

$$m_\mathrm{s} = \frac{2R_\infty h}{c\alpha^2} \frac{A_\mathrm{r}(\mathrm{Si})}{A_\mathrm{r}(\mathrm{e})} \frac{8V_\mathrm{s}}{a^3}. \tag{6}$$

In this equation, $2R_\infty h/(c\alpha^2)$ is the mass of an electron, $A_\mathrm{r}(\mathrm{Si})/A_\mathrm{r}(\mathrm{e})$ is the mass ratio of silicon to electron, and $8V_\mathrm{s}/a^3$ is the number of silicon atoms in the sphere. The mass of the sphere is therefore determined on the basis of h by counting the number of silicon atoms.

Equation (6) describes a perfect Si crystal. That is, the Si sphere is assumed to consist of only Si atom. However, the surface of Si spheres is covered by a surface layer mainly consisting of amorphous SiO_2 (Busch et al. 2011). Figure 4 shows the surface model of the Si sphere under vacuum, derived on the basis of surface characterization by various analysis techniques developed by the IAC project (Andreas et al. 2011a, Busch et al. 2011). In addition to the oxide layer (OL), a chemisorbed water layer (CWL) and a carbonaceous layer (CL) are also present. The CWL is a chemically absorbed water layer that remains under high-vacuum conditions. The CL is a carbonaceous contamination layer formed by different adsorbed gases and contaminants, stemming from the environment during the measurement, handling, storage, and cleaning of the sphere. These layers are hereinafter referred to

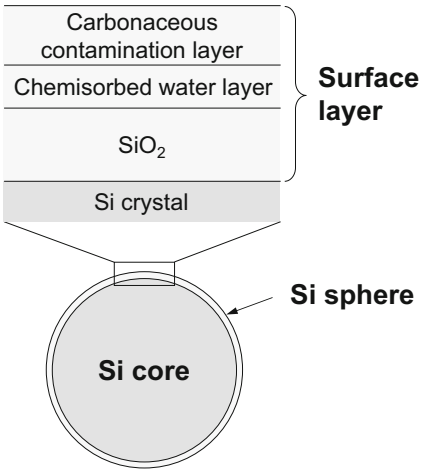

Fig. 4 Model of the surface layer of ^{28}Si-enriched spheres in vacuum. (Kuramoto 2021)

as the surface layer (SL). In addition, point defects are present inside the sphere. Equation (6) should therefore be modified to

$$m_{\mathrm{core}} = \frac{2R_\infty h}{c\alpha^2}\frac{A_{\mathrm{r}}(\mathrm{Si})}{A_{\mathrm{r}}(\mathrm{e})}\frac{8V_{\mathrm{core}}}{a^3} - m_{\mathrm{deficit}}, \tag{7}$$

where m_{core} and V_{core} are the mass and volume of the "Si core," which excludes the surface layer, respectively, and m_{deficit} is the effect of point defects (i.e., impurities and self-point defects in the crystal) on the core mass (Azuma et al. 2015). The mass of the sphere m_{sphere} including the mass of the surface layer m_{SL} is given by

$$m_{\mathrm{sphere}} = m_{\mathrm{core}} + m_{\mathrm{SL}}. \tag{8}$$

The relative uncertainty of $R_\infty/(\alpha^2 A_{\mathrm{r}}(\mathrm{e}))$ is estimated to be 3.0×10^{-10} (Tiesinga et al. 2021), and the values of h and c are exactly defined in the new SI (Stock et al. 2019). For the two 1 kg ^{28}Si-enriched spheres AVO28-S5c and AVO28-S8c shown in Fig. 3, the values of a, $A_{\mathrm{r}}(\mathrm{Si})$, and m_{deficit} were already measured by the IAC project with relative uncertainties at the level of 10^{-9} (Azuma et al. 2015, Bartl et al. 2017). There is no known mechanism that changes those parameters when the Si crystal is kept close to room temperature. The kilogram can therefore be realized by measuring V_{core} and m_{SL} of the ^{28}Si-enriched spheres at NMIJ. Details of the measurements for the realization are described in the following sections.

Procedure of Realization of the Kilogram at NMIJ

The masses of AVO28-S5c and AVO28-S8c are almost 1 kg, and details of the spheres are described by Azuma et al. (2015). To measure the sphere core volume V_{core} in Eq. (7), an optical interferometer for measuring the sphere diameter is used. However, the diameter measured using the interferometer is slightly different from the core diameter owing to the surface layer shown in Fig. 4. To calculate the core diameter from the measured diameter, the thickness of the surface layer is required. For the thickness measurement, an X-ray photoelectron spectroscopy (XPS) system and a spectroscopic ellipsometer are used. The surface characterization is also required to derive the mass of the surface layer, m_{SL} in Eq. (8). Details of each measurement apparatus are presented in the following sections. A realization result using AVO28-S5c is also shown as an example.

Sphere Volume Measurement by Optical Interferometry

Figure 5 shows a schematic drawing of the optical interferometer used to determine the volume of the ^{28}Si-enriched sphere by optical frequency tuning (Kuramoto et al. 2017a, 2019). A ^{28}Si-enriched sphere is placed in a fused-quartz Fabry–Perot etalon.

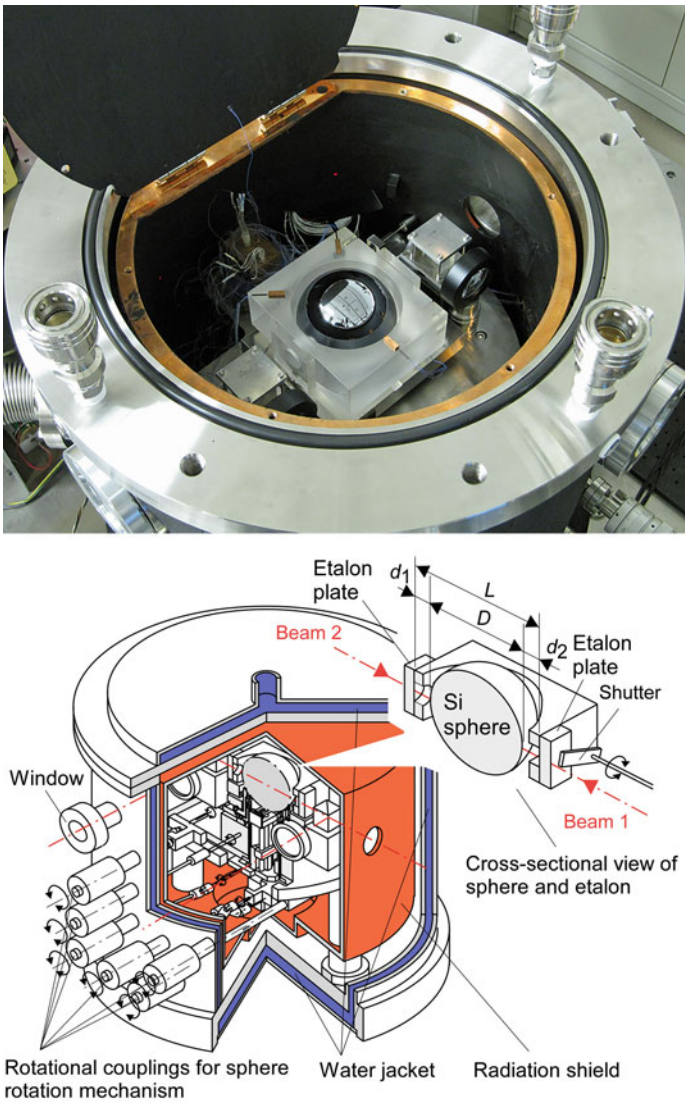

Fig. 5 Upper: Optical interferometer used to measure the volume of the ^{28}Si sphere developed by Kuramoto et al. (Photograph courtesy of AIST). Lower: Schematic of the optical interferometer. The ^{28}Si sphere and etalon are installed in a vacuum chamber equipped with an active radiation shield to control the sphere temperature (Kuramoto et al. 2017a)

The sphere and etalon are installed in a vacuum chamber equipped with an active radiation shield to control the sphere temperature. The pressure in the chamber is reduced to 10^{-2} Pa. Two beams (Beam 1 and Beam 2) from an external cavity diode laser are irradiated onto the sphere from opposite sides of the etalon. The light beams reflected from the inner surface of the etalon plate and the adjacent surface of the

sphere interfere to produce concentric circular fringes. These are projected onto CCD cameras. The fractional fringe orders of interference for the gaps between the sphere and the etalon, d_1 and d_2, are measured by phase-shifting interferometry (Andreas et al. 2011b, Kuramoto et al. 2011). The sphere diameter D is calculated as $D = L-(d_1 + d_2)$, where L is the etalon spacing. To determine L, the sphere is removed from the light path by a lifting device installed underneath the sphere, and Beam 1 is interrupted by a shutter. Beam 2 passes through a hole in the lifting device, and the beams reflected from the two etalon plates produce fringes on a CCD camera. The fringes are also analyzed by phase-shifting interferometry. The sphere volume is determined from the mean diameter calculated on the basis of the diameter measurement from many different directions. The phase shifts required for phase-shifting interferometry are produced by changing the optical frequency of the diode laser. The optical frequency is controlled on the basis of the optical frequency comb, which is used as the national length standard of Japan (Inaba et al. 2006, 2009).

The temperature of the sphere is measured using small platinum resistance thermometers (PRTs) inserted into copper blocks that come to contact with the sphere. The copper blocks are coated with polyether ether ketone (PEEK) to prevent damage of the silicon sphere. The PRTs are calibrated using temperature fixed points in ITS-90 (Preston-Thomas 1990). The measured diameters are converted to those at 20.000 °C using the thermal expansion coefficient of the ^{28}Si-enriched crystal (Bartl et al. 2011).

A sphere rotation mechanism installed under the sphere is used to measure the diameter from many different directions. In a set of diameter measurements, the diameter is measured from 145 directions distributed nearly uniformly on the sphere surface (Kuramoto et al. 2017a). Ten sets of diameter measurement are performed, and between each set, the sphere is rotated to distribute the starting point of each set of measurements to the vertices of a regular dodecahedron. Because the ten directions defined by the vertices of a regular dodecahedron are uniformly distributed, this procedure distributes all of the measurement points as uniformly as possible. The total number of measurement directions is therefore 1450. The sphere volume is calculated from the mean diameter.

As an example of the results of the diameter measurement, the Mollweide map projection of the distribution of the diameter based on the 145 directions for AVO28-S5c is shown in Fig. 6 (Kuramoto et al. 2021). The three-dimensional plot of the diameter is displayed in Fig. 7, where the deviation from the mean diameter is enhanced (Ota et al. 2021).

A different type of optical interferometer for the volume measurement of ^{28}Si-enriched spheres has been developed at Physikalisch-Technische Bundesanstalt (PTB, Germany) (Nicolaus et al. 2017). Figure 8 shows the mean diameters of two ^{28}Si-enriched spheres measured at PTB and NMIJ (Kuramoto 2021). In the interferometer developed at PTB, an etalon with spherical reference surfaces is used. The mean diameters obtained using the two interferometers with different optical configurations and phase-shifting algorithms show excellent agreement within their

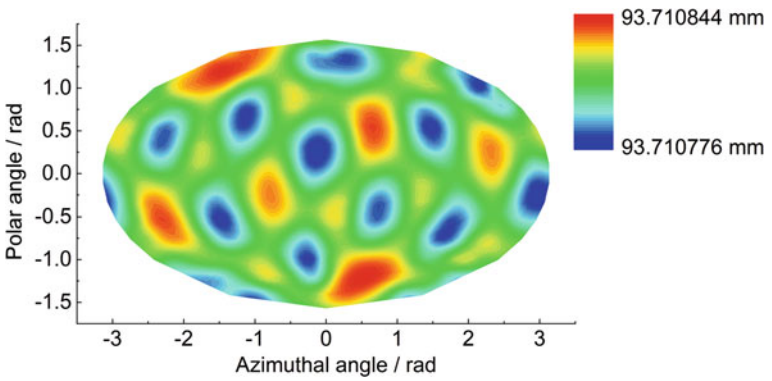

Fig. 6 Mollweide map projection of the distribution of the diameter based on 145 directions for AVO28-S5c. (Kuramoto et al. 2021)

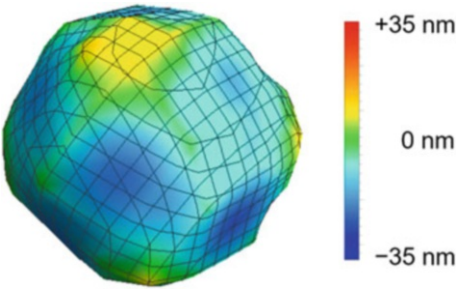

Fig. 7 Three-dimensional plots of the distribution of the diameter of AVO28-S5c. The peak-to-valley value of the diameter is 69 nm. (Ota et al. 2021)

uncertainties. This shows the high reliability of the diameter and volume measurements at the two national metrology institutes.

Sphere Surface Characterization by XPS and Ellipsometry

X-ray photoelectron spectroscopy (XPS) and ellipsometry are used for the sphere surface characterization at NMIJ. The main component of the XPS system is ULVAC-Phi 1600C equipped with a monochromatic Al Kα X-ray source. The pressure in the XPS chamber is reduced to 2.5×10^{-7} Pa. A manipulator with a five-axis freedom is installed in the XPS chamber to realize the rotation of the sphere around the horizontal and vertical axes for the mapping of the entire surface. The sphere is placed on two rollers of the manipulator during the measurement. The rollers are made of polyimide for protecting the sphere surface from damage during the rotation. Details of the XPS system are provided by Zhang et al. (2017).

The main component of the spectroscopic ellipsometer is Semilab GES5E. Its spectral bandwidth ranges from 250 nm to 990 nm. The ellipsometer and an automatic sphere rotation system are integrated to a vacuum chamber to characterize

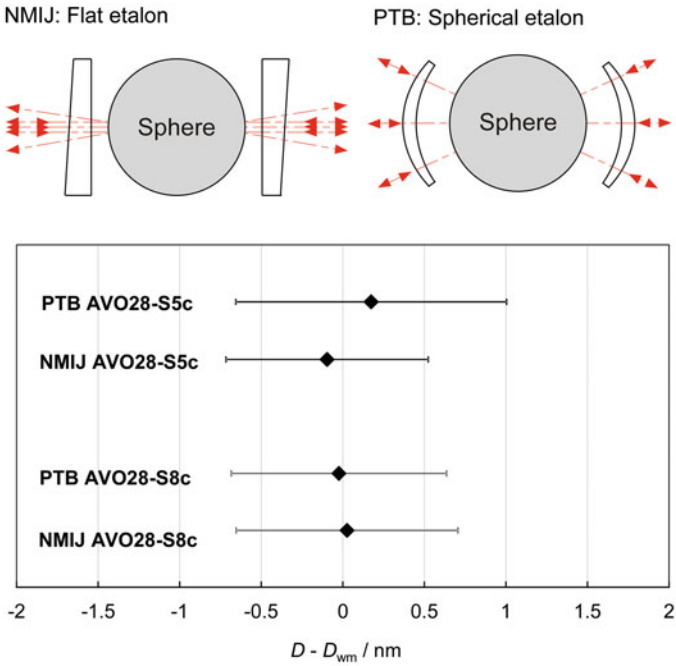

Fig. 8 Top: Optical configurations of the two interferometers of PTB and NMIJ. Bottom: Mean diameters of the ^{28}Si-enriched spheres measured at PTB and NMIJ. The difference from the weighted mean diameter D_{wm} calculated from the diameters measured at the two national metrology institutes is plotted. The horizontal error bars indicate the standard uncertainty of each value (Kuramoto 2021)

the surface layer in vacuum, where the pressure is reduced to 1×10^{-3} Pa. The ellipsometric measurement can be carried out over the entire sphere surface using the automatic sphere rotation system. Details of the ellipsometer are provided by Fujita et al. (2017).

The thicknesses of the CL and OL at 52 points on the sphere surface are measured using the XPS system. The 52 points are distributed nearly uniformly on the sphere surface. The ellipsometer is used to examine the uniformity of the thickness of the OL at 812 points on the sphere surface. Details of the strategy to distribute the measurement point by XPS and ellipsometry on the sphere surface as uniformly as possible are given by Kuramoto et al. (2017c).

Table 2 shows an example of the results of the surface characterization, where the thicknesses of all sublayers of AVO28-S5c measured by Kuramoto et al. (2021) are tabulated. The thickness of the CWL estimated from the water adsorption coefficient to silicon surface reported by Mizushima (2004) is also listed in this table. The total thickness of the surface layer is about 3 nm.

Table 2 Mass, thickness, and density of each sublayer in vacuum of AVO28-S5c (Kuramoto et al. 2021)

Layer	Thickness / nm	Density / (g cm^{-3})	Mass / μg
OL	1.26(7)	2.2(1)	76.5(5.4)
CL	0.81(9)	0.88(14)	19.6(3.8)
CWL	0.28(8)	1.0(1)	7.7(2.3)
SL			103.8(7.0)

Mass of Surface Layer

The mass of the surface layer m_{SL} is given by

$$m_{\mathrm{SL}} = m_{\mathrm{OL}} + m_{\mathrm{CL}} + m_{\mathrm{CWL}}, \tag{9}$$

where m_{OL}, m_{CL}, and m_{CWL} are the masses of the OL, CL, and CWL, respectively. The masses are calculated from the thickness and density of each sublayer. The masses of all sublayers of AVO28-S5c measured by Kuramoto et al. (2021) are summarized in Table 2 with the density and thickness of each sublayer. The mass of the surface layer was determined to be about 120 μg with a standard uncertainty of 8.9 μg.

Volume of Si Core

The volume measured using the optical interferometer is slightly different from the core volume owing to the presence of the surface layer shown in Fig. 4. To determine the Si core volume, the total phase retardation upon reflection at the sphere surface δ is calculated from the thickness and optical constants of each sublayer on the basis of the procedure described by Kuramoto et al. (2011). The value of δ is slightly different from π, and the effect of this phase shift on the gap measurement Δd is calculated using $\Delta d = \lambda\,(\delta - \pi)/(4\pi)$. This means that the actual diameter D_{actual} including the surface layer is larger than the apparent diameter measured by optical interferometry D_{app} by $-2\Delta d$. The phase shift correction to obtain the Si core diameter from the apparent diameter, Δd_0, was determined using $\Delta d_0 = -(2\Delta d + d_{\mathrm{total}})$, where d_{total} is the sum of the thicknesses of all sublayers. The Si core diameter D_{core} is determined using $D_{\mathrm{core}} = D_{\mathrm{app}} + \Delta d_0$.

Mass Deficit

Owing to point defects and impurities, there is a mass difference between a sphere having Si atoms occupying all regular sites and the real sphere. The mass difference, m_{deficit} in Eq. (7), is given by

$$m_{\mathrm{deficit}} = V_{\mathrm{core}} \sum_i (m_{28} - m_i) N_i, \tag{10}$$

where m_{28} and m_i are the mass of a ^{28}Si atom and that of the point defect named i, respectively. For a vacancy, $m_i = m_v = 0$. For interstitial point defects, m_i is the sum of the masses of the defect and a ^{28}Si atom. N_i is the concentration of the point defect i. For example, m_{deficit} of AVO28-S5c was estimated to be 3.6(3.6) μg (Azuma et al. 2015).

Lattice Constant

For the realization, NMIJ uses the value of the lattice constant measured in the IAC project. Thus, only the summary of the measurement procedure is introduced in this section. The lattice constant of silicon crystals can be measured accurately using the combination of X-ray and optical interferometers. Figure 9 shows the measurement principle (Kuramoto 2021). The X-ray interferometer consists of three Si crystal blades that are cut so that the {220} planes are orthogonal to the blade faces. An X-ray beam is split into two beams by the first blade (splitter). The two beams are split again by the second blade (mirror) and recombined by the third blade (analyzer). The X-ray interference fringes produced by the beam recombination are integrated in an X-ray detector. When the analyzer is displaced with respect to the other two blades in a direction orthogonal to the {220} planes, a periodic intensity variation of the X-ray interference signal is observed, as shown in Fig. 9. The period of the variation is the lattice spacing of {220}, d_{220}, and the displacement of the analyzer is measured using the optical interferometer. The fundamental concept of the combination of the X-ray and optical interferometers is to determine the unknown d_{220} on the basis of the known wavelength λ of the laser used in the optical interferometer. The displacement of the analyzer is measured by counting the number of the optical interference fringes having a period of λ/2. Simultaneously, the number of the X-ray fringes having a period of d_{220} is also counted. The lattice spacing d_{220} is determined by comparing the counts of the X-ray and optical interference fringes. The lattice constant a is determined as $a = \sqrt{8}\, d_{220}$, where $\sqrt{8}$ accounts for the different spacings of the {100} and {220} planes. Details of the lattice constant measurement are summarized by Ferroglio et al. (2008).

An X-ray interferometer was manufactured from the AVO28 crystal. The lattice constant of the X-ray interferometer was measured at Istituto Nazionale di Ricerca Metrologica (INRiM, Italy) by Massa et al. (2015). Since contaminants such as carbon and nitrogen strain the crystal lattice, a contamination gradient in the crystal makes the lattice parameters of the sphere different from that of the X-ray interferometer. To measure the contamination gradient, samples were taken from the AVO28 crystal around the sphere. The impurity concentrations in the samples were measured by infrared spectroscopy (Zakel et al. 2011). The lattice constant of AVO28-S5c was then calculated with a relative standard uncertainty of 1.8×10^{-9} by taking into account the different contaminations of the sphere and the X-ray interferometer (Azuma et al. 2015).

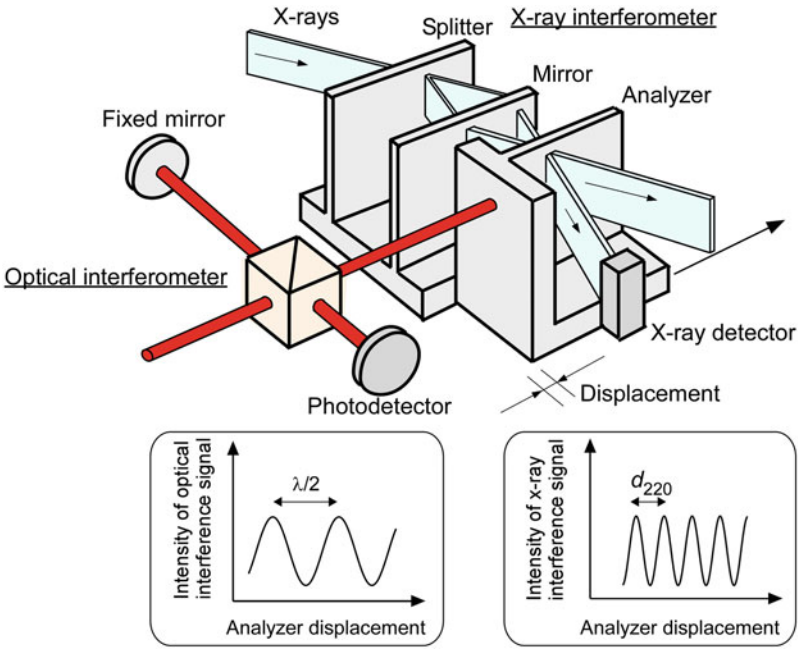

Fig. 9 Principle of the X-ray interferometer to measure the lattice constant. While the analyzer crystal is moved, its displacement is measured using the optical interferometer by counting the optical fringes having a period of λ/2. Simultaneously, the x-ray fringes having a period of d_{220} are also counted. d_{220} is determined on the basis of the laser wavelength λ by comparing the counts of X-ray and optical interference fringes. (Kuramoto 2021)

Molar Mass

For the realization, NMIJ uses the value of the molar mass measured in the IAC project. Thus, only the summary of the measurement procedure is briefly introduced in this section. The molar mass of a silicon crystal material is given by

$$M = \sum_{n=28}^{30} M(^{n}\mathrm{Si})x_n, \tag{11}$$

where $M(^{n}\mathrm{Si})$ is the molar mass of the silicon isotope ^{n}Si and x_n is the amount-of-substance fraction of ^{n}Si. The Institute of Reference Materials and Measurements (IRMM) measured x_n of the ^{28}Si-enriched crystal AVO28 by gas mass spectrometry, where samples prepared from the AVO28 crystal were converted to SiF_4 gas by several chemical processes and the ratios of the ion currents from $^{28}SiF_3^+$, $^{29}SiF_3^+$, and $^{30}SiF_3^+$ were measured (Bulska et al. 2011). However, a small amount of natural silicon was estimated to be contaminated during the conversion processes, and the effect of the contamination on the ^{28}Si fraction measurement could not be accurately corrected. Furthermore, owing to the extremely high isotopic enrichment, the range in which

isotope ratios had to be determined was extremely wide: $1 \times 10^{-6} \leq x(^{n}\mathrm{Si})/x(^{28}\mathrm{Si}) \leq 1$. This caused many difficulties owing to several issues such as detector linearity and dynamic range, limiting the improvement of the measurement uncertainty.

To overcome these difficulties, a new strategy based on isotope dilution mass spectrometry combined with multicollector inductively coupled plasma mass spectrometry was developed at PTB (Rienitz et al. 2010). This strategy does not directly measure $x(^{28}\mathrm{Si})$. Instead, $x(^{29}\mathrm{Si})$ and $x(^{30}\mathrm{Si})$ are measured using an enriched spike of ^{30}Si. Then, $x(^{28}\mathrm{Si})$ is obtained indirectly as $x(^{28}\mathrm{Si}) = 1 - x(^{29}\mathrm{Si}) - x(^{30}\mathrm{Si})$. This significantly narrows the isotope ratio measurement range. In addition, the conversion of the ^{28}Si-enriched crystal to a liquid sample introduced to the mass spectrometer is carried out quantitatively in a single step by using alkaline solutions, avoiding cumulative contaminations by natural silicon. With these improvements, it has become possible to markedly improve the accuracy of the molar mass measurement.

To determine the molar mass of AVO28-S5c, small samples were taken from the AVO28 crystal from both sides of the sphere. The molar masses of the samples were measured at PTB, NMIJ, and the National Institute of Standards and Technology (NIST, U.S.A) and used to estimate the molar mass of AVO28-S5c with a relative standard uncertainty of 5×10^{-9} (Azuma et al. 2015).

Mass of Si Sphere

The sphere mass m_{sphere} is derived from the Planck constant using Eqs. (7) and (8), realizing the new definition of the kilogram. As an example, the uncertainty budget of the determination of m_{sphere} using AVO28-S5c in 2019 is shown in Table 3 (Kuramoto et al. 2021). This determination was performed for the first key comparison of the realizations of the kilogram by NMIs, CCM.M-K8.2019 (Stock et al. 2020). The values of a and $A_{\mathrm{r}}(\mathrm{Si})$ of AVO28-S5c were measured with relative standard uncertainties of 1.8×10^{-9} and 5.4×10^{-9}, respectively, in the IAC project (Azuma et al. 2015, Bartl et al. 2017). The relative standard uncertainty of m_{sphere} was estimated to be 2.1×10^{-8}. This means that the relative standard uncertainty of the realization of the new kilogram at NMIJ was 2.1×10^{-8}, which corresponds to 21 μg for 1 kg.

The largest uncertainty source in the realization is the sphere volume determination by optical interferometry, as shown in Table 3. To enable a more accurate realization at NMIJ, the optical interferometer is being improved (Ota et al. 2021). This improvement will reduce the relative standard uncertainty of the realization of the kilogram to 1.7×10^{-8}, which corresponds to 17 μg for 1 kg.

In CCM.M-K8.2019, the level of agreement between realizations of the kilogram by NMIs was evaluated. This comparison was organized by BIPM and had seven participants including NMIJ (Stock et al. 2020, Davidson and Stock 2021). The participants determined the mass of one or two 1 kg standards by their realization experiment. At BIPM, all mass standards were compared with a reference standard using a mass comparator. These weighings, together with the mass values determined by the participants, allowed a comparison of the consistency of the individual

Table 3 Uncertainty budget for the realization of the new kilogram by the XRCD method using AVO28-S5c at NMIJ (Kuramoto et al. 2021)

Quantity	Relative standard uncertainty in m_{sphere}
Core volume, V_{core}	1.8×10^{-8}
Mass of the surface layer, m_{SL}	7.0×10^{-9}
Relative atomic mass of silicon, A_{r}(Si)	5.4×10^{-9}
Lattice parameter, a	5.5×10^{-9}
Mass deficit due to impurities and vacancies, m_{deficit}	3.8×10^{-9}
Relative combined standard uncertainty	2.1×10^{-8}

realizations. The chi-squared test for consistency using the 95 % cut-off criterion was passed, although the two results with the smallest uncertainty were not in agreement with each other within their standard uncertainties. For this comparison, NMIJ determined the masses two 1 kg platinum-iridium standards on the basis of the mass of AVO28-S5c determined by the XRCD method (Kuramoto et al. 2021). The result of NMIJ was in agreement with the results of the other participants and the key comparison reference value within their standard uncertainties.

Dissemination of Mass Standards Based on the ^{28}Si-Enriched Spheres

Figure 10 shows the traceability chain of mass standards planned at NMIJ after the use of individual realization experiment for the dissemination of mass standards becomes viable (Kuramoto et al. 2020). The masses of the ^{28}Si-enriched spheres are determined by the XRCD method on the basis of the Planck constant, as described in the previous sections. On the basis of the masses of the ^{28}Si-enriched spheres, the masses of 1 kg platinum–iridium weights and 1 kg stainless steel weights in air and vacuum are determined. These 1 kg weights will form an ensemble of reference mass standards and maintain the value of the realized kilogram at NMIJ.

The mass differences between the ^{28}Si-enriched spheres and the 1 kg weights are measured using a mass comparator installed in a vacuum chamber, which enables mass comparisons at a constant atmospheric pressure or under vacuum (Mizushima et al. 2017). Owing to density differences among silicon, stainless steel, and platinum–iridium, the ^{28}Si-enriched spheres and the 1 kg weights have different volumes. This requires air buoyancy corrections in the mass difference measurement. For a precise air buoyancy correction, artifacts are used to accurately determine the air density (Mizushima et al. 2004). The artifacts are a pair of weights that are equal in mass and surface area but different in volume. Furthermore, the masses of the ^{28}Si-enriched spheres and the 1 kg weights in air and those under vacuum are different owing to the difference in the amount of water adsorbed onto their surfaces. For the precise estimation of this sorption effect, a pair of weights that are equal in mass and volume but different in surface area are used (Mizushima et al. 2015).

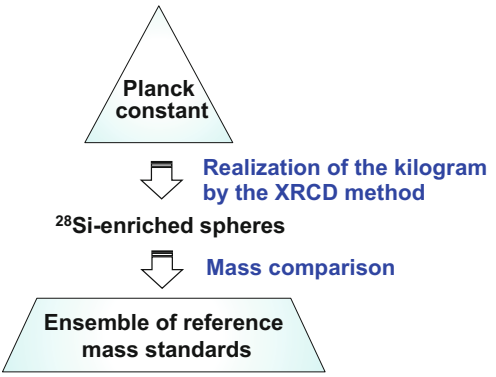

Fig. 10 Traceability chain from the new definition of the kilogram planned at NMIJ. (Kuramoto et al. 2020)

Small Mass Measurement Based on the Planck Constant

Under the previous definition of the kilogram, a reference weight calibrated in a manner traceable to the international prototype of the kilogram was essential to ensure the metrological traceability of mass measurements. Obtaining a reference weight with a mass of less than 1 kg requires submultiples of a primary 1 kg standard. Each time a mass is subdivided, the relative uncertainty of the mass of the weight calibrated by the subdivision process accrues progressively. Figure 11 shows the relative standard uncertainties of the masses of weights with various masses estimated from maximum possible error used in legal metrology (OIML 2004). At the level of 1 kg, the relative standard uncertainty of the mass is 8×10^{-6}. However, by the time the mass is subdivided to 1 mg, the relative standard uncertainty is increased approximately 2,400,000 times (Kuramoto 2021).

On the other hand, the new definition enables us to realize the kilogram using any measurement technology that relates the Planck constant to the kilogram (Kuramoto 2022). Furthermore, 1 kg is not the unique reference point anymore; thus, the kilogram can be directly realized in any range without using a reference weight. These advantages are exploited in the development of the electrostatic force balance for mass measurement in the sub-milligram range (Shaw et al. 2016). In the electrostatic force balance, electrostatic force is balanced with the gravity force acting on a sample. The electromagnetic force is measured using quantum electrical standards based on the Planck constant. The electrostatic force balance can therefore realize the kilogram in the new SI without using the reference weights. Recently, Shaw et al. extended the measurement range by this technique to the microgram range (Shaw et al. 2019). At NMIJ, Yamamoto et al. (2020) and Fujita and Kuramoto (2022) developed an electrostatic force balance for mass measurements in the milligram range. These balances will be also used for the realization of the kilogram at NMIJ in the future.

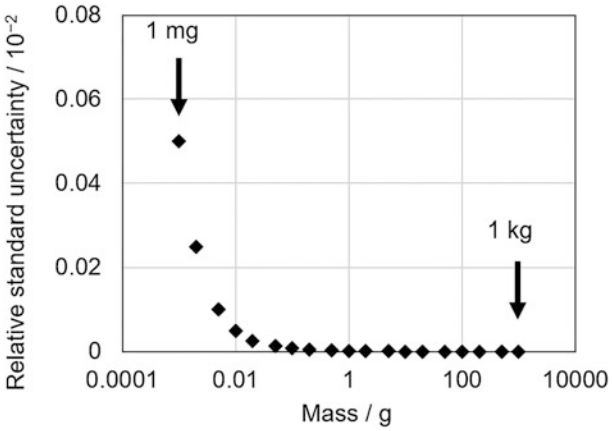

Fig. 11 Relative standard uncertainties of the masses of standard weights estimated from the maximum possible error in OIML R-111 (OIML 2004). Obtaining a standard weight with a mass less than 1 kg usually requires submultiples of a primary 1 kg standard. Each time a mass is subdivided, the relative uncertainties of the masses of the weights calibrated by the subdivision process accrues progressively. (Kuramoto 2021)

Conclusion

Under the new definition of the kilogram based on the Planck constant, it is, in principle, possible for each NMI to realize the kilogram independently. After the confirmation of the international consistency of the individual realizations by NMIs, NMIJ will realize the new kilogram by the XRCD method, where two ^{28}Si-enriched spheres manufactured by the International Avogadro Coordination project are used. The masses of the two spheres are almost 1 kg, and the relative standard uncertainty of the realization is estimated to be 2.1×10^{-8}, which corresponds to 21 μg for 1 kg. On the basis of the spheres, the masses of weights consisting of the NMIJ ensemble of reference mass standards are measured. The ensemble will be used for the dissemination of mass standards to scientific and industrial fields in Japan.

Abstract

This chapter deals with mass measurement and metrological activities from prehistoric civilizations until the present. The importance of the International Prototype of the Kilogram (IPK) and its limitations that created the need to redefine the kilogram in terms of the fundamental constant has been discussed. The redefinition of the kilogram in terms of Planck constant h is a result of the consequent efforts of the metrology community. Some of the significant events that took place in this process are highlighted in the chapter. An in-depth discussion is offered on the four-phase CCM dissemination method. Also, the

traceability of mass dissemination in India before and after redefinition has been discussed. One of the benefits of the new kilogram definition is that it allows each country to establish its realization capability. The basic principle of different realization techniques adopted by different NMIs to define the kilogram, which includes the Kibble balance, Joule balance, and XRCD method, is also provided. The role of two quantum effects, viz., quantum hall effect and Josephson effect, in defining kilogram using Kibbe balance is explained. Finally, a brief discussion on the present status of different NMI across the globe working on the different primary realization techniques is presented.

Introduction

The mass has been one of the most important physical quantities in day-to-day life for centuries as well as in the scientific study of nature, ranging from celestial to subatomic scales. The mass of an object is measured by weighing, and in popular parlance, mass is often synonymous with weight, but fundamentally they represent two different physical quantities though intimately connected. As the need for weighing different objects was crucial for many daily requirements of humankind, mass measuring tools came into practice at the early stages of human civilization using uniform size objects like stones, seeds, etc. Early developments happened in isolation in different parts of the world, and they primarily served the limited needs of the local communities in their respective areas. Those developments consisted of primitive tools, but they never lacked in ingenuity. Over time, more and more sophisticated techniques were developed that ultimately resulted in the availability of modern ultrahigh-precision balances of various types in use today. Meanwhile, the advent of international trade and commerce demanded the availability of a common set of standards and measuring methods for physical quantities that can facilitate creating a harmonious procedure for the activities concerned. The signing of the Meter Convention and the founding of the BIPM in 1875 heralded a new beginning for more comprehensive international cooperation to establish a common system of units, standards, and measurement methods accepted globally. The kilogram was accepted as the unit of mass, and subsequent events catalyzed its definition in terms of an artifact, which was termed the international prototype kilogram (IPK) in 1889. The kilogram is one of the seven base units in the SI system. Advances in twentieth-century physics paved the way for defining the SI base units in terms of fundamental physical constants, and this led to the abrogation of the artifact-dependent definitions of the SI base units one by one, and the kilogram is the last one that has been redefined in this manner. The IPK remained the primary standard of mass until it was replaced by its new definition, based on the Planck constant h, on 20th May 2019.

This chapter briefly describes the metrological practices prevalent in primitive civilizations and the subsequent evolutions, driven by human curiosity and the thirst to unravel nature. Next, the IPK and its role in ensuring traceability for mass measurements worldwide will be discussed. The shortcomings of the IPK as the primary standard of mass and the consequent efforts of the mass metrology

community in redefining the kilogram will also be addressed. Then the latest developments taking place in mass metrology post-redefinition of the kilogram will be presented in some detail. Finally, the details of different NMIs working on the primary realization method of the kilogram are discussed.

Weights and Measures in Ancient Times

Weighing things is one of the primary and essential needs of human civilization. The use of weights and measures can be traced back to the Egyptian civilization, the earliest civilization known. The most primitive form of metrology appeared around 8000 BC when human society transitioned from nomadic wandering to a settled existence. As a center of world trade, Egypt has a unit of mass that has varied over time, giving the median value of 9.33 g (Willard and Selin 2008; Alberti 2004). The hierarchy of weights in Egypt goes as 10 *qedet* = 1 *deben*; 10 *deben* = 1 *sept*. The Egyptian weights were usually made of stones, but gold and copper deben were also found with mass 12–14 g and 27 g, respectively. Egyptian balances were made of wood or bronze. Usually, loaf-shaped weights and a few animal-shaped weights (18th Dynasty characteristic weights) were used. Authorized reference standards of length, volume, and weight were preserved in places of sanctity like places of worship and royal palaces. In this era, weighing was mainly used for weighing jewels and metals in manufacturing. Figure 1 shows the oldest known Egyptian

Fig. 1 The oldest Egyptian balance is made from pinkish-brown limestone. (Source: Willard and Selin 2008)

balance based on the equal arm principle and made of limestone and belongs to the Predynastic Period (8000 BCE–3000 BCE). Balances were also used for religious purposes, like weighing tributes to the pharaoh and national god *Amun*. Over a while, various improvements were conducted to Egyptian balance, and it served as a standard weighing instrument till Roman times (Willard and Selin 2008).

Babylonia was a state of Mesopotamia, and it was one of the most developed civilizations around 2300 BC. The unit for weight was *shakel*, and 3000 *shakel* = 1 *talent*. The oldest available weights were limestone with a dome shape and a flat bottom. Some bronze specimens also exist. The mean mass of a *shakel* was found to be 11.4 g. *Tyrian shakel* weighs 14 g and was well-known for the pureness of metal and homogeneity of weight (Holland and Selin 2008). In Africa, Akan gold weights were made of bronze or brass (Niangoran-Bouah and Selin 2008). Some weights were made of silver, copper, and solid gold also. Akan weights can be divided into three categories: geometrical weights, figurative weights, and weights with graphic design. Irrespective of their shape and mass, all weights closely depict the Akan cultural beliefs and are called *abrammuo*. For example, gold weight is shown in Fig. 2, which shows a bird looking backward called *Sankofa* preached "to pick it up if it falls behind you," in other words, learn from your experience and never forget your roots. Figure 3 shows different types of weights used in Africa (Niangoran-Bouah and Selin 2008).

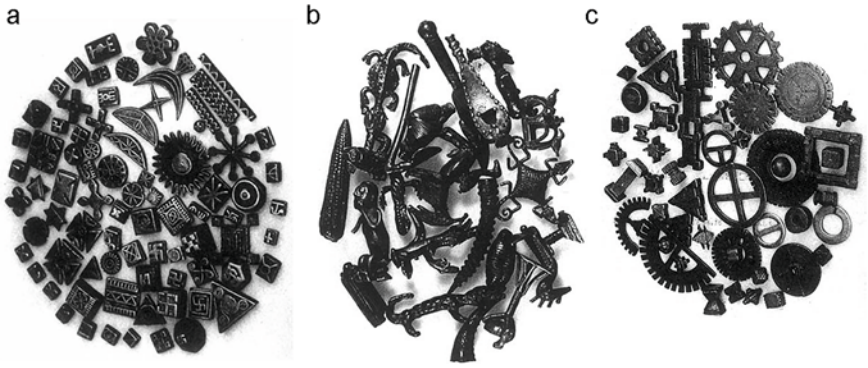

Fig. 3 Weights and measures in Africa: Akan gold weights. (**a**) Weights with graphic designs. (**b**) Weights with figurative elements. (**c**) Weights with geometric elements. (Source: (Niangoran-Bouah and Selin 2008))

Weights and measures for the Indus Valley civilization date back to the fifth millennium BCE. The Indus civilization comprised of Harappa and Mohenjo-Daro regions, and its spread was more than one million square kilometers. In ancient India, the flourishing trade of raw materials, both inland and overseas, led to a golden era of 550 years from 2300 BCE to 1750 BCE (Iwata and Selin 2008a). Weights mined from Mohenjo-Daro, Harappa, and Chanhu-Daro show elaborate systems of ascending weights. The first seven Indus weights double in size in ratio 1:2:4:8::16:32:64. As ratio 16th weight was widely excavated from these sites, which had a mean mass of 13.7 g, it is assumed to be the unit of mass for Indus people. These weights are cubic in shape, and 68% of excavated weights were made of chert, but a few weights made of agate and graphite were also found. The most significant weight found in Mohenjo-Daro is 10,865 g. These weights were used alongside two pan balances made of copper, bronze, ceramic, and sometimes terracotta. Figure 4 shows the weights used in the Indus civilization and excavated from Taxila (Iwata and Selin 2008a). In the Vedic era, different units of weights were used to measure different items. For example, the *drone* was the unit for food-related items, whereas *Aksa* was the unit to weigh gold (Gupta 2010). In the pre-Akbar period, precious metals like gold and silver were measured by the grain of wheat or barleycorn. Akbar standardizes the weight standard as *jau* (barleycorn). Before the arrival of the metric system in India (1853), the terminology being used for weights is given below (Shrivastava 2017):

4 chawal (grain of rice) = 1 dhan (weight of one wheat berry)
4 dhan = 1 ratti = 1.75 grains = 0.11339825 g
8 ratti = 1 masha = 0.9071856 g
12 masha = 96 ratti = 1 tola =180 grains = 11.66375 g
80 tolas = 1 seer = 870.89816 g
40 seers = 1 maund = 8 pasri = 37.32422 kg
1 chattank = 4 kancha = 5 tola 1 pav = 2 adh-pav = 4 chattank = ¼ seer

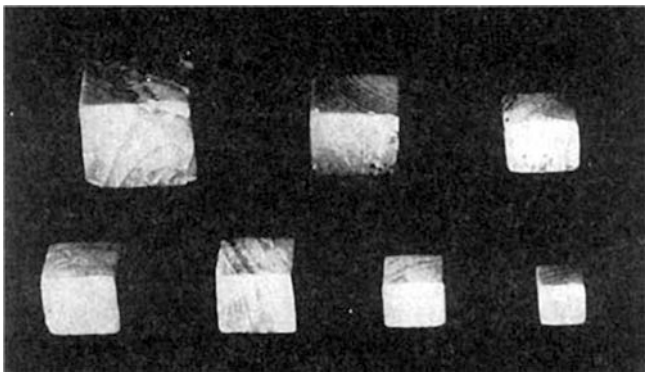

Fig. 4 The weights used in the Indus Valley civilization. (The figure is replicated from (Iwata and Selin 2008a))

1 seer = 4 pav = 16 chattank = 80 tola = 933.1 g
1 paseri = 5 seer

The Arabic physicists extensively studied concepts of weight, density, buoyancy, and their related measurements. They were conversant with Archimedes' principle and the law of the lever. Using these principles, they developed scientific apparatus, i.e., balance, to study in detail on areas such as specific weights. Thabit ibn Qurra (circa 836–901) worked in depth on the equi-armed balance. His ideas subsequently became quite effective in the West. Twelfth-century scientist Al-Khāzini (fl. 1115–1130) wrote *Kitāb Mizān al-Hikmah* (*Book of the Balance of Wisdom*) which encompasses formulae for the specific and absolute weights of various alloys. Further, a book entitled *Control of Weights and Measures* was written by eighth-century present-day Tunisian scientist *Yahyā al Kināni* (Rebstock and Selin 2008; McGrew and Selin 2008; Djebbar and Selin 2008).

There is evidence suggesting the existence of Peruvian's mass standard also; however, it has been challenging to estimate the mass standard precisely in view of the fewer weights discovered in this region as compared with the other civilizations. The notation was based on the decimal system. The largest unit was presumed to be 23.1 kg. In other civilizations like Egypt, Mesopotamia, Indus, and China, 27–30 kg was found to be the largest weight range, probably because of the low concentration of oxygen in the atmosphere in the Andean highlands.

The following are the material and the percentage used in making the weights:

Weight material	Percent
Stone	39
Iron	32
Lead	24
Nonferrous	5

The preferred shape was globe which comprises one-third of the weights; others were conical, cylindrical, or in the spindle and other irregular forms (Iwata and Selin

Fig. 5 Weights of different shapes used in Burma. (Taken from Gear et al. (2008))

2008b). *Mohists* were the followers of philosopher *Mo Zi* (warring states period, BC 480–221) and performed many experiments to determine the properties of levers and balance as discovered from Chinese text on physics. They gave the definition of forces and weights. Also, they used laws of lever and balance to develop a simple version of the "Atwood machine," which was later developed in Europe in 1780 (Smith and Selin 2008).

The Burmese empire used a weight system based on animal-shaped weights (Gear et al. 2008). These mythical animals are mainly in the shape of *leonine* (lion-like), *elephantine*, *ansorine* (goose-like), and *linaceous* (poultry-like), as shown in Fig. 5. These weights are highly influenced by the Buddhist art in India and usually are in the dimension of 70 × 120 mm. These weights were made of copper alloy, lead, and tin. *Kyat* was the unit of mass whose weight varied from 14 g to 16 g from the fifteenth century to the eighteenth century, respectively. One of the main duties of a monarch was to ensure the standardization of weights across the Burmese empire. An early record of nationwide standardization can be found, which dates back to the eleventh century. In the nineteenth century, legal weight was crafted in the palace under the direction of the chief minister. For measuring valuable commodities like seeds, etc., the equal arm balance of Chinese type was used (Gear et al. 2008).

Mass Measurements in the Modern Era

Human civilization has come a long way since 8000 BC, when Egyptians fabricated the first balance, and its illustrations can still be found on the wall of Egyptian tombs. The need to measure mass faster and with higher accuracy leads to the development of modern-era balance with elaborate techniques behind it. Presently there are various ultra-advanced balances to measure a wide range of masses with mind-boggling accuracy. There are different types of balance available these days. Though a complete description of the latest advancement in these types of balance is not

possible here, a few types of modern balances are described. The present-day **equal arm balance/trip balance** is an improved version of ancient Egyptian balance. As in ancient Egyptian balance, it also consists of two pans hung on each side of the lever. The quantity that must be measured is placed in one pan, and calibrated masses are put against it in another pan until both pans are balanced. The value of calibrated mass used to balance the item represents the mass of the measured quantity. This balance is also used when one item needs to be adjusted with respect to the other. Thus, it is helpful in situations like balancing tubes or centrifugation (Zimmerer 1983).

After World War II, **single pan substitution balance** became famous as they were faster in measurement than equal arm balance. Even less skilled operators could use it with relatively higher accuracy than equal arm balance. The second pan was replaced by the fixed calibrated counterweights securely put inside the balance frame. The operator can change these weights by a rotating knob depending on the measured mass. The main advantage of this balance was its more straightforward construction as it requires only two knife edges instead of three, as in the case of equal arm balance. The main knife edge was under constant load irrespective of the mass of the object (Jones and Schoonover 2002).

The fundamental principle of balance is that the gravitational force balances force on one object with the other object. However, there is a class of balance where the gravitational force is balanced by electromagnetic force, called **electronic balance**. A wide variety of principles is being used for electronic balances having the finest precession of 10^7 at full capacity (Guzy 2008). Two major types of electronic balances are **hybrid balance** and **electromotive force balance**. In hybrid balance, the large angular displacement of the balance beam is restricted by servo-controlled electromagnetic force being applied to the beam. In an electromagnetic force, the entire load is balanced either by direct levitation or through a fixed-ratio lever system (Jones and Schoonover 2002). The sensitivity and response of the balance do not depend on the dynamics of the balance beam but are primarily controlled by servo system characteristics. One of the highly accurate electronic balances is the **analytical balance** (Clark 1947). These are widely used in laboratories, especially in chemical analysis labs where precise mass measurement is necessary. Essential components of an analytical balance are a beam arrest, a measurement pan, levelling feet with a spirit level, and an enclosure. The primary function of beam arrest (a mechanical device) is to provide safety to the delicate internal system of balance when it is moved. An analytical balance is so sensitive that even an air current can alter its reading; thus, an enclosure is used around the measurement pan. A lower version of analytical balance called **precision balance** is also used in areas where extreme precision is not required. They are top-loading balance. Though the readability of the top-loading balance is less, they are a more convenient and economical choice as they can withstand harsh chemicals, dust, dirt, and even splashes of liquids.

Another principle widely used for electronic balance is the use of elastic force against gravitational force, e.g., the twisting property of wire. Microbalances and ultramicrobalances that weigh fractional gram values are **torsion balances**. As quarts are used to produce a very stable frequency, they are commonly used in

torsion balance. A thin wafer of quartz with electrodes on both surfaces produces vibrations through the piezoelectric effect (Zimmerer 1983; Gillies and Ritter 1993).

A triple beam balance is a type of balance commonly used in the laboratory to determine sample mass (by weight comparison). It is called a triple beam because of the three beams on the scale used to determine the item's weight. The first beam measures 0–10 g, the middle beam weighs 10 g increments, and the far beam weighs 100 g increments.

Platform scale is another type of balance, using a well-designed scheme of multiplying levers. In this type of balance, the weight of the measuring item is transferred to a moving beam which balances itself against a counterweight. This balance is widely used in veterinarian facilities for weighing animals.

Mass comparators are also a class of balances that offers high resolution and exceptional repeatability in weighing. This is why it is widely used in metrological institutes for the calibration and verification of masses. A window-range mass comparator is used for mass calibration within a range as they provide excellent resolution. Full-range mass comparators are multipurpose and very efficient when samples of different sizes need to be weighed together. Commercially mass comparators are available for masses in the range of 1 mg up to 5000 kg (Borys et al. 2012). There are various types of mass comparator, among which vacuum mass comparator and robotic mass comparator provide exceptionally accurate results. As the name suggests, vacuum mass comparators weigh mass in a vacuum, eliminating the need for buoyancy correction and significantly improving mass measurement uncertainty. Another highly accurate comparator is the robotic mass comparator. When the determination of mass value to the utmost accuracy is required, these comparators are used by laboratories. The entire calibration process is automated, and a robotic arm attached to the comparator transfers weights from magazine to comparator and vice versa. It can also calibrate complete weight sets having different values automatically (Toledo n.d.).

Artifact-Based Definition of Mass: Need to Change

The rapid developments in the seventeenth century onward resulted in the increase in global trade, exchange of social goods, scientific ideas, and technological know-how. This highlighted the need for some sort of universal system of units and measurements. In 1889, at the first General Conference on Weights and Measures (CGPM), the prototype of the kilogram called international prototype of kilogram (IPK) was adopted and declared unit of mass. The official definition of the unit of mass was adopted in the third meeting of the CGPM in 1903. The IPK served as the primary standard for mass from 1889 till 2018. It is an alloy of 90% platinum and 10% iridium alloy cast in the shape of a cylinder of 39 mm in height and diameter by Johnson Matthey in 1879 (Ehtesham et al. 2021). The choice of material required to construct mass standards was constrained by a host of physical and chemical properties which designated materials must possess, e.g., the materials needed to have properties such as high density, good hardness, good electrical and thermal

conductivity, immunity toward corrosion, and ability to minimize the effects of air buoyancy. A good electrical conductivity is necessary to eliminate parasitic forces due to static electricity. Another prerequisite is a low magnetic susceptibility to limit parasitic force due to magnetic field. In that era, platinum was considered to fulfil all these criteria except hardness. Thus, iridium was mixed with platinum to cast the primary standard of mass. Additionally, the technology for melting platinum and purifying it was just being perfected on an industrial level. Initially, three copies of the platinum-iridium prototype were fabricated by Johnson and Matthey, out of which one was made IPK or called Le Grand K, and the rest two were made its official copies. Later on, the number of official copies rose to six. Johnson and Matthey also produced the first 40 Pt-Ir prototypes, which were calibrated against IPK and distributed to the member state of the Meter Convention (Yadav and Aswal 2020). They are called the national prototype of the kilogram (NPK). The kilogram was the last unit until 2018 which was defined by a man-made object. Being an artifact, IPK is subjected to surface contamination or damage while cleaning, washing, or during measurements. The outcome of the second periodic verification held in 1946 shows the mass gain in some of the official copies with respect to IPK. This trend was confirmed by the third periodic verification held from 1939 to 1946. A careful comparison between IPK and its official copies kept at BIPM shows the drift of approximately 50 μg in IPK over 100 years, as shown in Fig. 6 (Ehtesham et al. 2021; Bosse et al. 2017).

Due to these reasons, on 16th November 2018 in the 26th CGPM conference held in Versailles, France, the old definition of mass, which was "The kilogram is the unit of mass; it is equal to the mass of international prototype of the kilogram" was

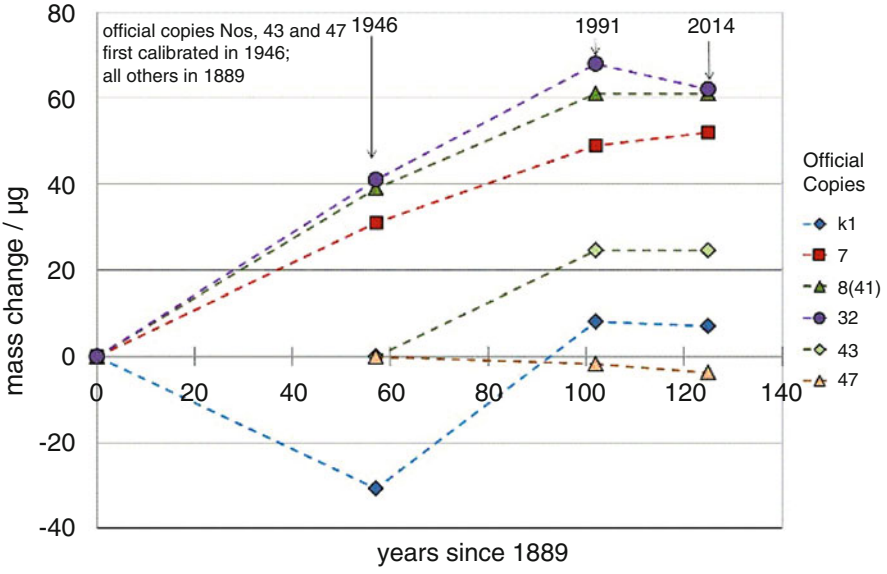

Fig. 6 The behavior of the six official copies over the period with respect to IPK

replaced by the new definition of the kilogram. The new definition of kilogram based on fundamental constant is "The kilogram, symbol kg, is the SI unit of mass. It is defined by taking the fixed numerical value of the Planck constant h to be $6.62607015 \times 10^{-34}$ when expressed in unit J s, which is equal to kg m^2 s^{-1}, where the meter and the second are defined in terms of c and Δv_{Cs}" (Ehtesham et al. 2020). The CSIR-NPL being the national metrology institute (NMI) of India also voted in favor of the redefinition of the kilogram in Versailles. India is also a member state of BIPM since 11th January 1957.

Events Leading to the Redefinition of the Kilogram

The need to express the kilogram in terms of the physical constant was thought around 1791 by King Louis XVI, who also passed a decree emphasizing the definition and realization of measurement units in terms of physical constants. In that era, the kilogram was initially expressed as the mass of 1 l (10^3 cm^3) of distilled water at 0 °C. Later in 1795, the reference temperature of the water was changed to 4 °C. The kilogram was then defined as the mass of 1 l (10^3 cm^3) of distilled water at 4 °C. In 1799, it was the first time when an artifact made of a platinum sponge was fabricated to realize the kilogram. The artifact called kilogram of archives, the **KA**, is cylindrical in shape (Davis et al. 2016). The more refined artifact called IPK was later fabricated with 90% platinum and 10% iridium alloy, and in 1901 at the third CGPM, official definition of mass, viz., "The kilogram is the unit of mass; it is equal to the mass of international prototype of the kilogram," was adopted. During the second (1939–1946) and third periodic verification (1988–1992) of IPK with its official copies, drift in the mass was observed (Davis et al. 2016; Girard 1994). The official copies of mass showed deviation of several tens of micrograms as compared to IPK. The nonconformity in the weights of IPK and its official copies implied that either the mass of IPK or its official copies or both are changing with time. In 1995, at the 20th CGPM, it was recommended to first monitor the stability of IPK and second to find new ways to express the kilogram in terms of fundamental constant. Two foremost methods were put forth and discussed to link mass to fundamental constant, viz., watt balance and X-ray crystal density (XRCD) method. In the watt balance principle, mass is realized in terms of the Planck constant (h), whereas in the XRCD method, mass is linked through the Avogadro constant. In 1990, two revolutionary developments of Josephson voltage standard (JVS) and quantum Hall resistance (QHR) standard linked voltage and resistance measurement to the Planck constant. Though the principle of watt balance was given by Dr. Bryan Kibble way back in 1975, with the advent of JVS and QHR, now the electrical measurement of watt balance can be traceable to "h." In 2011 at the 24th CGPM meeting, it was decided that the Planck constant would be used for the redefinition of mass with unit kg m^2 s^{-1}. There were four necessary conditions laid out by the Consultative Committee for Mass (CCM) to follow before the redefinition could happen. Details of these four conditions can be found in reference (Ehtesham et al. 2020). To redefine the kilogram in terms of the Planck constant, at least

Table 1 List of fixed value of fundamental constant assigned by CODATA in 2017

Quantity	Value
Planck constant (h)	$6.626070\ 15 \times 10^{-34}$ J s
Elementary charge (e)	$1.602176634 \times 10^{-19}$ C
Boltzmann constant (k)	1.380649×10^{-23} J K^{-1}
Avogadro constant (N_A)	$6.022140\ 76 \times 10^{23}$ mol^{-1}

3 independent results from the XRCD experiment or watt balance experiment should yield relative standard uncertainty of less than 5 parts in 10^8 (50 ppb), and at least 1 of the results should be less than 2 parts in 10^8 (20 ppb). In 2014, a pilot study was conducted by CCM called "The Extraordinary Calibration" to check the consistency in results of various ongoing experiments to realize a new definition. LNE, NIST, and NRC participated in the calibration with their results of Kibble balance, and NMIJ and PTB contributed with the results of XRCD experiments. The results of these five NMIs were compared with the results of IPK from BIPM to check the consistency (Stock et al. 2018). In 1966, the Committee on Data for Science and Technology (CODATA) was established with the purpose of providing the most accurate value of fundamental constants and conversion factors that can be used in various streams of research, including the metrology community. In 2017 CODATA provides exact values of fundamental constants, which will be going to use in the redefinition of SI units of mass, current, temperature, and amount of substance. The fixed values of fundamental constants are shown in Table 1 (Newell et al. 2018). Finally, on 16th November 2018, at the 26th CGPM meeting held in Versailles, France, delegates from the entire metrology community unanimously voted for the redefinition of kilogram, ampere, kelvin, and mole. Officially the new definition of the kilogram "The kilogram, symbol kg, is the SI unit of mass. It is defined by taking the fixed numerical value of the Planck constant h to be $6.626\ 070\ 15 \times 10^{-34}$ when expressed in unit J s, which is equal to kg m^2 s^{-1}, where the meter and the second are defined in terms of c and Δv_{Cs}" came into effect globally from 20th May 2019 (World Metrology Day). The IPK which prior has no uncertainty was assigned the uncertainty of 10 μg until the "consensus value" based on the first key comparison between various realization experiments (Kibble balance, joule balance, XRCD method) is completed. On completion of the first key comparison (CCM.M-K8.2019), on 1st February 2021, the standard uncertainty in the "consensus value" of the kilogram is set to be 20 μg (Davidson and Stock 2021).

Traceability of Mass Calibration in India

India signed the Meter Convention in 1957 and got prototype no. 57 (NPK-57). CSIR-National Physical Laboratory is the NMI of India. According to the subordinate legislation of the Weights and Measures Act 1956 passed by parliament, NPL is responsible for realizing the units of physical measurements based on the International System (SI units). It is the mandate of NPL to realize, establish, maintain, reproduce, and update the national standards of measurement and calibration

facilities for different parameters. NPL is presently maintaining standards for meter, kilogram, second, kelvin, ampere, and candela. NPL maintains the traceability of kilogram using NPK-57, which is kept under the custody of the director of CSIR-NPL. Once every 10 years, NPK-57 is sent to BIPM and is calibrated against IPK (CSIR-National Physical Laboratory n.d.). The last calibration occurred in 2012, and after following the CCM decision on implementing the redefinition of the kg, the uncertainty of NPK-57 is 49 μg at $k = 2$.

Within India, CSIR-NPL disseminates traceability to industries, government departments, R&D organizations, legal metrology organizations, regional calibration laboratories, and other customers through its calibration service traceable to NPK-57. The most important customers who avail of the calibration service of CSIR-NPL include the pharmaceutical industries, aviation industries, satellite or aerospace industries, bullion markets, automobile industries of India, Indian army, Indian navy, Indian air force, DRDO, ISRO, etc. CSIR-NPL also provides traceable calibration services to SARC NMIs.

NPK-57 is a very precious artifact, so it can't be used in day-to-day calibration works. For that, NPL has four transfer standards of 1 kg, two of them made of stainless steel and two of them made of Ni-Cr alloy. These transfer standards are calibrated against NPK-57 every 3 years, and they are used to calibrate other working standards that vary from 1 mg to 500 kg. Working standards are made of stainless steel, brass, and Ni-Cr alloy. Working standards of NPL are calibrated against the transfer standards for 1 or 2 years. These weights are used to calibrate customers' weights through the subdivision or substitution method. CSIR-NPL uses a high-precision mass comparator for calibration, such as a 1 kg vacuum mass comparator of Sartorius make, having repeatability in a vacuum less than 0.1 μg. For calibration up to 5 g mass, the manual mass comparator is used with a readability of 1 μg. To provide better accuracy in mass measurement to its user, CSIR-NPL has purchased a robotic mas comparator (Mettler Toledo, e5) for mass up to 5 g with improved readability of 0.1 μg. Mettler Toledo XP604KM mass comparator is used to calibrate masses of a higher order, such as 500 kg, with the readability of 50 mg. The maximum mass calibration capability of CSIR-NPL is 2000 kg which can be calibrated with repeatability of 1 g using the KE2000 mass comparator. Figure 7 depicts the hierarchy and traceability of mass standards starting from IPK in India before the redefinition of the kilogram. Following the kilogram's new definition, there is a change in the traceability pyramid shown in Fig. 8. As the change is in the definition of the kilogram only, the IPK will be replaced in due course by the new realization technique based on the Planck constant as the primary source of traceability in this chart.

Post-Redefinition and the Need for Establishing New Methods for Traceability

With the worldwide implementation of the new definition of the unit of mass, the IPK lost its status as the primary standard and ceased to be the source of traceability for mass calibrations. There is a transition period for which the Consultative

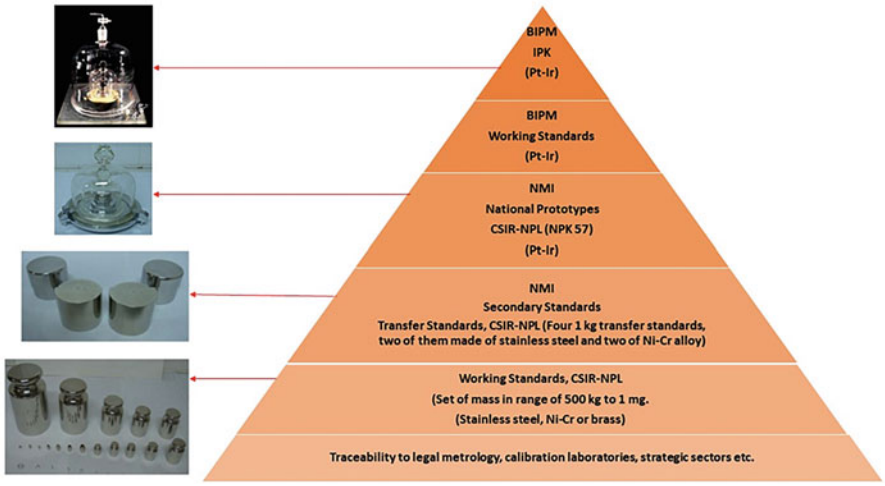

Fig. 7 Hierarchy of mass dissemination in India before redefinition

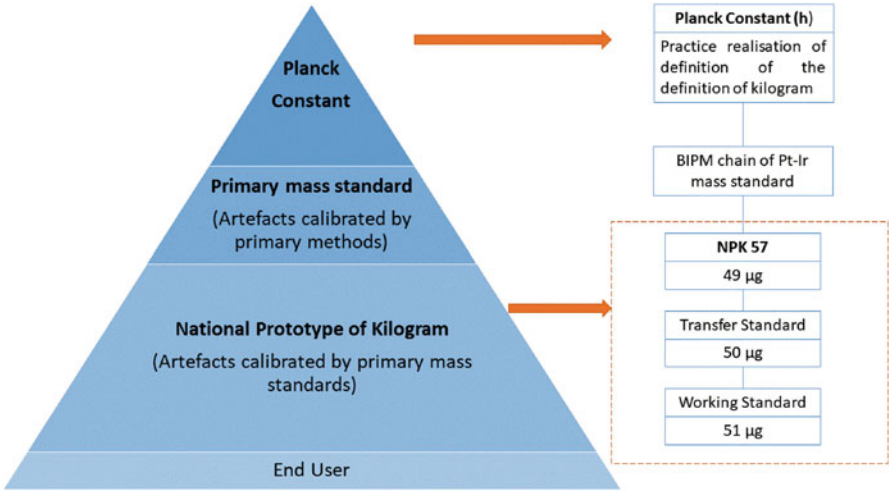

Fig. 8 Hierarchy of mass dissemination in India after redefinition

Committee for Mass and Related Quantities (CCM) has put in place a mechanism that follows a four-phase program that would ensure traceability of the measurements shown in Fig. 9; however, details can be found in (Ehtesham et al. 2020; Davidson and Stock 2021; CCM n.d.; Stock et al. 2020; Bettin et al. 2019). The end of phase 4 will mark the full implementation of the new definition, by which time the new realization methods based on h would become available to provide traceability. In this new scheme of things, there can be many sources for traceability, unlike the

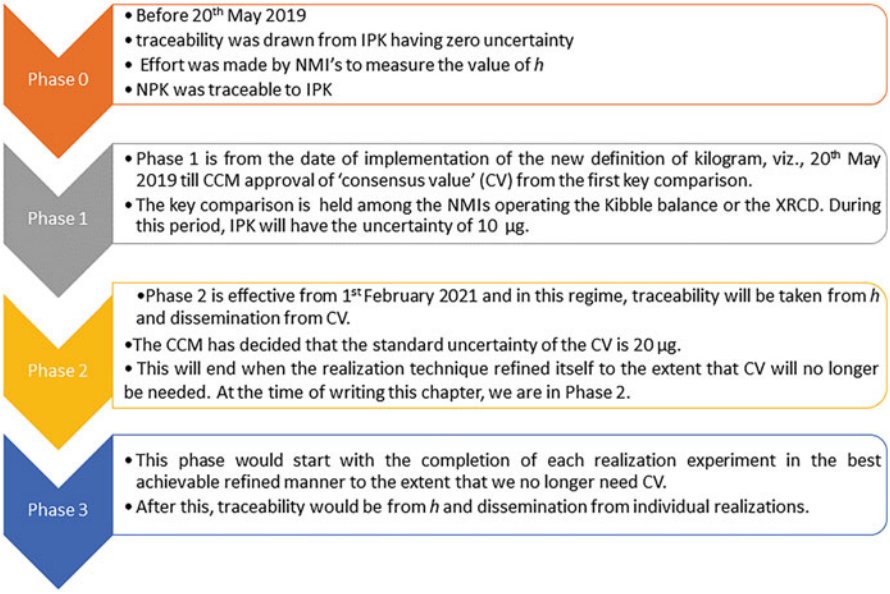

Fig. 9 Four-phase dissemination mechanism for kilogram

case with IPK, as any NMI that has established the new realization method can provide the needed traceability.

Basically, two methods, viz., the Kibble balance and the X-ray crystal density (XRCD) technique, are available to realize the mass unit based on *h* (Bettin et al. 2019; Kibble and Hunt 1979). As of now, a couple of leading NMIs, like NPL, UK, and NIST, USA, have been able to establish the Kibble balance facility in their countries. There are a few other NMIs, like the National Research Council (NRC-Canada), BIPM-France, Swiss Federal Office of Metrology and Accreditation (METAS-Switzerland), Centre de Metrologie Electrique (BNM-LNE/CME-France), National Institute of Metrology (NIM-China), Korea Research Institute of Standards and Science (KRISS-Republic of Korea), etc., which also have either developed their Kibble balance or have reached an advanced stage of the development. Once operational, all these countries will be able to provide traceability for mass measurements both nationally and internationally (Ehtesham et al. 2020).

Methods of Realization of New Definition of Kilogram

The new definition of kilogram eliminates the dependency on an artifact for the global traceability chain of mass; instead, it provides an opportunity for every NMI the possibility to realize a kilogram. There are two foremost techniques to realize kilogram from the atomic or quantum standards, i.e., Kibble balance and the XRCD method. Having redefined the kilogram, the emphasis now is on making an available

number of realization options with the required measurement accuracy and lowest possible uncertainty that would fulfil the CCM requirements envisioned in the four-phased traceability scheme. This will put in place a robust infrastructure necessary to fully implement the new definition by realizing the unit of mass widely. XRCD and Kibble balance are the two independent methods available for relating mass to the Planck constant *h*. Both these methods were used for the experimental determination of the most accurate value of *h* that has been used for the redefinition of the kilogram. Now, after the implementation of the new definition, both these techniques are being used reversely as realization methods for the redefined kilogram. Both of them have been able to realize the kilogram with an uncertainty of a few parts in 10^8. The laboratories that have developed them are working to improve their instruments and measurements to reduce uncertainty further increasingly.

The two laboratories, viz., PTB, Germany, and NMIJ, Japan, realized the kilogram by the XRCD method. The XRCD method involves counting the number of atoms in a crystal where the mass of the atom is related with h through the Avogadro number N_A and the Rydberg constant R_∞. The measurement is performed using a sphere made of silicon atoms of accurately known isotopic composition (^{28}Si), and the number of atoms in the sphere is counted by measuring its volume and lattice constant.

The Kibble balance works by balancing the gravitational force on the mass by an electromagnetic force generated by a current-carrying coil immersed in a magnetic field. Kibble balance was the first experiment that linked microscopic mass to macroscopic physical mass. The connection between the test mass and h is achieved through the two quantum phenomena based on electrical measurements that employ the Josephson effect and the quantum Hall effect. About a dozen NMIs are working on developing the Kibble balance in their countries. As of now, laboratories with operational Kibble balances include NIST, USA; BIPM, France; KRISS, Republic of Korea; NIM, China; and NRC, Canada, and they have participated in the first key comparison of realizations of the kilogram (CCM.M-K8.2019) conducted for verifying the consistency of these individual realizations, an essential step in the planned phase-wise dissemination of the kilogram. The remaining sections of this chapter will present the basic theory underlying both the XRCD and Kibble balance techniques. But before dealing in-depth with primary realization techniques for kilogram, the role of quantum metrology has to be discussed first.

The Josephson Voltage Standard

Before dealing further with the Kibble balance principle, it is important to discuss two quantum phenomena-based standards, viz., Josephson voltage standard (JVS) and quantum Hall effect-based resistance standard (QHRS). The quantum volt is based on the inverse AC variant of the Josephson effect. The Josephson effect,

discovered in 1962 by Brian Josephson, is the tunnelling of Cooper pair condensates through a thin tunnel barrier separating two superconducting electrodes without resistance. The Josephson effect links voltage to frequency, the fundamental constants h and e, and an integer "n" only:

$$V_J = n\frac{h}{2e}f$$

where V_J is the quantized Josephson voltage, f is the frequency of the RF radiation used to irradiate the Josephson junction, e is the electronic charge, and n is an integer. Irradiation of a Josephson junction by electromagnetic radiation of frequency f, the Josephson oscillations get synchronized with the irradiation frequency, and the voltage V across the junction is a stepwise function of the bias current. The height of the voltage step is given by $V = (h/2e)f$. Thus, the voltage V is independent of the materials of the junction and its operating temperature. The phenomenon described above is referred to as the AC Josephson effect or, strictly speaking, the inverse AC Josephson effect. Since the frequency can be measured with an uncertainty of the order of 10^{-15}, therefore, the Josephson effect provides a quantum voltage standard producing a voltage reference V_R with reproduction uncertainty unavailable to classical standards. The voltage V_R is given by the following:

$$V_R = n\frac{h}{2e}f = n\frac{f}{K_J}$$

Here n is the step number in the stepwise current-voltage characteristic. It is interesting to note that the value of the Josephson constant $K_J = 2e/h$ is determinable with an accuracy better than that of e and h separately. The BIPM has fixed the following value of $K_J = 2e/h$ to be 4835979×10^{12} Hz/V. This conventional value of the Josephson constant is denoted by $K_{J\text{-}90}$:

$$V_{90} = n\frac{f}{K_{J\text{-}90}}$$

The above equation represents the unit volt, and $K_{J\text{-}90}$ is taken as a constant with zero uncertainty as there is no comparison to SI quantities made. A realization of the volt is achieved; the SI definition of volt is used. The uncertainty of voltage measurements based on $K_{J\text{-}90}$ is a few parts in 10^{10} or better (Wood and Solve 2009).

The Quantum Hall Resistance Standard

The quantum Hall effect (QHE) is a characteristic of a perfectly quantized two-dimensional electron gas (2DEG) and provides an invariant reference for resistance

linked to the natural constants, "h" the Plank constant and "e" the electronic charge. The 2DEG can be realized in a high-mobility semiconductor device such as silicon MOSFET (metal-oxide-semiconductor field-effect transistor) or GaAs/$Al_xGa_{1-x}As$ heterostructure, monolayer graphene, and some topological insulator thin films. In the GaAs Hall device, the 2DEG is located in the inversion layer formed at the interface between two semiconductors, one of them acting as the insulator. When the Hall device is cooled to a low temperature (T ~ 1 K or lower) and subjected to a high magnetic field (6–12 T), the 2DEG is completely quantized, and for the fixed source to drain current, the Hall voltage V_H shows a series of constant voltage plateaux (called Hall plateau) as a function of the applied field. Simultaneous to these plateaux, the longitudinal transport becomes dissipationless, as shown by the vanishing longitudinal resistance. In the limit of zero dissipation, that is, the longitudinal resistance along the direction of the current remains zero over the plateau region, the Hall resistance of the ith plateau $R_H(i)$ is quantized according to the following relation:

$$R_H = \frac{V_H}{I_{SD}} = \frac{h}{ie^2} = \frac{R_K}{i}$$

Here "i" is an integer and R_K is the von Klitzing constant. It follows that for $i = 1$ R_H (1) = R_K. The QHE has a universal character, i.e., it does not depend on the (1) device type, (2) plateau index, (3) mobility of the charge carriers, and (4) device width at the level of the relative uncertainty of 3×10^{-10}. The $R_K = 25812.807\ \Omega$ was adopted by all member states of the Meter Convention and came into effect as of 1st January 1990. The resistance scaling process linking the quantum Hall resistance (QHR) to decade value resistors uses cryogenic current comparator (CCC), Josephson potentiometer, Hamon network, or direct current comparator (DCC) bridge. The smallest uncertainty can be obtained using a CCC and a 100 Ω standard resistor. The value of R_K agreed upon by the member states of BIPM was referred to as $R_{K\text{-}90}$ and $R_{K\text{-}90} = 25812.807\ \Omega$ in 1990. Just as in the case of the Josephson voltage standard, $R_K = \frac{R_{K\text{-}90}}{i}$ proves a representation of the unit of resistance, viz., Ohm. $R_{K\text{-}90}$ is treated as a constant with zero uncertainty. In the new SI, the elementary charge and the Planck constant are assigned fixed values. Consequently, the von Klitzing constant R_K and the Josephson constant K_J have fixed values with zero uncertainty (Jeckelmann and Jeanneret 2001).

Kibble Balance

The new definition links mass to the Planck constant, and its realization is performed with the Kibble balance. Dr. Bryan Peter Kibble (NPL, UK) in 1975 has given the principle of watt balance. After his death, in his honor, the watt balance was renamed as Kibble balance in 2016.

Dr. Bryan Peter Kibble (1938–2016) https://www.theguardian.com/science/2016/aug/11/bryan-kibble-obituary

Principle of Kibble Balance

The principle of Kibble balance involves balancing of mechanical power with electrical power and takes advantage of the fact that electrical power is linked to the Planck constant by two quantum phenomena, i.e., quantum Hall resistance (QHR) and Josephson voltage standard (JVS).

It operates in two different modes, i.e., static mode/force mode and dynamic mode/velocity mode as shown in Fig. 10. In static mode, a mass in association with coil is hanged from a knife edge in a balance. The coil having wire of length L is positioned in a magnetic field of flux density B. The suspended mass will experience downward gravitational force which is balanced by an equal and opposite electromagnetic force by sending a current I through the coil:

$$mg = ILB \tag{1}$$

In dynamic mode, the coil is moved through the magnetic field at a vertical speed v so that a voltage U is induced:

$$U = BLv \tag{2}$$

Assuming BL to be constant in both the modes and eliminating it from Eqs. (1) and (2):

$$mgv = UI \tag{3}$$

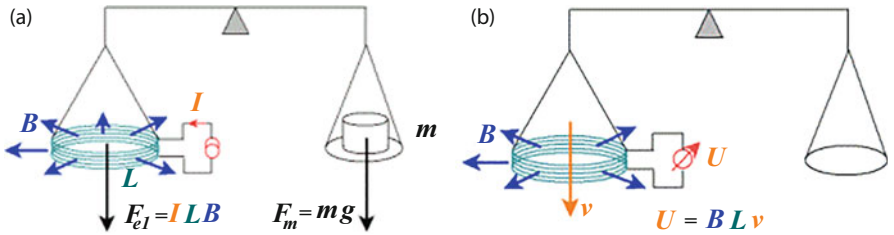

Fig. 10 Schematic depicting basic principle of Kibble balance. (**a**) Static mode of Kibble balance. (**b**) Dynamic mode of Kibble balance. (Adapted from https://www.bipm.org/en/bipm/mass/watt-balance/wb_principle.html)

From Eq. (3) it can be observed that the key quantities to be measured are the voltage (U) and current (I). From the primary standards of the voltage and resistance, i.e., Josephson voltage standard (JVS) and quantum Hall resistance (QHR), respectively, traceability of voltage and current can be achieved. The mass is given by the following:

$$m = \frac{UI}{gv} \tag{4}$$

From Ohm's law, I can be written as $I = V/R$, where V is the voltage drop across standard resistor R and then:

$$m = \frac{U}{gv}\frac{V}{R} \tag{5}$$

The two voltages U and V both are given in terms of the Josephson constant K_J:

$$K_J = \frac{2e}{h} \tag{6}$$

$$U_n = n\frac{hf}{2e} = nfK_J^{-1} \tag{7}$$

The resistance is expressed in terms of the von Klitzing constant (R_K) through the quantized Hall resistance:

$$R = \frac{1}{i}\frac{h}{e^2} = \frac{R_K}{i} \tag{8}$$

Thus, Eq. (5) can be written as follows:

$$m = \frac{in_1f_1n_2f_2K_J^{-2}}{gvR_K} = \frac{in_1f_1n_2f_2}{gv} \times \frac{h^2}{4e^2} \times \frac{e^2}{h} = (in_1n_2) \times \frac{f_1f_2}{4gv} \times h \tag{9}$$

Finally:

$$m = \frac{bf^2}{4gv}h \tag{10}$$

In Eq. (10), m is directly linked to h, where v is measured in m s^{-1} and g is measured in m s^{-2}. The frequency (f) is delivered as a constant in the Josephson standard, and b is determined by the quantized Hall plateau number (generally $i = 2$) and the Shapiro step number.

Planck Balance

The full-fledged Kibble balance is a very sophisticated system and requires a large amount of money and scientific skill to build. Additionally, it cannot be used for the day-to-day calibration purposes. Here the Planck balance provides a good alternate for NMI to carry out regular calibrations of E1 and E2 class weights. PTB-Germany plans to develop two tabletop Planck balance (PB). The first one is called PB2, and the second balance is called PB1 in collaboration with Technische Universität Ilmenau. Both balances will be robust in design and meant for regular calibration of masses of continuous range, unlike many fully developed Kibble balances in the world. Though PB is based on the principle of Kibble balance, it avoids some of the stringent requirements of Kibble balance as it is meant to calibrate E1 and E2 class weights only. Thus the low standard uncertainty set by CGPM for Kibble balance is not mandatory here. The major role of PB is not to accurately determine the value of the Planck constant but to be used in routine calibration to disseminate the unit kilogram to its nominal ranges. Unlike fully matured Kibble balance across the globe, which uses one nominal value for mass, generally 1 kg to measure the value of Planck constant as accurately as possible, PB can calibrate a various range of mass and is made for industrial use (Rothleitner et al. 2017).

PB1 calibrates weights in the range of 1 mg to 1 kg, and PB2 calibrates weights in the range of 1 mg to 100 gm. PB1 is aimed to calibrate E1 class weights with a relative uncertainty of 8.4×10^{-8}, and PB2 is meant to calibrate E2 class weights with a relative uncertainty of 2.7×10^{-7}. In the recent publication (Rothleitner et al. 2020), PTB has mentioned the development of PB1 so far. The balance is constructed mainly using standard industrial equipment such as commercial load cells and interferometers. Mass in the range of 1 kg to 100 g, 100 g to 10 g, and 10 g to 1 mg is tested for static and dynamic mode both in the vacuum chamber. For 1 kg mass, the relative standard deviation for static mode was 0.6 ppm, and for dynamic mode, it is 2.4 ppm (Rothleitner et al. 2020; Lin et al. 2020). For PB2 the latest combined uncertainty for 20 g measurement is reported as 2.47 ppm in which vertical alignment error is a significant factor (Vasilyan et al. 2021). PB2 can realize SI unit of mass for five decade values in range of 1 mg to 50 g.

Joule Balance

The NMI of China, National Institute of Metrology (NIM), had proposed the joule balance experiment back in 2006, and to date, they have developed two joule balances called NIM-1 and NIM-2. The joule balance is inspired by the Kibble balance, but unlike the two modes of measurement in Kibble balance, it has static mode only, with the dynamic mode replaced by inductance measurement, thus

changing the final power balancing equation of Kibble balance to energy balancing, from where it got its name (Li et al. 2015). Joule balance consists of two coils: an inner fixed coil called an exciting coil, which is used to produce a magnetic field when the current (I_{ex}) flows through it (Zhonghua et al. 2014; You et al. 2017). The outer coil is a set of two coils in which current (I_{mo}) is flowing in opposite directions to each other. In the static mode of joule balance, the gravitational force of mass is balanced by the electromagnetic force between the exciting coil and outer coil. It can be represented as follows (Zhonghua et al. 2014):

$$\underbrace{-\left(\frac{\partial M}{\partial z} I_{ex} I_{mo}\right)}_{\text{Force between exciting coil and movable coil}} + \underbrace{mg}_{} = \underbrace{\Delta f_z(z)}_{\text{Residual Force}} \tag{11}$$

Here, M is the mutual inductance between both coils, and z is the position where mutual inductance is being measured. By integrating Eq. (1) for position z_1 and z_2:

$$[M(z_1) - M(z_2)] I_{\text{ex}} I_{\text{mo}} + mg(z_1 - z_2) = \int_{z_1}^{z_2} \Delta f_z(z) dz \tag{12}$$

Equation (12) is the energy balancing equation of joule balance (Zhonghua et al. 2014). Mutual inductance can be measured in terms of change of flux, and change of flux can be accomplished by the integration of induced voltage (U) with respect to time in the coil. Thus Eq. (12) is traceable to h through JVS and QHR. The latest reported relative uncertainty by NIM-2 joule balance in 2019 was 5.2×10^{-8} for 1 kg Pt-Ir mass and 6.5×10^{-8} for 1 kg stainless steel mass (Li et al. 2020).

The XRCD Method

The next technique to realize a new definition is the XRCD method. The basic principle of the XRCD method is to compare the unknown mass to the mass of a single atom by counting atoms in a nearly perfect Si sphere. This method is easy to conceptualize as the quantity of the same type, i.e., counting the atomic mass of an atom to make it equal to mass. Here the mass of the atom is known in terms of the Planck constant:

$$N = \frac{8V_{\text{S}}}{a^3} \tag{13}$$

In Eq. (13), N is the number of Si atoms in the micro-volume of the crystal, V_{S} (a^3) is the volume of Si sphere, a is the lattice constant, and 8 is the number of atoms in one unit cell of Si. The mass of the Si sphere is given by the following:

$$m_{\text{s}} = Nm(\text{Si}) \tag{14}$$

Here m(Si) is the mass of a single Si atom. Planck constant h and mass of single-electron m(e) can be expressed as follows:

$$R_\infty = \frac{m(\mathrm{e})c\alpha^2}{2h} \tag{15}$$

Here c is the speed of light in a vacuum, α is the finite-structure constant, and R_∞ is the Rydberg constant. The relative uncertainty of R_∞ and a is 5.0×10^{-12} and 3.2×10^{-10}, respectively. Again, m(Si) is related to m(e) by the following:

$$\frac{A_\mathrm{r}(\mathrm{Si})}{A_\mathrm{r}(\mathrm{e})} = \frac{m(\mathrm{Si})}{m(\mathrm{e})} \tag{16}$$

Here A_r(e) and A_r(Si) are the relative atomic masses of electron and Si, respectively. The relationship between m(Si) and the Planck constant h is given by the following:

$$\frac{h}{m(\mathrm{Si})} = \frac{1}{2}\frac{A_\mathrm{r}(\mathrm{e})}{A_\mathrm{r}(\mathrm{Si})}\frac{\alpha^2 c}{R_\alpha} \tag{17}$$

Finally, the sphere mass is expressed in terms of h by the following:

$$m_\mathrm{s} = \frac{2R_\infty h}{\alpha^2 c}\frac{A_\mathrm{r}(\mathrm{Si})}{A_\mathrm{r}(\mathrm{e})}\frac{8V_\mathrm{s}}{a^3} \tag{18}$$

Taking into consideration mass deficit (m_d) due to impurities and vacancies and mass of the surface layer (m_SL) on Si sphere, Eq. (18) can be written as follows:

$$m_s = \underbrace{\frac{2R_\infty h}{\alpha^2 c}\frac{A_r(Si)}{A_r(e)}\frac{8V_s}{a^3} - m_d}_{\text{Mass of the Si Core}} + \underbrace{m_{SL}}_{\text{Mass of the surface layer}} \tag{19}$$

The National Metrology Institute of Japan (NMIJ) is realizing kilogram using the XRCD method with the help of two 1 kg ^{28}Si-enriched spheres fabricated by the International Avogadro Coordination project. As per their latest publication, the relative standard uncertainty is estimated as 2.1×10^{-8}, and the highest contributing factor is the core volume of Si sphere, estimated as 1.8×10^{-8} (Kuramoto et al. 2021).

Twin Pressure Balance

Measurement Standard Laboratory (MSL), New Zealand, is implementing the principle of Kibble balance in another unique way using two pressure balances joined together using a differential pressure sensor. In Kibble balance, force in static mode and velocity of the coil in dynamic mode must be in line with the gravitational force at the point of measurement. A difference in alignment between two modes of 75 μrad can cause a cosine error of 3 parts in 10^9, which is quite significant when the accuracy of Kibble balance is a concern (Sutton et al. 2016). Thus to eliminate the misalignment, the twin pressure balance attaches the coil to one of the pistons of

the piston-cylinder unit, and the downward force on the coil can be compared to the second pressure balance also called a reference pressure balance. This eliminates the horizontal movement of coil hence making the vertical movement reproducible and insensitive to the horizontal forces. In the static mode of measurement, the twin pressure balance works as a force comparator where force difference is measured by the pressure difference generated between two pressure balance. When mass is on the equation for static mode (Fung et al. 2020):

$$PA + I\gamma = (m + m_{\text{tare}})g \tag{20}$$

Here, m is the measured mass, mass of tare is m_{tare}, P is the pressure, I is the current in the coil, and γ is the flux linkage of magnetic field B. When mass is off the equation for static mode, it changes to the following:

$$(P + \Delta P)A = I\gamma + m_{\text{tare}}g \tag{21}$$

Combining Eqs. (20) and (21), final equation for static mode of measurement comes out to be:

$$mg = 2I\gamma - \Delta PA \tag{22}$$

For dynamic mode the coil is attached to the piston with the help of three rods and is moved with the constant velocity (v) guided by the second pressure balance in the presence of the constant magnetic field. The equation for induced voltage (U) in the coil for dynamic mode measurement is as follows:

$$U = -\gamma.v \tag{23}$$

Details of the MSL twin pressure balance can be obtained from (Sutton et al. 2016; Fung et al. 2020).

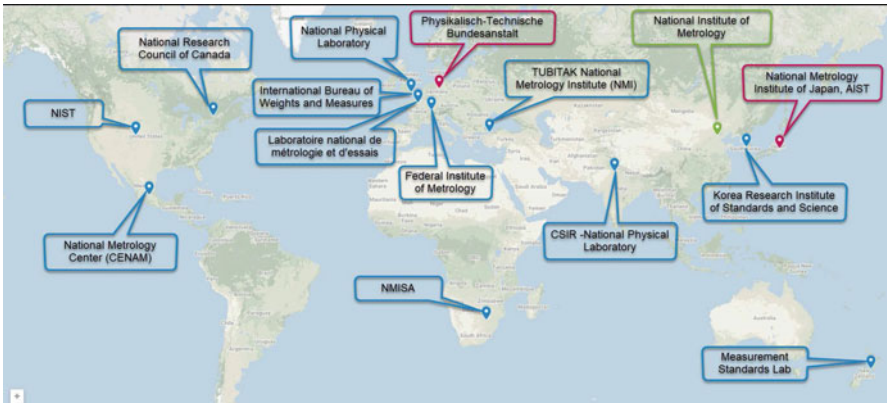

Fig. 11 World map showing the presence of Kibble balance technique (blue), joule balance technique (green), and XRCD method (red)

The International Status of Existing Primary Realization Methods (Fig. 11)

NPL, UK	Dr Bryan Peter Kibble invented Kibble balance in 1976 MARK-I and MARK-II are two Kibble balances of NPL MARK-I was the first Kibble balance having yoke-based permanent magnet system. A flat magnetic profile was achieved by a figure 8-shaped coil hung vertically in the center of the air gap having a magnetic field of 0.68 T The drawback of this design was that because only a fraction of the coil length was used to produce force, thus, to meet requirements, a massive system was fabricated having the weight of the magnet and coil to be 6000 kg and 30 kg, respectively. This significantly increases the heating of the system NPL, UK, is now working on a single-mode two-phase Kibble balance (Robinson 2012; Stock 2012)
NIST, USA	The initial results from NIST's Kibble balances were published in 1989 To date, they have developed four full-fledged Kibble balances The latest Kibble balance called NIST-4 uses Sm_2Co_{17} as a permanent magnet and low-carbon steel as a yoke It works in a vacuum, with a relative uncertainty of 1.3×10^{-8}, published in 2017 (Haddad et al. 2017) NIST has also developed a Lego Kibbe balance for 10 g and achieved uncertainty of the order of 10^{-2} (Chao et al. 2015) One of the recent activities taken up by NIST is developing a tabletop Kibble balance called "KIBB-g1 Kibble balance" for mass up to 10 g with targeted uncertainty of 10^{-6} (Chao et al. 2020; Chao et al. 2019)
NRC, Canada	The Kibble balance project started in 2009 When the MARK-II of NPL, UK, was sent to NRC Canada NRC successfully identified and corrected a systematic error relating to the effect of the test mass's weight on the equipment's construction (Wood et al. 2017) The relative uncertainty reported in 2017 is 9.1×10^{-9}, which is the smallest in the world (Wood et al. 2017)
BIPM, France	The Kibble balance project started in 2005 It operates in one-mode two-measurement scheme technique It operates in a vacuum and uses a bifilar coil The relative uncertainty of 1 kg Pt/Ir artifact published by BIPM in 2020 is 49 μg. Details of the BIPM Kibble balance can be read in (Fang et al. 2016, 2020)
KRISS, Korea	The Kibble balance project started in 2012 Out of four different permanent magnet configurations widely used by different NMIs, KRISS uses closed cylindrical permanent magnet system (Kim et al. 2014, 2017; Choi et al. 2016) The latest relative uncertainty of KRISS Kibble balance published in 2020 is 1.2×10^{-7} (Kim et al. 2020)

(continued)

LNE, France	The Kibble balance project started in 2002 It uses an indigenously designed flexure bearing balance, and in 2017, the balance was operated in air, and h is calculated with the relative uncertainty of 5.7×10^{-8} (Thomas et al. 2017) Recently the balance was operated in a vacuum, and details of the experiment can be read in (Espel et al. 2020)
Measurement Standard Laboratory (MSL), New Zealand	MSL Kibble balance is based on twin pressure balance Details of the MSL twin pressure balance can be obtained from (Sutton et al. 2016; Fung et al. 2020) The latest development on MSL Kibble balance like the development of mass loader with pneumatic control, construction of vacuum chamber for balance, magnet assembly and designing of coil, etc., is present in (Fu 2021)
Federal Institute of Metrology (METAS), Switzerland	METAS has created a 100 g balance called MARK II (Eichenberger et al. 2011; Schlamminger and Haddad 2019) They have also developed a 1 kg Kibble balance which operated in a vacuum, and the first set of measurements was conducted in 2021 (Eichenberger et al. 2022) The reported uncertainty published in 2022, for 1 kg stainless steel test mass at $k = 1$, is 43 parts in 10^9
National Metrology Institute of Japan (NMIJ)	Work on XRCD method The publication in 2021 reported the relative standard uncertainty to be 2.1×10^{-8} Details can be found in Kuramoto et al. (2021)
The NMI of China, National Institute of Metrology (NIM)	In 2006 principle of Joule balance was proposed by NIM China The first joule balance developed by China was called NIM 1 The advanced version of NIM 1 balance was NIM 2, which operates in a vacuum. Details of NIM 2 Joule balance can be read in Li et al. (2020)
The National Metrology Institute of Turkey (UME)	The National Metrology Institute of Turkey (UME) is using the oscillating magnet technique to realize the new definition of kilogram In this technique, the magnet oscillates around the equilibrium position, and the signal obtained from static mode and dynamic mode measurement is read in the frequency domain According to the latest publication (Haci et al. 2020), in this novel technique, the effect of environmental noise on the setup is comparatively lower than the traditional Kibble balance A commercial Michelson interferometer is used for displacement measurement in their Kibble balance
NMISA, South Africa	A Lego Kibble balance for 1–3 g and a modified equal arm Kibble balance for 1–3 g have been created by NMISA in South Africa A two pan equal arm balance has been converted to an equal arm Kibble balance by NMISA

(continued)

	On both sides, the 3D-printed structure has been adjusted to accommodate coil and magnet assembly. To create a magnetic field, a neodymium ring magnet (N42) is employed (Mametja et al. 2018) The coil is made up of copper wire of 0.1 mm diameter and has 3000 turns. The measured BL value for NMISA Kibble balance is 14.15 Tm ± 0.12% The modified equal arm model reported less than 1% relative uncertainty, with the Lego software resolution being a limiting factor as this was fixed to 2 decimal digits (Sonntag et al. 2020)
CSIR-National Physical Laboratory (NPL-India)	Developed demonstrational model of 1 g Kibble balance setup (Kumar et al. 2017; Ehtesham et al. 2022) Measurements were conducted for 1 g and achieved an uncertainty of less than 1% Balance is upgraded for 1–10 g, and measurements are conducted. Publication of these results is underway

Conclusion

This chapter discusses the advancement of the mass standard with respect to primitive as well as the modern era. Primary advances happened locally in different parts of the world, which predominantly attended to the requirements of the local communities in their respective areas. With the expansion and advent of trading, more and more sophisticated techniques were developed that eventually resulted in the modern ultrahigh-precision balances of various types in use today. Further authors also discuss the crucial advances that paved the path for the redefinition of the kilogram which advocate the philosophy of time-invariant measurement. The change in traceability chain after and before the redefinition of kilogram is covered for India as well as globally. The role of quantum standards in the realization of the new definition of kilogram is also explained in detail. Authors have briefly discussed the presently existing realization methods which includes fully established (Kibble balance and the XRCD) as well as methods which are under development. Briefly, the present status of different NMI across the globe working on the different primary realization techniques is also discussed. The advantage of the new definition is that it gives the flexibility to develop methods which are convenient to user for the realization of kg in terms of h.

Abstract

Optical Frequency comb has become a ruler of light nowadays for standard of length. A notable synergy among existing technologies occurs for stabilization of laser frequencies in the rule of the frequency spectrum, called "comb" of sharp and equidistance lines. With such an optical frequency comb, the exact frequencies of the entire comb lines are measured, revolutionizing the measurement of length in more precise way and realizing SI Unit Meter with better accuracy. This capability has transformed optical frequency metrology for better precision. The pulse from Optical Frequency Comb can produce a temporal coherence interference fringe pattern, which can be used as a practical method for realization of SI Unit Meter. The emergence of the optical frequency comb know-how, in 2005 (Nobel Prize in Physics) has eliminated the demand for knotty frequency chains. By straight connecting, the second, using frequency standards of Cs, or Rb, by optical frequency comb, we can set up a novel technique for realistic realization of length of the SI unit Meter (Primary Standard). By means of stabilizing and characterizing the two different constraints – the carrier offset frequency f_0 and the repetition frequency f_r of the optical comb is effectively used for practical realization of SI unit "Metre." The accuracy in the measurement of the length

increased by many order using optical frequency comb, i.e., 2×10^{-13} instead 10^{-7} by using Iodine stabilized He-Ne Laser. In this chapter we present a review of optical frequency comb as a new quantum standard for realization of SI unit "Metre." A brief review of determining the absolute value of laser frequency in calibration using an optical frequency comb is illustrated here in this chapter.

In this chapter we reviewed the optical frequency comb as a novel tool for realization of SI unit Meter for length metrology. Particularly, an iodine-stabilized He-Ne laser incessantly sweeps to a steady optical frequency comb, where its output frequency is modulated over a wide spectrum to determine the exact frequency using optical interferometry. This method established a practical method to measure length in terms of SI unit meter with minimum uncertainty, which is straight traceable to SI unit second (Time Standard).

Introduction

Length is one of the most vital physical parameter, and its accurate measurement is of most significance for development of science and technology for the benefit of human race. It is the most common measurement system used by human from finding the smallest distance inside a nucleus to farthest interstellar bodies. It is the most familiar unit of measurement in our daily life. In prehistoric Egypt and Mesopotamia, one of the initial standards of measuring the length was the cubit. The royal cubit, as shown in Fig. 1, was used to construct the key structures, which is even found today in Egypt. This cubit was the length, determined by taking the length of the pharaoh's arm, from elbow to the end of the middle finger plus the span of his hand. The royal cubit was made of granite and standardized using a rod. Similarly at other places where length measurements were used, they were determined using the length of the human body parts like foot, hand, and palm. In India and China, they standardized their units based on yard, Gaj, etc., but length measurements in Europe were still mainly using body parts until the eighteenth century.

The development of the metric system in eighteenth century is innovative. A French king tried to create a worldwide organism of measurement, which wasn't depend on human body size that is diverse from one person's body to another person's body or body parts or from one place to another place with different

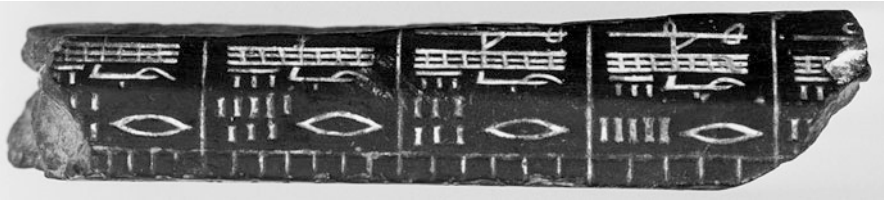

Fig. 1 A Royal Cubit as a standard for length used by rulers of Egypt (https://www.nist.gov/sites/default/files/images/2019/05/09/fragment_of_a_cubit_measuring_rod_met_102082_cropped.jpg)

geographical locations. A committee was formed for this, which wanted to establish a system "for all times, for all peoples." After the French revolution, the idea of a metric system of units initiated. There was a strong will among the people of the committee that the new unit that was going to be defined for length shall be equal to "one ten-millionth of the distance from the North Pole to the Equator (the one fourth part (quadrant) of the Earth's circumference). This was measured along a straight line over the meridian that was passing through Paris" (Larousse 1874). It took more than 6 years (1792–1798) by Pierre Méchain and Jean-Baptiste Delambre and their team for surveying the meridian arc (Alder 2002). In 1799, several platinum bars were made, and based on those bars the definition of the meter was decided and kept in the National Archives in the form of Meter Bar known as the mètre des Archives on 22 June 1799 (Comptes Rendus de la 7e CGPM 1927; Babinet 1829).

The meter was legitimately recognized as an international unit of measurement of length by "Metre Convention" of 1875. In 1889, BIPM introduced an element alloy rod made of platinum/iridium with a cross-shaped section, on which "one meter was fixed as the distance between two center lines, at a 0 °C", as shown in Fig. 2 [dimension of bar are in mm]. Thereafter in the seventh Conférence Générale des Poids et Mesures (CGPM), which took place in 1927, it was defined that this platinum–iridium bar is under atmospheric pressure and supported by two rollers and one meter is the distance between two points under atmospheric pressure (International Committee of Poinds and Measures and the Consultative Committee for the Definition of the Meter 1984; Quinn 1999, 2003; CSIR-National Physical Laboratory).

The first proposal that light could be a means for the realization of the length was probably made by the Babinet (A French natural philosopher) in 1827 (Meggers 1948). In 1893, Albert A Michelson declared in a review article that "light waves [were] now the most convenient and universally employed means we [possessed] for making accurate measurements" (Michelson 1893; Bönsch and Potulski 1998; The International Metre Commission 1870; The BIPM and the evolution of the definition

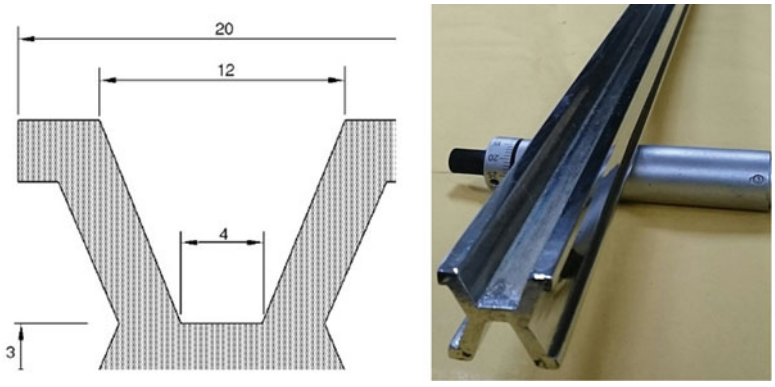

Fig. 2 The Tresca Meter Bar, a replica of National Prototype Metre Bar No. 57, given to India in 1957 for SI unit "metre" (Sharma et al. 2020)

of the metre 2016; Article 3; Barrell 1962; Phelps III 1966; https://en.wikipedia.org/wiki/International_Bureau_of_Weights_and_Measures; Michelson and Benoît 1895). In 1960 the definition of the meter closed relying on meter bar, which was based on an artifact and needed maintenance and continuous monitoring. At the 11th CGPM, in 1960, the meter was defined as the "**length equal to 1 650 763.73 wavelengths in vacuum of the light radiated at the transition between the levels $5d_5$ and $2p_{10}$ of 86Kr**" (International Committee of Poinds and Measures and the Consultative Committee for the Definition of the Meter 1984; Quinn 1999, 2003). This definition was decisively rooted in a krypton-86 spectral lamp with a wavelength of approximately 606 nm, which was realized by the German national metrology institute {Physikalisch-Technische Bundesanstalt (PTB)}, by Johann Georg Ernst Engelhard. With the discovery of laser parallel it was felt that one meter defined based on krypton is not able to stabilize and the definition needsa to be changed based on laser light. In the 12th CGPM, 1983, the Meter was defined again as "**The length of the path travelled by light in vacuum during a time interval of 1/299 792 458 of a second**." Light is understood as a plane electromagnetic wave or a superposition of plane waves and the length is considered along the propagating direction of the light wave. Under vacuum conditions there is a strict relationship between the frequency ν and the wavelength λ_0 of monochromatic light:

$$c_0 = \lambda_0 \cdot \nu = 299{,}792{,}458 \text{ ms}^{-1} \tag{1}$$

in which c_0 represents the speed of light in vacuum. It is having a fixed value by the meter definition in 1983. The realization of SI unit meter based on the 1983 definition needs superposition of at least two lights. Since the definition for the meter is valid for vacuum conditions, in most situations and in laboratory conditions the realization of the length is carried out at atmospheric conditions. Here, the accurate quantification of the air on the speed of light is of importance for correct measurement. Under atmospheric conditions, the air refractive index n gives reduction in the speed of light ($c = c_0/n$) as well as the wavelength. The relative effect of n is around 3×10^{-4} orders corresponding to 0.3 mm per meter of measured length under standard air conditions (Bönsch and Potulski 1998; Phelps III 1966; Michelson and Benoît 1895).

Realization of meter in terms of length traveled by light requires the measurement method. The SI definition for the meter presumes a measuring method based on laser interferometer. The accuracy of the realization of lengths is in perpetual development, triggered by new requirements placed on their accuracy.

The first physical phenomenon used was a multiple of a specific lamp's wavelength (CIPM 1960). The most important point of the post-1983 definition of the meter is that time is included in the definition. The accuracy demanded by the time of 1/299,792,458th of a second is precisely the accuracy in the definition of the meter, and, thus, length. Since time is the inverse of frequency, the precision by which a frequency is found translates into the precision of the length. The model light source that maintains a consistent frequency (wavelength) with high accuracy is the laser light source. This is why, initially, the iodine stabilized helium-neon laser's

wavelength was used as the practical means of realizing the length standard. BIPM recommend use of interferometry. In this we use lasers that need a quantum reference like hyperfine transitions of iodine, which act as reference for stabilization of He Ne lasers.

So for realization of SI Unit "Metre," an iodine-stabilized He Ne laser operating at 633 nm (474 THz) was employed and it is the most used laser in dimension metrology because of its easy operation, maintenance, and accuracy up to 10^{-11} part for calibration of commercial displacement measuring interferometer (see Fig. 3). The beat frequency method is used for calibration at 474 THz (633 nm) frequency/wavelength. This method is used for measurement of frequency difference between two stabilized lasers. The reference as said above in terms of frequency comes from another iodine-stabilized He- Ne laser having offset frequency controlled by a PLL (phase-locked loop) controller (Riehle et al. 2018; Pollock et al. 1983; Jennings et al. 1983a, b; Schweitzer et al. 1973; Layer et al. 1976; Layer 1980; Holzwarth et al. 2001; Yu et al. 2001; Gillespie and Fraser 1936; Ye et al. 1999, 2000; Zhang et al. 2001). In this laser the beat frequency of offset lock He-Ne lasers is controlled corresponding to the offset frequency, which is determined by temperature compensated crystal oscillator (TCXO). The frequency of the offset lock He-Ne laser is stabilized holding the offset frequency. But the stabilized laser frequency has some uncertainty for stabilization so a new definition is introduced and a new method is adopted to realize SI unit meter.

The latest definition of SI unit meter approved by 26th CGPM, put into practice on 20 May 2019 is "***The metre, symbol m, is the SI unit of length. It is defined by taking the fixed numerical value of the speed of light in vacuum c to be 299 792 458 when expressed in the unit m s–1, where the second is defined in terms of the caesium frequency ΔˇCs***."

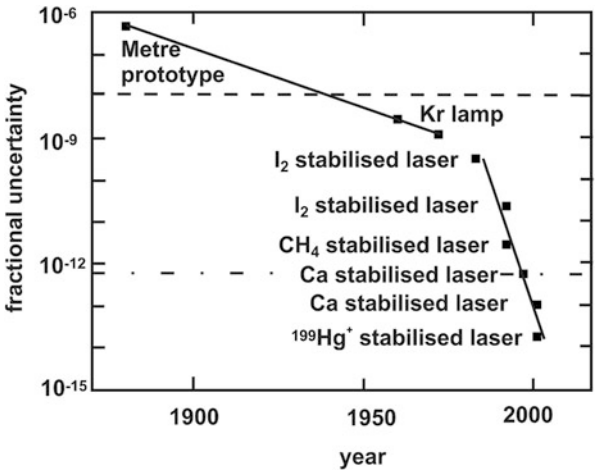

Fig. 4 Evolution of the realization of the meter according to the *mise en pratique* (MeP) (Quinn 2003)

Since there are teething troubles in measuring accurate and precise frequency of reference used, i.e., hyperfine transition in cesium atom, the accurate and precise information of reference frequencies is needed for tying optical frequencies with microwave. The main problem in the measurement of optical frequency is that the frequency in visible region is about a factor of 50,000 more than that of time standard (Cs clock) and there is hardly any technique available for frequency counting for frequencies in visible region. In this regard frequency comb is a new candidate for realization of new definition of SI unit meter (Udem et al. 2002; Ferreira-Barragáns et al. 2011). A pictorial view of realization of SI unit meter is shown in Fig. 4 and below time line in Table 1.

Realizing Meter Using an Intelligent Method by Ruler of Light: mb

As per new the definition, the most convenient method for realization of Si unit meter is to map out the laser frequency of optical frequency comb to the microwave standard, which is linked to the time. In this method, the second is directly linked to the meter. Its practical realization is by taking the fixed value of speed of light, $c_0 =$ 299,792,458 m/s, and the frequency of transition used. The Comité International des Poids et Mesures (CIPM) gave suggestions for the practical realization of the meter, as per methods mentioned in mise en pratique (in later text referenced as **MeP**) to define meter. The three methods to realize SI unit meter are as follows: (Gill 2005; Hollberg et al. 2005; Baklanov and Dmitriev 2002; Ye 2004; Joo et al. 2008; Salvadé et al. 2008; Cui et al. 2008; Minoshima et al. 2007).

(a) By means of the length l of the path traveled in vacuum by a plane electromagnetic wave in a time t; this length is obtained from the measured time t, using the

relation $l = c_0 \cdot t$ and the value of the speed of light in vacuum c_0 = 299,792,458 m/s.

(b) By means of the wavelength in vacuum l of a plane electromagnetic wave of frequency f; this wavelength is obtained from the measured frequency f using the relation $l = c_0/f$ and the value of the speed of light in vacuum c_0 = 299,792,458 m/s.

(c) By means of one of the radiations from a given list, whose stated wavelength in vacuum or whose stated frequency can be used with the uncertainty shown, provided that the given specifications and accepted good practice are followed.

In method (c) one can use a wave of known wavelength (in vacuum), which can be done by a direct measurement or a frequency given by one of the reference value of the recommended vacuum wavelengths listed by CIPM (Quinn 2003) below. In 2003, the International Committee for Weights and Measures (CIPM) recommended updated values for the wavelengths for the realization of the SI unit meter for practical definition.

CIPM recommended wavelengths for the definition of SI unit meter (Quinn 2003):

Frequency (THz)	Fractional uncertainty	Wavelength (nm)	Laser used
473.612,7	1.5×10^{-6}	632.990,8	HeNe unstabilized
473.612,353,604	2.1×10^{-11}	632.991,212,58	HeNe/I2
551.580,162,400	4.5×10^{-11}	543.515,663,608	HeNe/I2
563.260,223,513	8.9×10^{-12}	532.245,036,104	2*f* (Nd:YAG)/I2

One of the vital wavelength for length metrology is 633 nm (474 THz) from an iodine ($^{127}I_2$) He–Ne-stabilized laser. This $^{127}I_2$ He-Ne laser is used for realization of the SI meter and is nowadays in most NMIs commonly used for calibrating the frequency of lasers as recommended by committee (474 THz).

The International Committee for Weights and Measures (CIPM) Report on CCTF (CCL-CCTF WGFS & WGPSFS) on 6 June 2017 made its recommendations to all national metrology institutes (NMIs) to practice the optical frequency comb technique to the uppermost level of accuracy, for length calibration. The comb techniques are very convenient because it can offer traceability to the SI unit meter through Second and an optical frequency tuneable source as well as measurement technique (Ferreira-Barragáns et al. 2011; Samoudi et al. 2012).

What Is an Optical Frequency Comb and How Does It Work

Optical frequency comb is an optical frequency ruler in terahertz frequency region. It is composed of equally spaced electromagnetic field in frequency domain, generated by a femto-second laser in regular intervals of frequency and having a coherent phase with each other. The frequency of a piece of mode is given as per the following relation:

$$\nu_N = N \times f_{rep} + f_0 \tag{2}$$

Here ν_N: the optical frequency of the mode, N: a large integer (typically of the order of 10^6), f_{rep}: repetition rate of the laser pulses, and f_0: "carrier-envelop offset frequency," which is the difference of group velocity and phase velocity. It is to be noted that the electric field in each mode is not firmly the same, but it maintains a constant separation between two pulses as shown in Fig. 5.

The electromagnetic fields created by a fs laser is mixed with a cw laser whose frequency is ν_{cw} for measurement and detection. The corresponding mixed field is detected using a fast photodiode (whose bandwidth is f_{BW}). This results in a radio-frequency spectrum, consisting of two parts, the repetition rate f_{rep} and optical beat-notes frequency $f_{b,N} = |\nu_{cw} - N \times f_{rep} - f_0|$, where N is integer value such that $f_{b,N} < f_{BW}$. For detection of f_{rep} the photodiode are required. We have some specific operation region for residual noise of f_{rep} that enables the detection. At the current stage one can only rely on particular photodiode that is fully committed for the detection of f_{rep}.

f_0 is determined by the self-referencing technique or there are many other known techniques (like zero offset), which requires at least one octave (Ell et al. 2006; Matos et al. 2006; Fortier et al. 2006; O. l. w. G. r. r. IdeestaQE 2014; Coddington et al. 2008). A highly nonlinear fiber causes the broadening of the spectrum sufficiently to reach the octave spanning condition. These highly nonlinear fibers are engineered such that the pulses that are propagating inside it keeps a short pulse time duration and high peak intensity for creating high nonlinear effects. By four-wave mixing method, the nonlinear fiber gradually broadens the spectrum with a

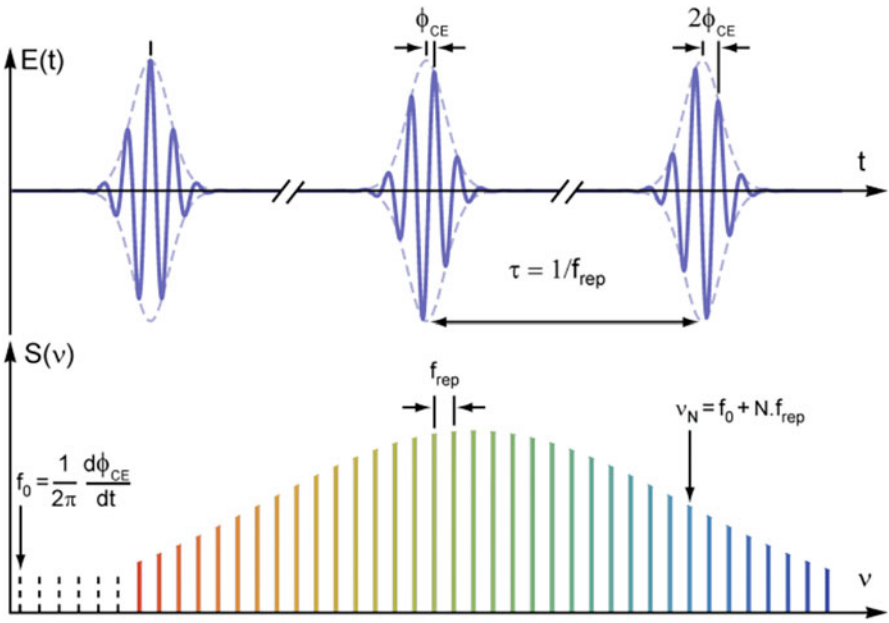

Fig. 5 An optical frequency comb with equally spaced frequency modes

factor equal or higher than two times the f_0. Using this one can calculate optical frequency $\nu_N = N \times f_{rep} + f_0$ and other with $\nu_{2N} = 2N \times f_{rep} + f_0$. By keeping two times the frequency ν_N in a nonlinear crystal, and detecting the optical beat-note frequency $2 \times \nu_N$ and ν_{2N} using a fast photodiode, one can get signal at frequency $|2N \times f_{rep} + 2f_0 - 2N \times f_{rep} - f_0| = f_0$. The frequencies in the mode of $2\nu_N$ and ν_{2N} to the signal are favorable, because these added up coherently to generate a signal of larger amplitude. Since typical optical power per mode is in the pW range, this coherent signal is easy to detect. The set of radio-frequency signals fb, Ncw, f_{rep}, and f_0 give all the parameters that completely define Eq. 1, and therefore provides a mean to compare optical to microwave frequencies.

Practical Realization of Meter

Optical frequency combs, nowadays are known as ruler of light and they are employed to generate optical frequencies with an uncertainty limited to the uncertainty of the master clock. These optical frequency combs are designed in such a way that the round trip time for all longitudinal modes remains constant.

To realize the mode configuration of an optical frequency comb and its stabilization technique, let's consider an idealized case of a pulse in cavity whose length is L and whose carrier frequency is fc. The emitted pulse is basically a repetition of the first pulse separated by the round trip time:

$$T = 2\,L/v_g \tag{3}$$

where v_g: cavity mean group velocity.

Emitted pulses are not symmetrical because of pulse envelope A(t). The pulse is propagating with two different velocities: a group velocity (v_g) and phase velocity (carrier wave) and both have a difference. Consequently, a single round trip of a carrier pulse phase has angle $\Delta\phi$ as shown in Fig. 6. In this case, the electric field at a given place can be written as,

$$E(t) = Re\,[A(t)\exp(-i2\pi f_c)t]. \tag{4}$$

Because the envelope is periodic

$$E(t) = Re\left[\sum\nolimits_n A_n \exp(-i2\pi(f_c + nf_r))t\right], \tag{5}$$

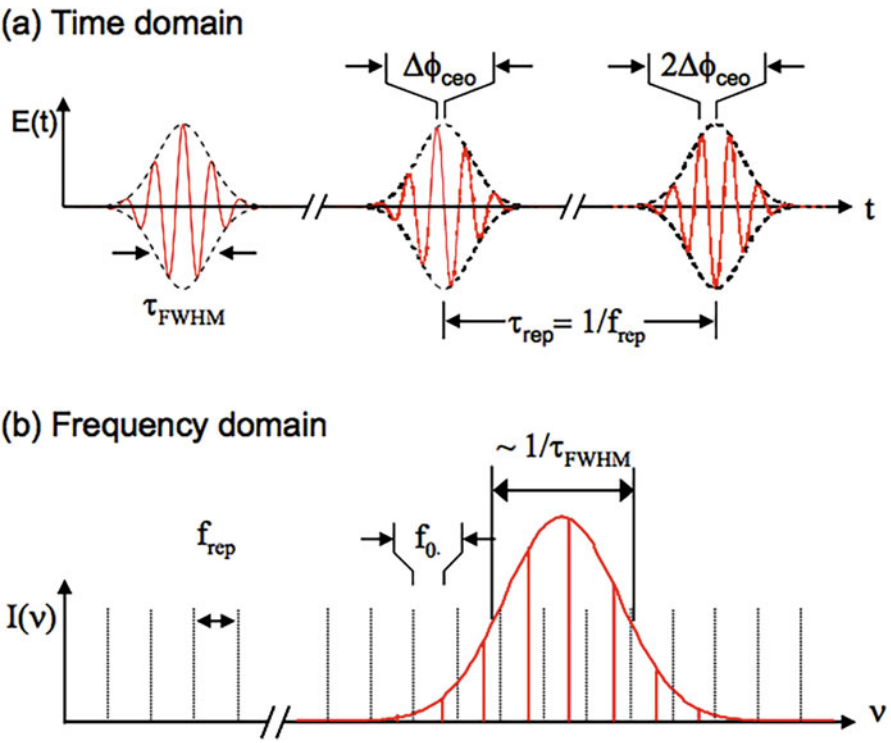

Fig. 6 An optical frequency comb representing time domain and frequency domains for the EM fields

where An are Fourier components of A(t), carrier frequency f_c is not essentially an integer multiple of f_r. The offset are selected by satisfying $f_0 < f_r$, so that modes will shift with respect to the harmonics of the repetition frequency

$$f_n = f_0 + nf_r, \tag{6}$$

where n is the integer value of the order of 10^6. Using above Eq. 6 one can mix two radio frequencies (RF) f_r and f_0 onto an optical frequencies f_n. f_0 is detected by the self-referencing technique as described above with an f–2f interferometer setup in most of the cases; however there are other techniques available (Jones et al. 2000; Holzwarth et al. 2000). If the optical comb gives a complete optical octave, then there is a mode, with the number 2n, which shall oscillate at the same time at

$$f_{2n} = f_0 + 2nf_r. \tag{7}$$

The beat note between n and 2n (the mode and frequency doubled mode at 2n) gives the offset frequency as

$$2(f_0 + nf_r) - (f_0 + 2nf_r) = f_0. \tag{8}$$

The frequency of another laser, which is under calibration (continuous wave), its f_{cw}, is measured by a beat frequency, f_{beat}, with the adjacent mode of the optical comb. In this case, the value of f_{cw} is written as follows:

$$f_{cw} = nf_r \pm f_0 \pm f_{beat}. \tag{9}$$

The polarity of Eq. 9 is decided by measurement conditions, changing f_0 and f_r. If second harmonic generation (SHG) is takes into consideration, the zero offset value f_0 has to be multiplied by a factor of 2 as shown in the following equation

$$f_{cw} = nf_r \pm 2f_0 \pm f_{beat}. \tag{10}$$

The repetition rate stays constant because sum frequency generation is dominant process in SHG.

Experimental Setup

Most of the NMIs are using optical frequency comb with 250 MHz repetition rate mode-locked erbium fiber-ring laser and a nonlinear micro-structured fiber for realization of SI unit meter. The main component of optical frequency comb is a fiber laser with erbium-doped fiber amplifier (EDFA) for high power generation up to 2 mW at 1500 nm central wavelength as shown in Fig. 7. The femtosecond pulse is divided into two parts and sends to the monitor dock and to the external parts of the OFC. One part is amplified in an erbium-doped fiber amplifier and gets broadened using highly nonlinear fiber to cover a full spectrum. The beat signal of offset

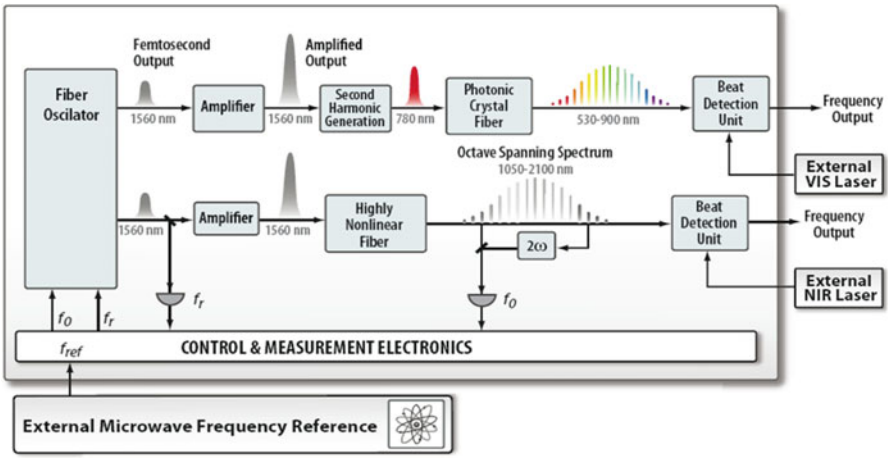

Fig. 7 Experimental setup for an optical frequency comb for calibration of $^{127}I_2$ He–Ne lasers at 633 nm (Samoudi 2017)

frequency f_0 is measured using a f−2f interferometer. Another part of the beam is used for generating high power.

A fast p-i-n junction (PIN) diode is used to measure the carrier offset frequency. The fiber laser head has an inbuilt fast PIN photodiode, which is used to measure the fourth harmonic of fr with better phase sensitivity. Electronic circuits of two phase-locked loops are used to lock the repetition rate and offset frequency. A Frequency counter is used without dead time to detect the beat signals with cw lasers and to control the phase-locked loop. An oscilloscope and a spectrum analyzer are used for monitoring of electronic signals, pulse, and beats.

A beat detection component (Fig. 8) is composed of silver/gold coated mirrors, polarized beam splitters, half or quarter wave plates and is used to direct the beams to a photodetector for measurement. A Cesium (Cs) atomic clock is used to be referenced to a primary frequency standard for repetition rate frequency, fr, and the carrier envelope offset frequency (20 MHz), f_0, and $f_{beat.}$

To realize the SI unit meter Zeeman-stabilized 633 nm He–Ne lasers are used. A grating having 2100 lines/mm is used for spectral filtering. The 633 nm laser is calibrated with optical frequency comb pulse of 633 nm. It is vital to give surety that both beams of 633 nm should overlap with each other, should pass precisely in same path, and have same beam size to get a good beat signal ration for better sensitivity. This beat note frequency is measured by an avalanche photo detector. Most of the significant frequencies are measured and counted by a spectrum analyzer and frequency counters, respectively, which are referenced to Cesium clock. This has good stability value for length measurements. To realize long-term stability it is plausible to use H-Masers and fountains based on cold atoms. During frequency detection, the optical frequency comb as well as the residual phase is very consistently locked. A frequency counter is employed to count the frequency of pulse under measurement continuously for every second without dead time for more than 5 h.

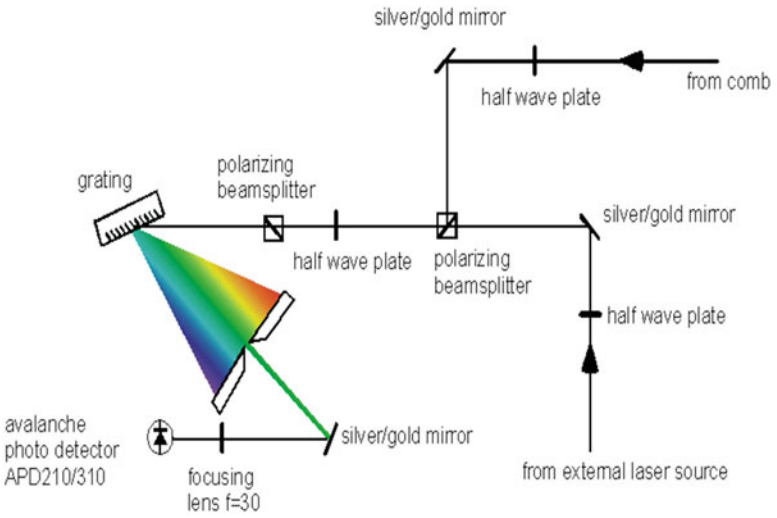

Fig. 8 Beat detection unit used for measurement of 633 nm He–Ne lasers using a optical frequency comb (Samoudi 2017)

As we have seen, to realize the SI unit meter an iodine-stabilized 633 nm (474 THz) He-Ne wavelength/frequency is calibrated against the optical frequency comb frequency of 474 THz. For a known frequency f, the analogous wavelength λ in a medium is represented by $\lambda = c/fn$, where c is the speed of light in vacuum and n is the refractive index of the medium. When measurement is executed in air, the refractive index can be known, so using Edlen's equation, by monitoring the temperature, pressure, humidity, and CO_2 concentration (Hyun et al. 2009; Birch and Downs 1993), the compensation factor for wavelength correction can be applied. In this case the length L to be determined is given as $L = \lambda(m + \varepsilon)$, where m is a positive integer, and ε is an excess fraction ($1 > \varepsilon \geq 0$). The accurate determination of L necessitates both m and ε to be correctly known, but using interferometer method for a single wavelength allows only the value of ε to be known. To determine the absolute value of L, the wavelength needs to be modulated over an extensive range in either hopping or sweeping mode, which can be only possible using optical frequency comb that covers the entire range of spectrum. Measurement uncertainty for optical frequency comb-based 633 nm He-Ne laser calibrations can be done in accordance with GUM analysis (BIPM 2008).

Conclusions

Optical frequency combs have obtained much consideration in modern days because of their huge prospective in length metrology and other applications. The absolute wavelength/frequency measurements 633 nm He–Ne lasers with optical frequency comb are in good agreement. The stability of beat frequency for longer averaging

times is reported by many researchers. Using Allan deviation analysis and Edlen equation, a correction can be applied to measurement for accurate determination of wavelength/frequency. Measurement uncertainty can be calculated in accordance with GUM analysis. The realization of SI unit meter using optical frequency comb improves many order as compared to the present method based on iodine-stabilized 633 nm He-Ne lasers.

Abstract

In the efforts of redefining the SI units with fundamental constants of nature, kelvin (K), the SI unit of thermodynamic temperatures (T), was redefined based on the Boltzmann constant (k) in the 26th meeting of the General Conference on Weights and Measures (CGPM) held in November 2018. The new definitions of four SI base units, kilogram, ampere, kelvin, and mole, have been implemented since May 20, 2019. The redefined kelvin by fixing the value of Boltzmann constant ($k = 1.380649 \times 10^{-23}\,JK^{-1}$) has opened the door for the realization and dissemination of the thermodynamic temperature, independent of any material

property. Before the redefinition, the temperature dissemination was made through the practical scales, the International Temperature Scale of 1990 (ITS-90) using defined fixed points from 0.65 K to 1357.77 K and Provisional Low Temperature Scale of 2000 (PLTS-2000) in the temperature range from 0.9 mK to 1 K. Now, through the *mise en pratique* (MeP-K) for the realization of new kelvin, the Consultative Committee for Thermometry (CCT) has proposed the primary thermometry methods to realize *k* and dissemination of thermodynamic temperature. The primary methods such as acoustic gas thermometry, dielectric constant gas thermometry, Johnson noise thermometry, and Doppler-broadening thermometry have made immense contributions in low uncertainty realization of *k* and dissemination of thermodynamic temperatures (T) with direct traceability to redefined kelvin. The redefinition approach, various primary thermometric methods and their capabilities, implications of redefinition, and way forward have been discussed in detail in this chapter.

Introduction

International System of Units (SI) was formulated to bring the uniformity in the measurement system, and the ninth edition of SI describes how the definition of the SI units is established in terms of a set of seven defining constants (BIPM 2019). In 2005 Consultative Committee for Thermometry (CCT) expressed about the requirement of redefinition of kelvin in terms of fundamental constant (CCT 2005). Consequently, in 2011, at its 24th meeting, the General Conference on Weights and Measures (CGPM) proposed to redefine kilogram, ampere, kelvin, and mole in terms of the fundamental constants Planck's constant (*h*), elementary charge (e), Boltzmann constant (*k*), and Avogadro constant (N_A), respectively (BIPM 2019; 24th General Conference on Weights and Measures (CGPM) 2011). In its 26th meeting held on November 2018, CGPM has redefined all the SI units in terms of fundamental constant (26th General Conference on Weights and Measures (CGPM) 2018).

Since 1954, kelvin, the unit of thermodynamic temperature, was defined in terms of triple point of water as "the kelvin is the fraction 1/273.16 of the thermodynamic temperature of the triple point of water." The thermodynamic temperature of 273.16 K was assigned to TPW. TPW was realized with the best possible uncertainty of 3.4×10^{-7} relative standard uncertainty and remained as the basis of kelvin definition from ITS-68 to ITS-90. In 2005, it was noticed that the isotopic composition of water affects the measurement and contributes in uncertainty. It was observed in the CCT-K7 intercomparison that the standard deviation of TPW measured data of the transfer TPW cells of several national metrology institutes (NMIs) with BIPM reference TPW cells was 50 μK. Majority of TPW cells were constructed using continental water, which resulted in the temperature corrections of +50 μK and the standard uncertainty

of 35 μK, because of isotopic variation in water (Stock et al. 2006; Babita et al. 2021). Moreover, ITS-90 and PLTS-2000 with temperature range above 0.65 K and 0.9 mK to 1 K, respectively, are formulated for the practical realization of the kelvin (Preston-Thomas 1990; Rusby et al. 2002). These temperature scales are realized using the set of defined fixed points (such as boiling, melting, and freezing, triple point states of high pure substances) and the measuring devices, where TPW temperature is taken as a reference point at 273.16 K. The interpolating polynomial function generated for temperature sensors using these defined fixed points provides the value of T_{90} and helps to estimate T-$T_{90.}$ However, for temperature away from TPW, the T-T_{90} and associated uncertainty are several orders higher than at TPW, because of the propagation of drifts. The above discussion depicts that the definition based on TPW is material dependent and measured T-T_{90} varies with the temperature (Fischer et al. 2011). Hence, the efforts were taken for the redefinition of kelvin in terms of Boltzmann constant (k) for the direct measurement of thermodynamic temperature to make it free from material-dependent property and to maintain the uniformity in measurement throughout the temperature scale, by primary thermometry methods (Fellmuth et al. 2006; Fischer et al. 2007).

In the nineteenth century, Ludwig Boltzmann derived the Maxwell-Boltzmann velocity distribution in terms of microscopic thermal energy (kT) (Fischer et al. 2018). Kelvin, the unit of temperature, is directly linked to the joule, the unit of energy, by fixing the value of the Boltzmann constant k. Therefore, CCT and CIPM had decided to redefine the kelvin in terms of k, but before that, it was essential to realize the value of k with an uncertainty comparable to the uncertainty of the realization of TPW. With the effort of world-leading NMIs, the kelvin is redefined by fixing the numerical value of the Boltzmann constant as 1.380649×10^{-23} J.K^{-1}. Before redefinition, the primary thermometric methods employed to determine Boltzmann constant are acoustic gas thermometry (AGT), dielectric constant gas thermometry (DCGT), Johnson noise thermometry (JNT), and Doppler-broadening thermometry (DBT). The relative standard uncertainty in the determination of Boltzmann constant is 0.37 ppm in CODATA 2017, which satisfies the mise en pratique (MeP-K) criteria for the redefinition of kelvin (Newell et al. 2018). The recent MeP-K for the definition of the kelvin in the SI describes primary thermometry methods for the practical realization of new kelvin based on k (2019). In this chapter, the detailed description of primary thermometry methods defined in MeP-K for measurement and dissemination of thermodynamic temperature and its impact on present international temperature scale are presented.

Historical Prospects of Temperature Measurements

Temperature can be sensed by human touch in terms of hot and cold. Thermodynamically it can be explained as when two bodies are brought into contact, the heat transfers from hotter to cooler until both the bodies come to thermal equilibrium. Temperature is an intensive quantity, which makes it a nonadditive quantity. This implies that the 2T temperature cannot be achieved by mixing two systems maintained at the same temperature, T. The measurement of temperature is known

as thermometry. The zeroth law of thermodynamics is considered as a fundamental law for thermometry, which states that "if two systems are separately in thermal equilibrium with the third, then they are in thermal equilibrium with each other" (Quinn 1990).

The first instrument made up of the glass bulb connected to a long tube immersed in a liquid was invented by Galileo Galilei to measure the degree of hotness and coldness between the year 1592 and 1603. In this device, the liquid height of the liquid column varies as a function of ambient temperature. The first thermometer, which measures temperature, was developed by the Florentine Academy of Sciences around 1650 using a spiral-shaped tube with a closed end and graduation. With the development of thermometers, the necessity of standardizing these thermometers using fixed points has arisen. In seventeenth century, D.G. Fahrenheit employed three fixed points: a mixture of ice, water, and ammonium chloride; a mixture of ice and water; and the human body temperature with the corresponding defined temperature as 0 °F, 32 °F, and 96 °F, respectively, to develop a mercury-in-glass thermometer (Fischer and Fellmuth 2005). In another development, Swedish astronomer and physicist Andres Celsius described the scale of mercury-in-glass thermometer with ice point (0 °C) and boiling point (100 °C) of water at standard atmospheric pressure (101.325 kPa) in 1742. The scale was defined by dividing the gap in 100 equal parts, and unit was termed as degree Celsius (°C). At the start of eighteenth century, two approaches given by Fahrenheit and Amontons became the basis of further advancement in thermometry. The need of temperature measurements in BIPM activities started in 1878 during the preparation of the meter prototype. The temperature and thermal expansion coefficient of the platinum-iridium meter bar need to be measured. Therefore, it was decided that each national meter prototype should be equipped with two mercury-in-glass thermometers calibrated at BIPM. After that, it was crucial to develop a uniform temperature scale for the calibration of thermometers. Initially, the practical temperature scale was described using ice point (0 °C) and steam point (100 °C). Later in 1854, William Thomson (Lord Kelvin) introduced the new temperature scale using triple point of water temperature and absolute zero temperature. Eventually, the thermodynamic temperature of the triple point of water (TPW) was recommended as the primary reference fixed point to define unit kelvin in 1948 at the 9th CGPM. Since the ice and the boiling point of water depends on the atmospheric pressure, the TPW temperature was more stable because it exists at a fixed temperature (273.16 K) and pressure (611.657 Pa). The thermodynamic temperature of the TPW was determined by Gay-Lussac's gas law as 273.16 K (0.01 °C). In 1954, CGPM officially accepted the definition of the kelvin (K), the SI unit of thermodynamic temperature, based on TPW state as "the kelvin is the fraction 1/273.16 of the thermodynamic temperature of the triple point of water (TPW)." In 1967, at the 13th CGPM meeting, kelvin was defined as the unit of temperature, denoted by K, and it was listed as one of the seven SI base units. Apart from impurities, water used to realize TPW state consists of different isotopic compositions of oxygen ($_8O^{16}$, $_8O^{17}$, $_8O^{18}$) and hydrogen ($_1H^1$, $_1H^2$) atoms. Therefore, the isotopic composition of water also affects the accuracy of TPW temperature realization. To address this issue, CIPM in 2005 made the

resolution to use the water standard as VSMOW water for the realization definition of kelvin based on TPW. The isotopic composition defined in VSMOW is as follows (Proceedings of the 23rd meeting of the general conference on weights and measures 2007): "0.00015576 mole of ^{2}H per mole of ^{1}H; 0.0003799 mole of ^{17}O per mole of ^{16}O; and, 0.0020052 mole of ^{18}O per mole of ^{16}O." Hence, it was required to eliminate the material-dependent property from the definition of SI unit of temperature. Consequently, in the 24th CGPM meeting, it was decided to redefine kelvin in terms of the fundamental constant, which is *k* (24th General Conference on Weights and Measures (CGPM) 2011). After many international efforts, in the 26th CGPM meeting held in November 2018, kelvin was successfully redefined in terms of the Boltzmann constant (*k*) (26th General Conference on Weights and Measures (CGPM) 2018; Fischer 2019).

At present, kelvin (K) is defined as follows:

> The kelvin, symbol *K*, is the SI unit of thermodynamic temperature. It is defined by taking the fixed numerical value of the Boltzmann constant '*k*' to be 1.380 649 $\times$ 10^{-23} when expressed in the unit J K^{-1}, which is equal to kg m^2 s^{-2} K^{-1}, where the kilogram, metre and second are defined in terms of *h*, *c* and $\Delta\nu_{Cs}$. Where *h* is the Planck constant, *c* is the speed of light in vacuum and $\Delta\nu_{Cs}$ is the cesium frequency corresponding to the transition between the two hyperfine levels of the unperturbed ground state of the ^{133}Cs atom. (CCT 2019)

The Redefinition of SI Kelvin

Prior to redefinition, the definition of kelvin was based on TPW, which was material-dependent quasi-artefact that involved in definition as well as dissemination in ITS-90 scale. Efforts were made to define all seven base units in terms of the fundamental constant, the constants of nature invariant in time and space. The Boltzmann constant (*k*) appears in the expression of the mean microscopic thermal energy (*k*T) to determine the mean kinetic energy of the particle of an ideal gas (Fellmuth et al. 2006). By fixing the numerical value of *k*, the kelvin is directly related to the unit of thermal energy: the joule. Therefore, thermal metrologist made efforts to realize *k* with lowest possible uncertainty for redefinition of kelvin. The primary thermometric methods were employed to determine the Boltzmann constant, and the following criterion was ensured in the *mise en pratique* (MeP-K) for the redefinition of kelvin (C.C. for T 2014; Fellmuth et al. 2016a): "The relative standard uncertainty of the adjusted value of *k* is less than 1 $\times$ 10^{-6}; and the determination of *k* is based on at least two fundamentally different methods, of which at least one result for each shall have a relative standard uncertainty less than 3 $\times$ 10^{-6}."

Hence, it was the challenging task to determine Boltzmann constant (*k*) with low uncertainty (below 1 ppm) by employing different primary thermometric methods. To make new definition consistent with the earlier definition, *k* was realized at TPW temperature. After fixing the value of *k*, the thermodynamic temperature with minimum possible uncertainty can be determined directly using primary

thermometers (Fellmuth et al. 2006). For a decade, researchers from various NMIs have carried out rigorous research to develop primary thermometers for low uncertainty determination of the Boltzmann constant. The CODATA Task Group on Fundamental Physical Constants (TGFC) periodically reviewed the progress of the state-of-the-art determinations of the values of physical fundamental constants. In CODATA 2017, the adjusted value of Boltzmann constant was determined with a relative standard uncertainty of 0.37 ppm (Newell et al. 2018). This determination of k is based on the three primary thermometry methods: AGT, DCGT, and JNT. Apart from this, the DBT was used to determine k with slightly higher uncertainties for additional confirmation. The status of all determination of k using three primary thermometers (AGT, DCGT, and JNT) and adjusted CODATA value of k is presented in Fig. 1.

This adjusted CODATA 2017 value of k was fixed as 1.380649×10^{-23} J/K with relative standard uncertainty of 0.37 ppm. Consequently, in 2018 CGPM, this value of k was considered for the redefinition of kelvin without assigning any uncertainty to it. This also ensures that the best estimate of the value of T_{TPW} remains 273.16 K, to make ITS-90-based measurements consistent. One of the implications of the 2018 definition is that the determined relative uncertainty in k, 3.7×10^{-7}, is transferred to the temperature of the triple point of water, T_{TPW}. Therefore, the standard uncertainty of T_{TPW} is hence now $u(T_{TPW}) = 0.1$ mK compared to the best TPW CMCs of 0.06 mK. The new definition was implemented worldwide on May 20, 2019.

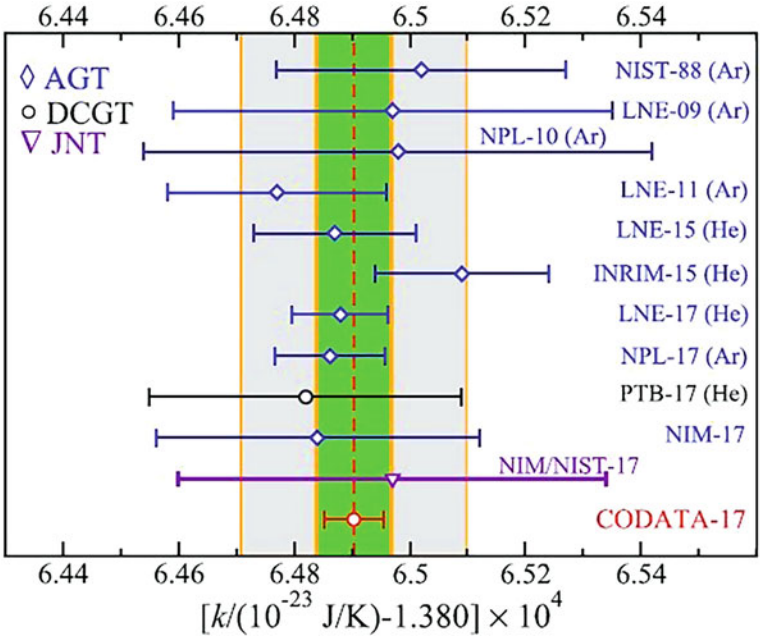

Fig. 1 The final determination of Boltzmann constant (k) in CODATA 2017, highlighting the contribution of AGT, DCGT, and JNT primary thermometry methods (Fischer et al. 2018)

Mise en Pratique (MeP-K) for the Realization of Kelvin

The *mise en pratique* for the definition of the kelvin in the SI (*MeP*-K) is formulated by the Consultative Committee for Thermometry (CCT) of the International Committee for Weights and Measures (CIPM) to describe the methods for the practical realization of redefined kelvin based on the Boltzmann constant (k) (CCT 2019). Primary thermometers based on well-understood physical system are employed for the direct measurement of the thermodynamic temperature. Further, these thermometers are subdivided into two categories: absolute and relative primary thermometry methods. In absolute primary thermometry method, the thermodynamic temperature is measured directly using the defined numerical value of Boltzmann constant. It does not require any fixed point ($n = 0$, $n =$ no. of fixed points), and parameters specified in the equation of state are measured, whereas in relative primary thermometry method, one or more reference fixed points ($n > 0$) are used to determine the one key parameter (speed of sound in AGT, dielectric constant in DCGT, etc.) to measure the thermodynamic temperature. *MeP*-K also includes the practical realization of the kelvin applying defined temperature scales, ITS-90 (0.65 K and higher) and the PLTS-2000 (0.9 mK to 1 K), and their measured temperatures are denoted by T_{90} and T_{2000}, respectively. The *MeP*-K also describes the T-T_{90} and T-T_{2000} for these two temperature scales and their corresponding uncertainties. The present *MeP*-K illustrates the use of the following primary thermometers for direct thermodynamic temperature measurement: acoustic gas thermometry (AGT), spectral-band radiometric thermometry (1235 K and above), polarizing gas thermometry (dielectric constant gas thermometry (DCGT) and refractive-index gas thermometry (RIGT)), and Johnson noise thermometry (JNT). However, there are other primary thermometers based on equation of state-based method, statistical- and quantum-based method can be evolved for the best dissemination method for Boltzmann constant-based new kelvin. No single method or fixed point is preferred in the dissemination of new kelvin. Therefore, it is very coherent, robust, and quantum mechanical-based dissemination process.

Primary Thermometry Methods for the Realization and Dissemination of New Kelvin

Primary thermometers are based on the well-understood physical systems. At the microscopic level, kinetic energy of the gas particles in a close volume is defined by thermal energy of the system, given as k.T. In primary thermometry methods, the equation of state that describes the relation between thermodynamic temperature and independent quantities can be written down explicitly without having any unknown or temperature-dependent constant (Quinn 1990). Mean microscopic energy of gas system cannot be measured directly. By using statistical mechanics, the microscopic average kinetic energy of gas molecules will provide thermal energy k.T of the system and which is related to different macroscopic quantities of primary thermometry methods (Fischer et al. 2007).

Internationally different NMIs used different methods for the determination of k and thermodynamic temperature since the last three decades. Each method is dependent on some temperature-dependent variable; like in gas thermometric methods, temperature is measured by using extensive property of amount of gas in constant volume gas thermometer (CVGT) method and the intensive property of gas such as the speed of sound, the refractive index, and dielectric property of gas in AGT, RIGT, and DCGT methods, respectively. Other than gas thermometry, there are few other methods like JNT, radiation thermometry, and DBT that depend on electronic noise in resistor, Stefan's and Planck's law of radiation, and broadening of absorption line of molecules, respectively. In gas thermometry, kinetic energy is responsible for the increase of the momentum of a gas particles in a closed volume, which causes an increase of the macroscopic quantity, pressure "P." In gas thermometry, statistical thermodynamics relate classical quantity, pressure to the quantum mean thermal energy kT of the gas molecules system, by equation of state.

The primary thermometry methods described in *MeP*-K used for the measurement of thermodynamic temperature are given below (Fischer et al. 2018; CCT 2019; Fischer 2019):

- Acoustic gas thermometry (AGT)
- Dielectric constant gas thermometry (DCGT)
- Refractive-index gas thermometry (RIGT)
- Spectral radiation thermometry (SRT)
- Johnson noise thermometry (JNT)
- Doppler-broadening thermometry (DBT)

Acoustic Gas Thermometry (AGT)

In acoustic gas thermometry, thermodynamic temperature is determined by the measurement of speed of sound in a monoatomic gas medium with average molar mass M (Fellmuth et al. 2006) (Fig. 2).

To determine Boltzmann constant (k) by using AGT method, the relation between k and the limiting low-pressure speed of sound u_0 in an ideal gas medium is derived from an equation given by (De Podesta et al. 2013; Pitre et al. 2011):

$$k = \frac{Mu_o^2}{\gamma_o T N_A} \tag{1}$$

In the above equation, γ_o is the zero-density ratio of the constant-pressure-specific heat to the constant-volume-specific heat, M is the molar mass of the gas, N_A is the Avogadro constant, and T is the thermodynamic temperature.

Similar to CVGT method, to consider the nonideal behavior of the real gases, the speed of sound in a dilute gas medium is expressed in terms of the virial expansion coefficient in pressure (Moldover et al. 2014):

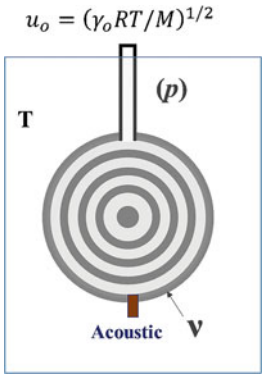

Fig. 2 Principle for acoustic gas thermometry (AGT) method (Fellmuth et al. 2006)

$$u^2 = \frac{\gamma_o k\, T}{m} + A_1(T)p + A_2(T)\, p^2 \ldots \tag{2}$$

where m is the average mass of one atom or molecule in gas medium and $A_1(T)$ and $A_2(T)$ are the virial expansion coefficient in pressure.

In low pressure limit, Eq. (2) reduces to Eq. (1) for the calculation of Boltzmann constant. For the realization of Boltzmann constant with uncertainty below 1 ppm, the measurement of speed of sound was carried out at TPW, reference fixed point, to make it consistent with the earlier definition by using absolute acoustic gas thermometry method.

After fixing the value of k, the unknown thermodynamic temperatures (T) can be measured by using relative AGT method, i.e., by taking the ratio with reference of TPW temperature, and the ratio of speed of sound at both temperature, which is given as

$$\frac{T}{273.16\ \mathrm{K}} = \frac{m_T}{m_{TPW}} \left(\frac{u_{0,T}}{u_{0,TPW}}\right)^2 \tag{3}$$

While using the same gas with same isotopic composition inside the resonator, the above equation reduces to

$$\frac{T}{273.16\ \mathrm{K}} = \left(\frac{u_{0,T}}{u_{0,TPW}}\right)^2 \tag{4}$$

In 1877, the principle of sound wave propagation in cylindrical and spherical resonators was introduced by the Rayleigh in his work "The Theory of Sound." A.R. Colclough has developed the first cylindrical acoustic interferometer with fixed frequency and variable path in helium gas medium to determine the gas constant near TPW temperature (Colclough et al. 1979). In 1988, Moldover et al. determined universal gas constant (R) using AGT with argon gas-filled stainless steel spherical resonator. For that measurement, the volume of resonator was estimated by

pycnometry, which has higher measurement uncertainty in the volume measurement than the recently used microwave measurements. With this stainless steel spherical resonator, Moldover et al. estimated the numerical value of k using AGT with the relative uncertainty of 1.8 ppm as mentioned in Table 1 (Moldover et al. 1988; Moldover and Trusler 1988).

To discuss the scientific and technological aspects involved in the determination of Boltzmann constant, a workshop was held on January 21, 2005, at PTB Germany, and after analyzing state-of-the-art method, M. Moldover of NIST claimed that the Boltzmann constant could be determined with the relative uncertainty of 1 ppm. Later, many groups have worked on this method and could achieve the uncertainty in the determination of k below 1 ppm. The measurement uncertainty for the realization of k was estimated by the different groups, shown in Tables 1 and 2.

Results obtained from AGT method have a major contribution in CODATA value for the realization of k and hence in the redefinition of kelvin. LNE France and NPL UK developed AGT using quasi-spherical resonator and realized k with uncertainty of 0.6 ppm (2017) and 0.7 ppm (2017), respectively. These two results further became basis for CODATA 2017 value of k. The NPL UK acoustic resonator for the measurement of acoustic and microwave frequencies is shown in Fig. 3.

After redefinition of kelvin, the AGT is being used for low uncertainty measurement of thermodynamic temperature for the wide range, i.e., from 7 K to 550 K, having the possibility from LHe (4 K) temperature to freezing point of copper (1350 K) (Moldover et al. 2014). In recent developments, INRiM has used He gas in AGT method for the determination of thermodynamic temperature in low temperature range from 236 K to 430 K, and uncertainty in measurement is from

Dielectric Constant Gas Thermometry (DCGT)

The principle of DCGT method describes the thermodynamic temperature estimation based on the measurement of intensive property, the dielectric constant. But this method is different from AGT method as in this method, a reference temperature fixed point is always required for the molar polarizability.

In DCGT, the density in the state of equation of a gas was replaced by the dielectric constant (ε), which is measured by the change in capacitance of a capacitor filled with gas at different pressures and constant temperature (measurement of isotherms). If the gas is ideal or there are no interactions between gas particles, the working equation for DCGT method can be derived simply by combining the classical ideal gas law and Clausius-Mossotti Eq. (15) (Fig. 4).

In DCGT method from the known value of gas pressure p, change of the capacitance C(p) in a capacitor will be calculated.

For an ideal gas, the dielectric constant is given by the relation

$$\varepsilon = \varepsilon_o + \frac{\alpha_o N}{V} \tag{5}$$

Here, $\varepsilon_{0\ \mathrm{is}}$ permittivity of vacuum; ε is permittivity of medium; $\varepsilon/\varepsilon_0$ will provide dielectric constant; α_0 = static electric dipole polarizability of atoms, which is $2.28151331(23) \times 10^{-41}$ C m^2 V^{-1} for He atoms with uncertainty of 0.1 ppm; and $n = N/V$ is the number density.

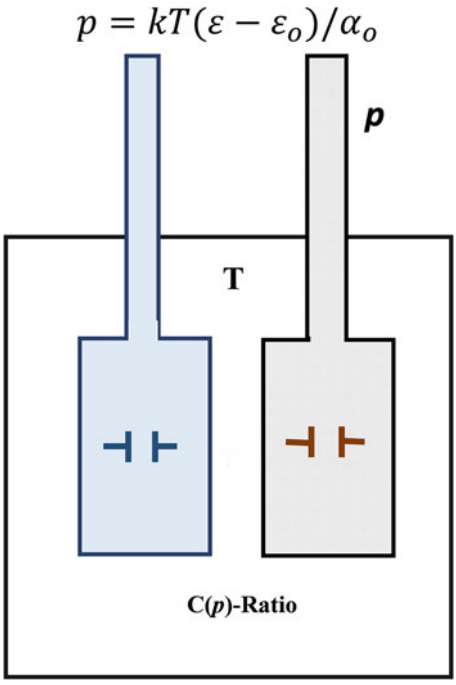

Fig. 4 Principle of dielectric constant gas thermometry (DCGT) method (Fellmuth et al. 2006)

Therefore, state equation (pV = NRT) becomes

$$p = \frac{kT(\varepsilon - \varepsilon_0)}{\alpha_0} \tag{6}$$

In the above equation, pressure of filled gas and dielectric properties are known; then temperature can be calculated.

Mathematically relation between molar polarizability A_ε and Boltzmann constant is related as

$$k = \frac{\alpha_o}{3\varepsilon_o} / \frac{A_\varepsilon}{R} \tag{7}$$

$$A_\varepsilon = \frac{N_A \mathrm{A} \alpha_0}{3\varepsilon_0} \tag{8}$$

N_A is the Avogadro constant in Eq. (8).

For a real gas, based on virial expansion and Clausius-Mossotti equation, p is given by

$$p \approx \frac{\chi}{\frac{3A_\varepsilon}{RT} + k_{\mathrm{eff}}} \left[1 + \frac{B(T)}{3A_\varepsilon}\chi + \frac{C(T)}{(3A_\varepsilon)^2}\chi^2 + \ldots \right] \tag{9}$$

where $\chi = \varepsilon/\varepsilon_0 - 1$ is the dielectric susceptibility and k_{eff} is effective compressibility of capacitor calculated from the material parameters of the capacitor.

The relative change in capacitance $(C(p) - C(0))/C(0) = \chi + (\varepsilon/\varepsilon_0)\, k_{\mathrm{eff}} p$ of the gas-filled capacitor is determined as a function of pressure p of the gas. C(p) is measured for various gas pressures between the capacitor electrodes and at evacuated condition.

A polynomial fit to the resulting p vs relative change in capacitance, i.e., $(C(p) - C(0))/C(0)$ yields $3A_\varepsilon/RT$, which is a macroscopic quantity.

In 1970s, the DCGT method was first developed in H.H. Wills Physics Laboratory, University of Bristol, UK, for the precise measurement of thermodynamic temperature (Quinn 1990). PTB Germany developed DCGT method with He gas for the determination of k. Because of low uncertainty in theoretically calculated value of static electric dipole polarizability of He gas, it was preferred while taking measurement (Gaiser et al. 2015). To measure k by DCGT, the temperature of gas and capacitor requires the low uncertainty measurement of the temperature, and the temperature must be traceable to TPW with a standard uncertainty better than 0.1 mK. By applying virial expansion, the pressure and relative capacitance change data pairs are fitted, which reflects the interaction of the atoms of the real helium gas having bosonic interaction and takes account of thermodynamic temperature as one of the parameters (Fellmuth et al. 2009).

In 2017, PTB Germany published results obtained for the realization of Boltzmann constant, and the results were enhanced by few changes in measurement

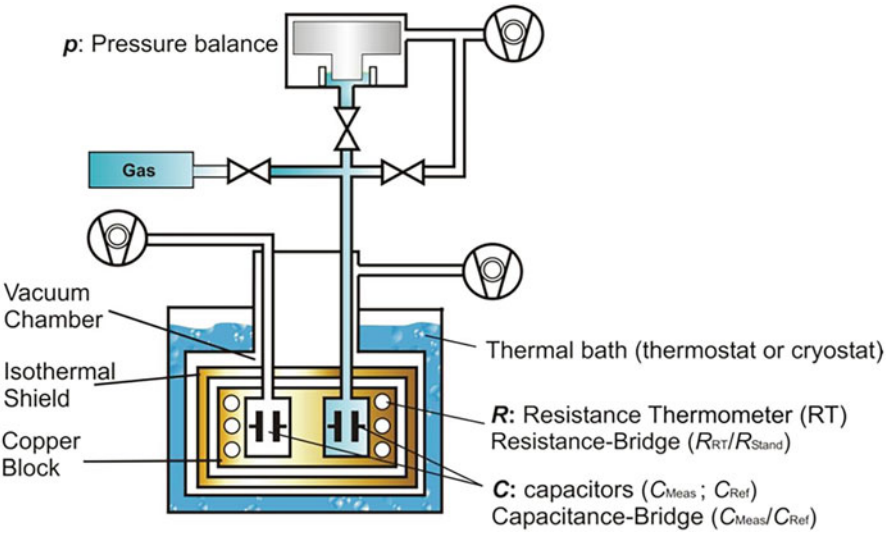

Fig. 5 Schematic diagram of the PTB Germany DCGT setup (Gaiser et al. 2015)

setup, which includes the use of three capacitors for experiment, reducing uncertainty in compressibility of electrodes due to individual determination of adiabatic compressibility of electrodes and additional shielding of capacitor electrodes for better stability (Gaiser et al. 2017) (Fig. 5).

Since 2011, PTB Germany has been continuously working on the development and advancement of DCGT method, which is summarized in Table 3 and achieved the best uncertainty as 1.9 ppm in the determination of *k*. This estimation using DCGT has contributed in CODATA 2017 to estimate the numerical value of *k*.

For thermodynamic temperature measurement, DCGT method was used by PTB for the calculation of standard uncertainty in the thermodynamic temperature range from 4.8 K to 25 K and uncertainty lies between 0.23 mK to 0.29 mK in 2015 (Gaiser et al. 2015).

In 2020, PTB has measured thermodynamic temperature from 30 K to 200 K, which was done by using three different gases (He, Ne, and Ar) in DCGT setup, and combined the results for T-T_{90} with the results obtained from RIGT and AGT methods (Gaiser et al. 2020).

Refractive-Index Gas Thermometry

The relation between refractive index of gas and density of gas medium is used to measure thermodynamic temperature. The refractive index of any gas medium is calculated by using the relation

Table 3 List of work done for the determination of k by using DCGT method

$$n = \frac{c_o}{c} = \sqrt{\varepsilon_r \mu_r} \tag{10}$$

where ε_r is the relative dielectric permittivity, μ_r is the relative magnetic permeability, c_o is the speed of light in vacuum, and c is the speed of light in gas medium (Rourke et al. 2019).

The principle of RIGT is similar to DCGT and can easily be derived from the Clausius-Mossotti equation by replacing dielectric constant with n^2 where n is the refractive index of gas as shown in Fig. 6.

The equation in terms of virial expansion coefficient can be written as follows:

$$\frac{n^2 - 1}{n^2 + 2} = A_R \rho \left(1 + b_R \rho + c_R \rho^2 + \ldots\right) \tag{11}$$

where A_R, b_R, and c_R are refractivity virial coefficients. This equation is called as Lorentz-Lorenz equation (Fellmuth et al. 2006; Colclough 1974).

RIGT was first proposed by A.R. Colclough in 1974 (Colclough 1974). The experimental setup for RIGT is similar to AGT method. In 2004, May et al. has evaluated relative dielectric permittivity in He and Ar gas medium using oxygen-free high thermal conductivity (OFHC) copper quasi-spherical cavity resonator (QSCR) by measuring resonance frequencies (May et al. 2004). Nowadays, the realization of

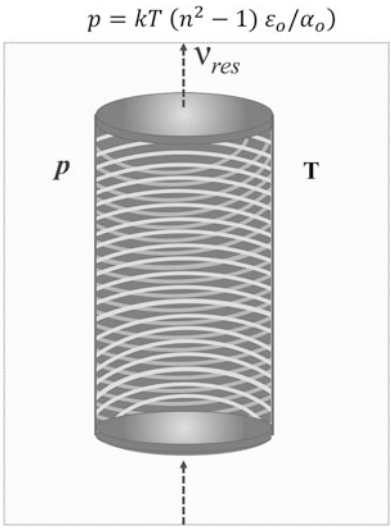

Fig. 6 Principle of refractive-index gas thermometry (RIGT) method (Fellmuth et al. 2006)

RIGT is generally done using the gas-filled quasi-spherical cavity resonator (QSCR) by measuring the microwave frequencies. The measurement of microwave frequencies is similar as in AGT.

In 2017, Bo Gao et al. at NIMs China developed single-pressure refractive-index gas thermometry (SPRIGT) method for the measurement of thermodynamic temperature. At a single pressure of gas inside the cavity, refractive index at one reference point (TPW) was measured, and by taking the ratio with refractive index at other temperatures, the thermodynamic temperature can be calculated (Gao et al. 2017). In 2018, SPRIGT working group improved the stability of pressure from 30 kPa to 90 kPa below 0.1 ppm (Gao et al. 2018).

NIST USA has developed RIGT method for the determination of k, and the measured value and relative standard uncertainty are presented in Table 4.

In 2016, NRC Canada used RIGT method for the measurement of thermodynamic temperature in the temperature range 24.5 K to 84 K by using copper quasi-spherical resonator filled with He gas and obtained the standard uncertainty in T-T_{90} in the range from 0.56 mK to 2.9 mK (Rourke 2017). Later on, the group has published a review article on the development of RIGT in 2019 (Rourke et al. 2019).

In 2020, Gao et al. carried out the thermodynamic temperature measurement from 5 K to 24.5 K by using the same methodology. The accuracy in thermodynamic temperature measurement is in the range 0.05 K to 0.17 mK and which is comparable to the previous measurement taken by using other methods (Gao et al. 2020). In 2021, D. Madonna Ripa et al. measured refractive index of helium and neon gas at five different temperatures in the interval between the triple point of hydrogen at 13.8 K and the triple point of xenon at 161.4 K for pressures up to 380 kPa (Ripa et al. 2021). The T-T_{90} was determined with different methods of analysis with improved uncertainties. The measurement of thermodynamic temperature can

be done in the temperature range 2.6 K to 1000 K in the present RIGT developed setup.

Radiometric Thermometry

The absolute measurement of the blackbody radiation is based on the Planck's law of thermal radiation. According to the Planck's law, the spectral radiance of a blackbody cavity is the radiative power emitted per unit area per unit solid angle per unit wavelength, given as follows (Todd et al. 2017):

$$L_{b,\lambda}(\lambda, T) = \frac{2hc^2}{n^2\lambda^5} \frac{1}{\exp\left(\frac{hc}{n.\lambda.k.T}\right) - 1} \tag{12}$$

where the spectral radiance concentration $L_{b,\lambda}(\lambda, T)$ is independent of the material and shape of the cavity wall and function of the vacuum wavelength λ and temperature T. The h stands for the Planck's constant, c is the speed of light, n stands for the refractive index of gas inside cavity, and k is the Boltzmann constant. The unit of the spectral radiance is $Wm^{-2}\ sr^{-1}\ nm^{-1}$.

Equation (12) can be written in the simplified form:

$$L_{b,\lambda}(\lambda, T) = \frac{c_1}{n^2\lambda^5} \frac{1}{\exp\left(\frac{c_2}{n\lambda T}\right) - 1} \tag{13}$$

where c_1 and c_2 are the first and second radiation constants, respectively:

$$c_1 = 2hc^2 = 3.7417749\ \text{W.m}^2$$

$$c_2 = hc/k = 0.014388\ \text{K.m}$$

The total radiation (L) emitted by the blackbody cavity can be calculated by integrating spectral power over all wavelengths over the solid angle 2π, which gives the Stefan-Boltzmann law of total radiation:

$$L_b(T) = \int_0^\infty L_\lambda d\lambda = \frac{2\pi^5 k^4 n^2}{15h^3 c^2} T^4 \tag{14}$$

Total radiation thermometers are based on the Stefan-Boltzmann law of thermal radiation. Total radiant energy emitted by a surface per unit area of a blackbody at temperature T is given by Eq. (15):

$$L_b(T) = \frac{2\pi^5 k^4 n^2}{15h^3 c^2} T^4 = \sigma T^4 \tag{15}$$

where σ is the Stefan-Boltzmann constant ($5.670374419 \times 10^{-8}$ W m^{-2} K^{-4}).

The ratio of radiation power can estimate the unknown temperature at temperature T and at triple point of water temperature T_{TPW}. The equation can be written as follows:

$$\frac{L_b(T)}{L_b\left(T_{TPW}\right)} = \frac{T^4}{{T_{TPW}}^4} \tag{16}$$

Absolute radiometric measurement has been carried out to measure thermodynamic temperature by a total radiation thermometer. The absolute total radiometric thermometry and spectral-band radiometric thermometry will play a vital role in the dissemination of new kelvin in high-temperature range above 1235 K.

The spectral-band radiometry has advantage over total radiation thermometer that it can be operated over the spectral range chosen via filter, whereas in total radiation thermometer, spectral power was calculated over the overall wavelength. The limited spectral range provides better signal-to-noise ratio. The recent *mise en pratique* include "spectral-band radiometric thermometry" for the determination of thermodynamic temperature above 1235 K (CCT 2019). This method includes two approaches: absolute primary radiometric thermometry and relative primary radiometric thermometry. In absolute primary radiometric thermometry, the spectral power of the blackbody source is determined using a detector of known (absolute) spectral responsivity in a particular waveband and in a defined solid angle. The measurement of the spectral power requires the knowledge of detector and the spectral responsivity of the filter. Also, the geometric factor such as A1, A2, and distance (d) between blackbody source should be known to define solid angle (Anhalt and Machin 2016). A typical schematic of the measurement of spectral radiance or irradiance is shown in Fig. 7.

In the case of relative primary radiometric thermometry, the spectral responsivity of the filter is not required to be known. The optical power is measured on the fixed-point blackbodies with known thermodynamic temperatures. There are three approaches to measure thermodynamic temperature using relative primary radiometric thermometry: (1) extrapolation from one fixed point, which requires only knowledge of the relative spectral responsivity of the detector and filter; (2) interpolation or extrapolation from two fixed points, which requires only the bandwidth of

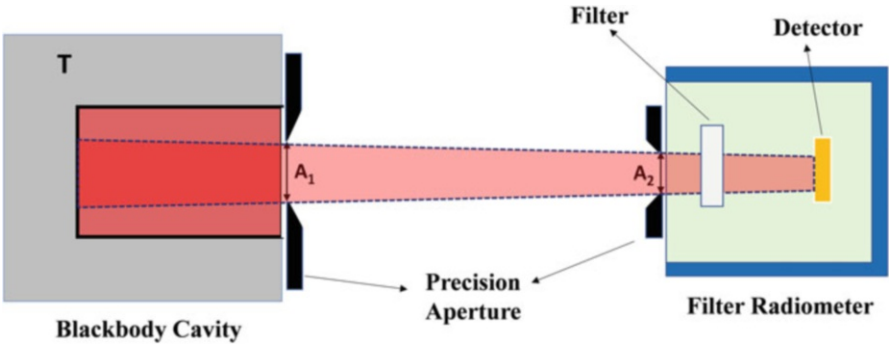

Fig. 7 Schematic for the measurement of thermal radiation using filter radiometer, where A_1 and A_2 are the precision apertures (Fischer 2019)

the responsivity; and (3) interpolation or extrapolation from three or more fixed points, for which detailed measurements of responsivity are not required (CCT 2019). The Planck's form of the Sakuma-Hattori equation, a well-understood parametric approximation of the integral expression of the radiative power, is used for the simplification of interpolation and extrapolation. The relative primary radiometric thermometry has slightly higher uncertainties than absolute primary radiometric thermometry. However, absolute primary radiometric thermometry required a sound knowledge of the absolute spectral responsivity of filter lens. The calibration facility of spectral responsivity of a filter lens is expensive and time consuming. Therefore, relative primary radiometric thermometry using multiple fixed points has an advantage over absolute primary radiometric thermometry, where calibration of the filter is not required. The high-temperature fixed points (HTFP), metal-carbon (M-C) eutectic fixed points in combination with pure metal fixed point (Ag, Au, or Cu), are employed to disseminate thermodynamic temperature above 1235 K using relative radiometric thermometry (Sadli et al. 2016; Woolliams et al. 2016). The M-C eutectic fixed points ranging up to 3200 °C, as shown in Fig. 8, are being developed and realized for the last two decades for the dissemination of thermodynamic temperature in high-temperature range at NMIs (Woolliams et al. 2006; Machin 2013; Pant et al. 2018, 2019, 2020).

Johnson Noise Thermometry (JNT)

Johnson noise thermometry (JNT) is based on the electrical noise generated in conductors due to the zigzag momentum (similar to Brownian motion invented by Einstein in 1906) of charge carriers in it as shown in Fig. 9. In this method, microscopic quantity is electrical noise, related to the temperature, and macroscopic quantity is electrical resistance.

JNT method was first introduced by J.B. Johnson in 1927, and later on, in 1928, H. Nyquist reported theoretical prospectus of it and derived expression from Planck's blackbody law. They provided a different outlook toward the determination

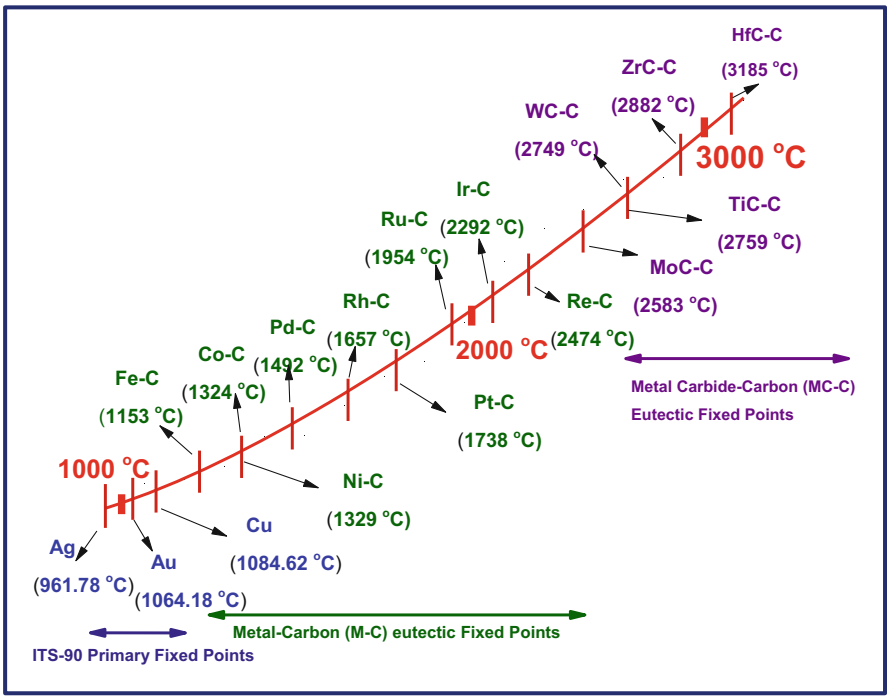

Fig. 8 Metal-carbon (M-C) and metal carbide-carbon (MC-C) fixed points

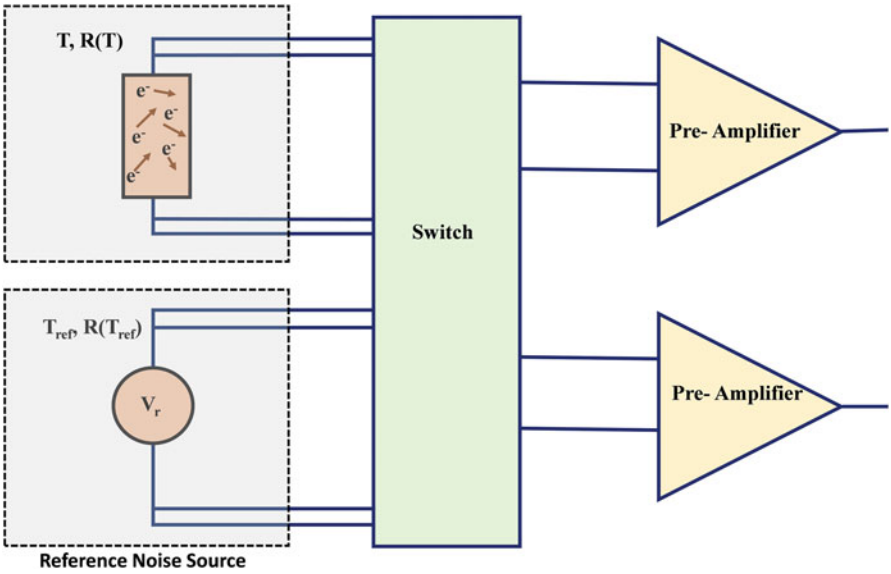

Fig. 9 Block diagram for Johnson noise thermometry method where thermal noise in electrical resistor at T is compared with the reference voltage source at T_{ref} (Fischer 2019)

of k by taking the concept of electromotive force that is responsible for the flow of electrons (electricity) through conductors, which creates thermal effect (Johnson 1928; White et al. 1996). After 1950s, JNT method was developed internationally for the measurement of thermodynamic temperature at different fixed points (Qu et al. 2019).

In JNT method, the thermodynamic temperature measurement is based on the mean square noise voltage U, caused due to the statistical motion of particles in a resistor.

The temperature dependence of the developed voltage is given by Nyquist formula:

$$\left\langle U^2 \right\rangle = 4kT.R\Delta\nu \tag{17}$$

valid for frequencies, $\nu << kT/h$

Electrical resistance R, a frequency-independent quantity, and $\Delta\nu$ are measured at TPW (Nam et al. 2003, 2004).

In noise thermometry method, Boltzmann constant can be determined directly from the ratio of mean square of the noise voltage and resistance. If the sensing resistor is replaced with an AC Josephson voltage standard, the absolute measurement at TPW would directly provide a determination of k.

As the noise voltages are extremely small, one has to use special electronic circuit and arrangements, with reference voltage source traceable to quantum standard of voltage. The main challenges in this method are to optimize the performance of the electronic system such as drift in the gain and bandwidth and the parameters, viz., long measurement time, nonlinearity, and transmission-line effects. The initial efforts brought the uncertainty value to 1×10^{-5}, when measured at zinc fixed point. NIST and the Measurement Standards Laboratory of New Zealand proposed the perfect quantization of voltages from the Josephson effect (Tew et al. 2007).

In 2003, for improving JNT method, a reference voltage source was used called quantized voltage noise source (QVNS). With this improved setup, the expected relative uncertainty is below 10 ppm in the thermodynamic temperature range 270 K to 1000 K (Nam et al. 2003).

In this direction after 2003, many improvements have been made in the experimental setup of JNT specially in circuit design for the thermodynamic temperature measurement with low uncertainty in the last two decades (Nam et al. 2004; Sun et al. 2011; Qu et al. 2013).

In 2014, a systematic error that arises due to software part instead of hardware part was considered for the measurement of k. The experiment setup includes two different resistors, and their noise ratio contributed 12 ppm systemic error (Pollarolo et al. 2014). For the wide range of temperature measurement, i.e., from 3 K to 300 K with high sensitivity 110 ppm (5.5 mK), boron nitride-encapsulated monolayer graphene device is used for thermal conductance in 2015 by Jesse Crossno et al. (Crossno et al. 2015).

In 2016, a reference point of water was chosen for the determination of k, and systematic error in JNT method was resolved at NIST USA (Bull 2016). At NIST

USA, a new approach was introduced for improving spectral irregularity in JNT method; electromagnetic interference (EMI) was examined by two QVNS chips, in 2016 (Pollarolo et al. 2016). In 2017, the NIM-NIST reported a relative standard uncertainty of 2.71×10^{-6} in Boltzmann constant by using purely electronic approach and contributed in CODATA 2017 value (Flowers-Jacobs et al. 2017a). Internationally, there are few groups that published their work on JNT method in the direction of Boltzmann constant realization and redefinition of kelvin summarized in Table 5.

In 2007, for the realization of T-$T_{90,}$ NIST used JNT method for the temperature value close to freezing point of zinc and obtained the uncertainty in measurement −14.24 mK. In 2010, by using QVNS, thermodynamic temperature measurements at freezing point of tin (505 K) and freezing point of zinc 693 K were taken. By using absolute JNT method, obtained values of T-T_{90} are −2.5 mK and + 6.7 mK for FP of Zn and FP of Sn, respectively, whereas from relative JNT method, the measurement of T-T_{90} was found to be +4.18 mK for FP of Zn by taking FP of Sn as reference point (Tew et al. 2010). The measurement of thermodynamic temperature using JNT was further extended for the temperature range 505 K to 800 K in 2013 after the 24th CGPM meeting, and the measurement data was compared with AGT and radiation thermometry method (Yamazawa et al. 2013).

In 2019, a review article on JNT method was publish by J.F. Qu in which authors explained the historical development of AGT, its contribution in redefinition of kelvin and thermodynamic temperature measurement (Qu et al. 2019).

JNT is purely electronic-based method, and it can be used for satellites, industrial applications, and high-accuracy thermodynamic temperature measurement in metrology. The main advantage of JNT method over other primary thermometry methods in present situation is that this method can be used for thermodynamic temperature measurement in the broadest anticipated temperature range, i.e., from 50 nK to 2473 K, and provide best uncertainty in measurement as compared to other methods (Dedyulin et al. 2022).

Doppler-Broadening Thermometry

DBT method provides Maxwell-Boltzmann velocity distribution along the axis of laser beam. In 2000, this method was first time purposed by Ch.J. Borde for the realization of Boltzmann constant (Dzcke 1953; Galatry 1961; Bordé 2002). This is the primary thermometry utilizing EM radiation measurements (LASERs), it depends on the Doppler shift of the recurrence of an electromagnetic wave in a moving frame of reference when contrasted with a rest frame. Doppler shift contains a linear and a quadratic part in terms of velocity of moving frame.

For atomic thermal velocities at room temperature, it is sufficient to consider only the linear dependence of Doppler shift, given as

$$\nu = \nu_0 \, (1 - \beta . K/k) \tag{18}$$

with small corrections in Doppler shift. Here, ν_0 is resonance frequency at rest.

Doppler broadening $\Delta\nu = \nu - \nu_0$, $\beta = v/c_0$, K is wave vector in laboratory frame of reference, and k is Boltzmann constant. If a laser is used to irradiate the atom in laboratory moving with velocity v, for which ν_0 is the resonance frequency for the atom at rest, the absorption will occur at a laser frequency of $\nu = \nu_0 \, (1 + \beta . K/k)$.

The thermodynamic temperature is related to Doppler-broadened absorption line as $\Delta\nu = [2kT/(mc_0^2)]$ when laser beam is propagated through an absorption cell containing an ideal gas of atoms or molecules at temperature T as shown in Fig. 10.

The main advantage of this method is that the Doppler profile and hence the Boltzmann constant can be determined by relative radiation measurements. Laser frequency can be easily controlled up to a high precision with small uncertainties (Gianfrani 2016).

For the determination of k, the experiment was performed in an ammonia line at 30 THz with a CO_2 laser. The uncertainty value in the Boltzmann constant inferred from the line width from this experiment was found to be within 3.6×10^{-5}. Since then, it was proposed to consider as an effective method to determine k with a reduced uncertainty of the level of 10^{-6}. A related joint project of universities of Naples, Milan, and INRiM was being carried out where they determined Doppler broadening of absorption line of water vapor with a diode laser in the near infrared spectral range using a high-resolution spectroscopy. The lowest uncertainty value achieved was 2.4×10^{-6}. However, it was still a tedious task to separate the effect of

Doppler broadening from the other effects causing the line broadening. Hence, this method is still to reach the criteria to fulfil the condition of the determination of k with the required uncertainty.

The values of Boltzmann constant with uncertainty obtained from DBT method for the corresponding laboratories are summarized in Table 6.

At ASI Italy, a new approach in primary thermometry was used to estimate the T-T_{90} in the temperature range 9 K to 700 K, under mK. $YLiF_4$ crystal doped with erbium (Er), and CO molecules are used as the transition medium in temperature range 9 K to 100 K and 80 K to 700 K, respectively (Amato 2019). DBT thermometry has a major contribution in astrophysical observation, plasma thermometry, and gas detection (Truong et al. 2015).

Implications and Way Forward

Before the redefinition of the kelvin, the practical realization and dissemination of temperature is achieved using the practical temperature scales (ITS-90 and PLTS-2000). Post redefinition, the ways for practical realization and dissemination of thermodynamics temperature are described in the *mise en pratique* for the definition of the kelvin (MePK-19), as shown in Fig. 11 (CCT 2019; Fellmuth et al. 2016b). The practical realization of new kelvin is not linked to a specific or single preferred

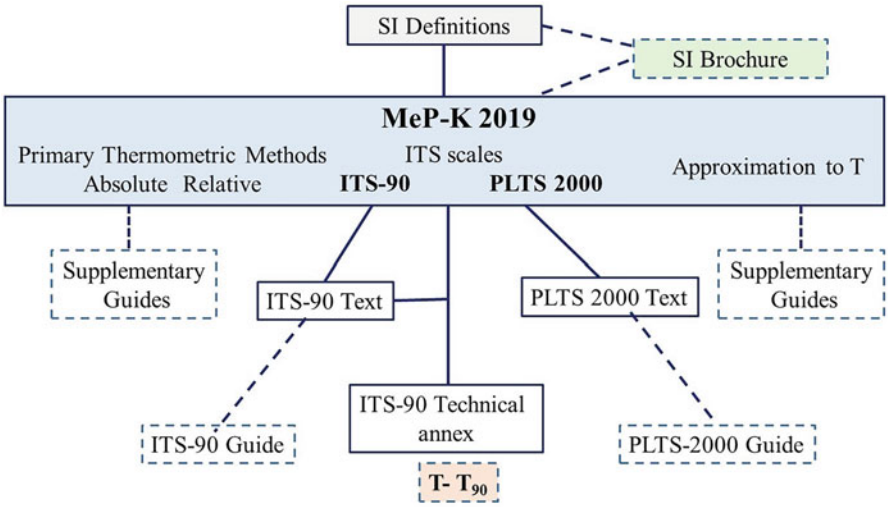

Fig. 11 MeP-K 2019 for the definition of the kelvin (Fellmuth et al. 2016b)

method, as before for TPW in ITS-90. Any method that is traceable to fundamental constant to derive thermodynamic temperature can be used for the practical realization. In this section, we describe the progress in realizing redefined kelvin and its impact on the current temperature scale. The MePK-19 describes methods that are easiest to implement and provides low uncertainty in temperature measurement.

The implications of the redefined kelvin based on Boltzmann constant are as follows:

- Before the new definition (till May 19, 2019):
  - $u_r(k) = 3.7 \times 10^{-7}$.
  - $T_{TPW} = 273.16$ K was exact without any uncertainty; $u(T_{TPW}) = 0$.
- After the new definition (from May 20, 2019).
  - Boltzmann constant is fixed as $k = 1.380649 \times 10^{-23}$ JK^{-1} without any uncertainty; $u(k) = 0$.
  - $u_r(T_{TPW}) = 3.7 \times 10^{-7}$, which makes $u(T_{TPW}) = 0.1$ mK.
- However, ITS-90 still remains as unchanged.
  - Within the use of ITS-90, $u(T_{90}(TPW)) = 0$, and $T_{90}(TPW) = 273.16$ K exactly.
- The new definition based on Boltzmann constant links the kelvin, the unit of thermodynamic temperature, to the thermal energy of the atoms or molecules of the system.
- The thermodynamic temperature can be realized and disseminated using primary thermometers based on a well-understood physical system where temperature is determined from measurements of other quantities.
- Primary thermometric methods for the measurement of thermodynamic temperature described in the MePK-19 are acoustic gas thermometry (AGT), dielectric

constant gas thermometry (DCGT), refractive-index gas thermometry (RIGT), Johnson noise thermometry (JNT), and spectral-band radiometric thermometry.
- Both absolute thermometry and relative thermometry are successfully used to measure and disseminate thermodynamic temperature, without linking to any specific fixed point.
- The redefined kelvin has no immediate effect on the current status of the ITS-90 and the PLTS-2000. However, the temperature range below 20 K and above 1300 K can be significantly benefited as the measurement of thermodynamic temperature in this can provide lower uncertainty than currently measured T_{90} and T_{2000}.
- The newly developed metal-carbon eutectic high-temperature fixed-point blackbodies can be used along with radiometers for direct thermodynamic temperature realization with improved uncertainties in a very high-temperature range above 1300 K.
- Coulomb blockade thermometry (CBT), Johnson noise thermometry (JNT), and low-temperature acoustic gas thermometry (AGT) are being employed for the realization of low temperature scale below 25 K to replace the current complex ITS-90 and PLTS-2000 temperature scale.
- Efforts are being made to improve the uncertainty and applicability of primary thermometers for the measurement and dissemination of thermodynamic temperature and better estimation of T-T_{90} (Machin 2023). Consequently, the traceability of temperature measurement will have direct linkage to redefined kelvin using primary thermometry methods, which is independent of any temperature scale.

Conclusion

The kelvin, the unit of thermodynamic temperature, is redefined in terms of the Boltzmann constant in Nov 2018 and implemented from May 20, 2019. The primary thermometry methods involved to determine Boltzmann constant with low uncertainty for redefinition are acoustic gas thermometry (AGT), dielectric constant gas thermometry (DCGT), Johnson noise thermometry (JNT), and Doppler-broadening thermometry (DBT). Further, these primary thermometric methods in combination with radiometric thermometry and present ITS-90 and PLTS-2000 scale are employed for the practical realization of redefined kelvin as described in the *mise en pratique* for the definition of the kelvin (MePK-19). The primary thermometry methods (absolute and relative) are used for the direct measurement of thermodynamic temperature as well as the dissemination of new kelvin based on Boltzmann constant.

This chapter describes the progress in the development of primary thermometers defined in MePK-19. The national metrology institutes (NMIs) across the world are developing different primary thermometers for the direct measurement and dissemination of thermodynamic temperature. Methods such as AGT, DCGT, RIGT, JNT, DBT, and radiometric thermometry and their status toward the redefined kelvin are presented. This fundamental constant quantum standard-based redefinition will give

the stability to the temperature measuring system without propagating the uncertainties, as happens with the triple point of water-based definition. New pathways have been opened for the realization of absolute scale, by using the primary thermometry methods, without any material-dependent properties like TPW and ITS-90 fixed points. Boltzmann constant is fixed as $k = 1.380649 \times 10^{-23}$ JK^{-1} without any uncertainty, u(k) =0, and the realization uncertainty of k has been transferred to TPW as $u_r(T_{TPW}) = 3.7 \times 10^{-7}$, which makes $u(T_{TPW}) = 0.1$ mK. The new definition has greater opportunities in reducing the uncertainties below 25 K and above 1200 K. Also the measurement of thermodynamic temperature (T) and estimates of T-T_{90} will bring in more thermodynamically close assignments to defined fixed points and a robust new practical temperature of ITS-20XX.

Abstract

The new definitions of seven SI base units, which are now based on their respective defining constants, were approved and adopted by the 26th CGPM. Candela, being one of the seven SI base units, was also redefined in terms of a defining constant, K_{cd} (maximum luminous efficacy of photopic vision). It is the only SI base unit which is derived from a physiological phenomenon of human vision. Candela has seen a long route of evolution from being defined on the basis

Candela · Photometry · Metrology · Quantum photometry

Introduction

Measurement is the process of quantifying some property of a phenomenon, or a physical entity, which can be expressed in terms of numbers, and assigning the number to that property. This facilitates quantitative comparison of that property. Though this sounds simple, a lot of efforts are involved in making a precise scientific measurement. This branch of science dealing with measurement is called metrology.

At present, scientific metrology is carried out under the umbrella of the General Conference on Weights and Measures (CGPM) and revolves around the seven SI base units. Out of these seven base units, candela (cd) is the one used for the measurement of light. The measurement of light is always associated with a geometrical aspect and hence, manifests as more than one parameter for measuring light for different applications, candela being one of them. Candela is the unit of luminous intensity which is the measure of the power (as perceived by the human eye) of a light source, along a particular direction, within one steradian (Roychoudhury 2014).

However, apart from the geometrical consideration, measurement of light is also associated with physiological phenomenon of vision. Thus, candela is the only base unit which gives a physical basis to a physiological phenomenon. Photometry deals with measurement of light that is perceived by the human eye. Thus, photometry is limited only in the visible range of the electromagnetic spectrum. On the other hand, when the physiological aspect of human vision is removed from consideration, the measurement of light is termed as radiometry. The radiometric counterpart of luminous intensity is radiant intensity having the unit of watt per steradian.

Candela has been a unit that has evolved with the evolution of scientific endeavor of mankind. As human beings evolved, the artificial lighting became a basic requirement. Though the requirement of light measurement came up from a field of science, industrial development propelled the standardization of light measurement that would encourage seamless exchange. During the evolution of light measurement, initially the unit and the ways of realization were different across region which are finally adopted to be known as candela. However, the method of realization of candela has kept evolving, even till recently. The evolution of light measurement is pictorially shown in Fig. 1 (Zwinkels et al. 2010; International metrology in the field of Photometry and Radiometry BIPM 2020; Johnston 2001; Resolution 6 of the 10th CGPM 1954; Resolution 12 of the 11th CGPM 1960; Resolution 5 of the 13th CGPM 1967; Resolution 3 of the 16th CGPM 1979; Resolution 1 of the 24th CGPM 2011a; Resolution 1 of the 26th CGPM 2018).

A Brief History of Measurement of Light

Light has been indispensable for mankind even before the present-day societal arrangement. As the scientific knowledge and capability of the human species progressed, the artificial illumination became a basic requirement for the humanity. Though initially illumination may have been a social requirement, slowly with rising scientific queries, light became a quantity requiring measurement.

The modern strategy of quantification owes its origin to the interests of the stargazers. This prompted a gentle progress from subjective to quantitative strategies for light measurement in the late nineteenth century (Johnston 2001). The industrial requirement of measuring brightness in the gas-lighting sector became the initial driving factor for quantification of light for commercial purposes (Roychoudhury 2014). As the electric illumination industry started maturing by the end of the 1800s, requirement for quantification of illumination gained further importance. In the mid-1900s, measurements of light by scientific techniques started to take over the strategies based on visual evaluation, since by that time, the scientists had recognized that the physiological conditions strongly affect the brightness perceived by the human eye. In this period, though, quantitative measurements had become quite established in many areas of science, yet the quantification of light was still in its infancy (Johnston 2001). As the light measurements entered the commercial arena, the requirement for proper and reproducible measurements lead to the interest of the academic community in the measurements which manifested in the form of responsibilities for measurement

reliability on national laboratories, which then started establishing standards for light intensity (Johnston 2001). This period also witnessed the shaping up of professional bodies like CIE (Commission Internationale de l'éclairage or International Commission on Illumination), which in turn initiated the standardization of light measurement (ABOUT THE CIE 2022). As industrialization further progressed, both the aspects of light measurements, viz., radiometry (physical aspect of light measurement) and photometry (physiological aspect of light measurement) started to gradually rise to prominence (Johnston 2001).

In the present time, the necessity of quantification of light has not simply been confined to the illumination business. Imperative sectors like defense, pharmaceutical, aeronautics, aviation, etc. are dependent on reliable measurements of light, both radiometry and photometry. Additionally, in the era of atmospheric extremities, excessive use of energy has turned into a serious concern. The assurance of good energy efficacy of lighting is sure to assume a big role, which in turn requires reliable and accurate light measurement. Along these lines, over around 150 years, estimation of light has progressed from basic visual scrutiny to a shift toward the quantum regime (Zwinkels et al. 2010; International metrology in the field of Photometry and Radiometry BIPM 2020; Johnston 2001).

Apart from geometric consideration, as light is perceived through vision, photometric measurements gained more initial attention as compared to the radiometric measurements leading to a photometric parameter holding the position of being one of the seven base units.

Realization of Candela

Candela being the unit of luminous intensity is defined as lumen per steradian. The radiant power of electromagnetic radiation when weighed by the average human eye response gives the luminous power. Thus, candela quantifies the luminous power from a light source within a solid angle of one steradian (Roychoudhury 2014).

Fig. 2 shows a geometrical representation of derivation of luminous intensity. The ray lines in the figure depict luminous power (dP_v) being emitted by the source along a direction and within a solid angle of $d\Omega$. In this case, luminous intensity would be

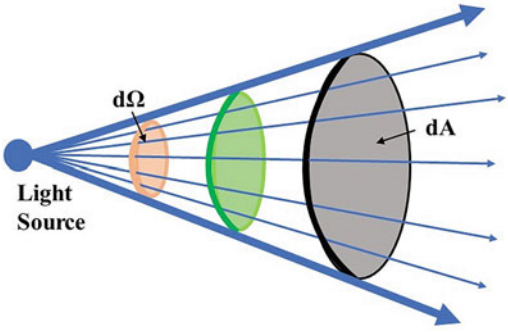

Fig. 2 Geometrical representation of derivation of luminous intensity

defined as $dP_v/d\Omega$, i.e., luminous power per unit solid angle. It can be observed from the figure that the number of lines representing luminous power remains invariant within the solid angle $d\Omega$, even on moving away from source. Thus, the geometrical aspect of the unit candela ensures its invariance over source-observer distance. Realizing this merit, metrologists are in a constant pursuit for realization of luminous intensity with lowest possible uncertainty.

The Path to Candela: Initial Realizations

During the period of late nineteenth century, luminous intensity was termed as candle power and was evaluated through comparison with candle flames. Luminous intensity was realized independently by various nations on the basis of their own respective artifacts which were the prototype candles. The British characterized their unit of candlepower, in 1860, on the basis of a prototype whale-oil candle (Treese 2018). During this period, the French too demarcated Carcel as the unit for measurement of light intensity which was based on the Carcel burner (Treese 2018). This was closely followed by the Germans in the late part of the nineteenth century as the Hefner lamp was established for defining their own unit of Hefner (Treese 2018). As compared to the present-day definition of candela, the British and the Germans were almost near to one candela; however, the French unit of Carcel was close to ten candela (Treese 2018). Nonetheless, the early day principles compromised on reliability owing to the reliance on composition of fuel and the testing conditions. Though this had provided some initial standardization, measurement uniformity across the nations could not have been seamlessly possible. In the standards based on combustion, the composition of fuel played a major role apart from the laboratory environment. Hence, its reproducibility would have been an issue that was to be addressed.

The drawback of the standards based on fuel combustion would later be overcome by a physical method. The physical standardization was proposed on the basis of emission of light from a one square centimeter area of molten platinum maintained at its melting point. The corresponding standard unit was named as Violle and in 1889, one Violle was characterized to be equivalent to twenty standard candle. However, owing to the issue of dealing with high temperature, the physical standardization based on molten platinum was dropped, though a similar principle was to be later accepted internationally. In this time, new candle was characterized equivalent to one Hefner unit (Treese 2018).

The international candle was adopted in 1909 as a mutually agreed standard by England, the USA, and Germany (Treese 2018; A Proposed International Unit of Light 1909). However, the standardization was now based on incandescent carbon-filament lamp, a transition toward an international physical standard. Nonetheless, standards based on respective lamps based on combustible fuels were still maintained by France, England, and Germany. However, adoption of the international candle based on incandescent carbon-filament lamp by the CIE, in 1921, lead to its wider international acceptance (Treese 2018).

The standardization based on filament lamp was a giant leap in the direction of defining an internationally acceptable unit of light measurement. Till this time of the early twentieth century, though a mutual international unit existed, it was still far away from the present-day definition of candela in terms of physical realization. Though the application of the incandescent lamps was a major step toward physical standardization as compared to the fuel-based combustion lamps, it had its own set of difficulties. The filament-based lamps' light output does not remain stable as the lamps age over time (Treese 2018; Greene 2003). Further, the fluctuation in the electrical inputs also contributed to the instability of the light output of the lamps. These were enough a reason for the metrologist to look for a standard that would remain stable as well as easily reproducible internationally.

Candela Based on Blackbody Radiation

The search for a source of light that would qualify to be an internationally accepted standard took the metrologist back to the point of standardizing the illumination from a body at high temperature. A perfect blackbody is such a source whose emission is the property of its temperature. For a blackbody radiator, the total power emitted and the spectra of the emission are a function of its temperature. Thus, the emission from the blackbody, being based on the physical quantity of temperature, could be standardized easily across laboratories. Planck's law establishes mathematically the spectral radiance produced by a blackbody radiator over a wide spectral range, in vacuum at a particular temperature. According to Planck's law (Zwinkels et al. 2010):

$$L_{e,\lambda}(\lambda, T) = \frac{2hc^2}{\lambda^5}\left(\frac{1}{e^{hc/\lambda kT} - 1}\right) \tag{1}$$

where the symbols represent physical quantities as follows:

h: Planck's constant.
k: Boltzmann's constant.
c: speed of light in free space.
λ: wavelength of radiation in vacuum.
T: temperature of blackbody radiator in Kelvin.

The blackbody now proved to be a more consistent candidate for defining luminous intensity as compared to its predecessors, combustion lamps, and incandescent lamps.

In this scenario by 1937, the CIE and CIPM (*Comité International des Poids et Mesures* or International Committee of Weights and Measures) prepared a new definition for luminous intensity based on the physical phenomenon of blackbody radiation. CIPM promulgated this definition, in 1946, through its resolution and thus a unit then known as "new candle" got an international acceptance which would read as (Taylor and Thompson 2008):

> "The value of the new candle is such that the brightness of the full radiator at the temperature of solidification of platinum is 60 new candles per square centimetre."

As apparent, the definition now standardized that a one square centimeter area of a blackbody radiator held at a temperature as that of freezing platinum would radiate a brightness of sixty new candles (Taylor and Thompson 2008; Parr 2000). This was a giant leap for photometry; as of now, its basis would change to be relying on a physical phenomenon instead of being based on artifacts. This paved the path for universal realization of a photometric unit leading to international acceptance. Being reliant on a physical principle, the unit took a step further on international reliability and lowering of uncertainty in measurements, in contrast to the artifact-based standardizations. In the year 1948, the apex intergovernmental body of measurement approved the definition in the ninth CGPM and adopted the present-day internationally accepted name for the unit of luminous intensity, the candela (cd) (Taylor and Thompson 2008; Resolution 7 of the 9th CGPM 1948).

Till now, though photometric unit had matured to be defined on the basis of a physical phenomenon, it was not recognized as one of the base units. In 1954, the tenth CGPM recognized candela as one of the base units in the system of units (Resolution 6 of the 10th CGPM 1954; Taylor and Thompson 2008). This system of units would later (in 1960) be coined as presently known *Syst'eme international d'unit'es* abbreviated as SI (Resolution 12 of the 11th CGPM 1960). The recognition of candela as one of the seven base units was followed by its amendment in 1967, by the thirteenth CGPM. Now the candela was defined as (Resolution 5 of the 13th CGPM 1967):

> "The Candela is the luminous intensity, in the perpendicular direction, of a surface of 1/600,000 square metre of a blackbody at the temperature of freezing platinum under a pressure of 101,325 newtons per square metre."

This definition had two main changes. The new candle (later renamed as candela) was established in terms of sixty new candle which was defined to be the radiation from one square centimeter of a blackbody held at a particular temperature. The new definition now defined one candela instead of sixty new candle, and hence, instead of defining the radiation from a one square centimeter area, the radiation from an area of one part of six hundred thousand square meters was defined. Thus, there was no change in realization of the level of brightness but the change brought the definition close to the base units. The other important change, worth a mention, was the introduction of a definite pressure. The freezing point of a substance does change with pressure. Hence, by defining the pressure, a more accurate temperature point was established by the new definition. With this, an internationally accepted candela was established which was defined in terms of law of physics.

The blackbody radiator thus overcame the predicament of instability of the filament-based lamps, and on the other hand, it also addressed the issues with reproducibility of the fuels for the combustion lamps. By now, as the spectrum of the blackbody radiation was well established; hence the concerns of visual physiological assessment of the Candela, prevailing during the photometric measurements, could be dealt with (Sperling and Kuck 2019).

The spectrum of the radiation emitted by a blackbody radiator at a particular temperature is defined by Eq. 1. The radiance of the radiation being emitted by the blackbody (in vacuum) at a particular temperature T can be calculated by integrating the LHS of Eq. 1 over wavelength and can be represented as:

$$L_e(T) = \int_0^\infty \frac{2hc^2}{\lambda^5}\left(\frac{1}{e^{hc/\lambda kT} - 1}\right)d\lambda \tag{2}$$

Eq. 2 gives the radiance of the blackbody radiator which is basically the radiant power being emitted by a unit area of the radiator into a solid angle of one steradian. If the area of the radiator is known, then the radiant intensity can be calculated by multiplying Eq. 2 with the said area. As the definition of candela defines the area of the radiator to be one part in six hundred thousand square meter and the temperature to be the freezing point of platinum at a pressure of 101,325 pascal (T_{FP}), hence the radiant intensity which would be perceived as one candela by an average human eye would be given as:

$$I_e(T = T_{FP}) = \frac{1}{600000}\int_0^\infty \frac{2hc^2}{\lambda^5}\left(\frac{1}{e^{\frac{hc}{\lambda kT_{FP}}} - 1}\right)d\lambda \tag{3}$$

and the corresponding spectral radiant intensity would be given as:

$$I_{e,\lambda}(\lambda, T_{FP}) = \frac{1}{600000}\frac{2hc^2}{\lambda^5}\left(\frac{1}{e^{\frac{hc}{\lambda kT_{FP}}} - 1}\right) \tag{4}$$

Since the blackbody radiator was accepted internationally as the standard for radiometric and photometric measurements, leading National Measurement Institutes (NMIs) like NPL, UK; NIST, USA; PTB, Germany; and VNIIOFI, Russia, established their radiation scale toward the end of the last century (Johnson et al. 1994; Harrison et al. 1998; White et al. 1995; Sperfeld et al. 1995; Sapritsky et al. 2003). In 2007, India established its variable temperature blackbody radiator (BB3200pg, 1800–3200 K, emissivity ~0.999) as the primary standard for optical radiation at CSIR-National Physical Laboratory (CSIR-NPL), India.

Defining the Response Function of Human Eye

In nature, two basic aspects of light are emission and detection. The light sources, natural or artificial, emit light, and on the other hand, detectors, natural (eye) or man-made, detect the light. On similar lines, the optical radiation standards can be source based (blackbody radiators discussed in previous section) and detector based. The detector-based standard, in contrast to blackbody radiators, should detect and quantify the radiation. However, all detectors have their own characteristic spectral responsivity. Hence, when the detectors are being used for measurement of

photometric parameter like candela, then it becomes important for the detectors to imitate the human eye response, as they detect and quantify radiation. Not only the unit of candela but all photometric parameters are quantified on the basis of the power of radiation as per the perception of the human eye.

Thus, for reliable measurement of photometric parameters, it becomes important to closely correlate measurements with vision characteristic of an average human observer. This correlation can be established only by knowing the human eye characteristics. Though we cannot perceive this in our day-to-day life, our eye does not behave in the same way to all the wavelengths of radiation even within the visible range.

With the passage of time, requirement for the standardization of the physiological aspect of vision was felt. A number of experiments involving a plethora of human subjects were carried out to reach a point where a function of the responsivity of the eye with respect to wavelength could be deduced (Schanda 2007). The response function of an average human eye is now well known and is in the form of a bell-shaped curve peaking at a wavelength of 555 nm and going to zero on either side around 380 nm and 780 nm (Fig. 3). The curve truly depicts the natural marvel of the eye, which responds best to green light (555 nm) and its vision dies down in the UV and IR regions for the human. This function came to be known as the luminous efficacy function of an average human eye, and it was adopted by the CIE in 1924 in its initial form (Rovamo et al. 1996). In other words, luminous efficacy function for the human eye depicts the inverse of the relative radiant power that would be required to produce the identical visual perception of brightness over all the wavelengths in the visible region of the electromagnetic spectrum (Schanda 2007). Luminous efficacy is basically the luminous value perceived per unit radiant power. It is important to point out that the luminous efficacy function being currently discussed represents the human eye response in well-lit conditions and hence also

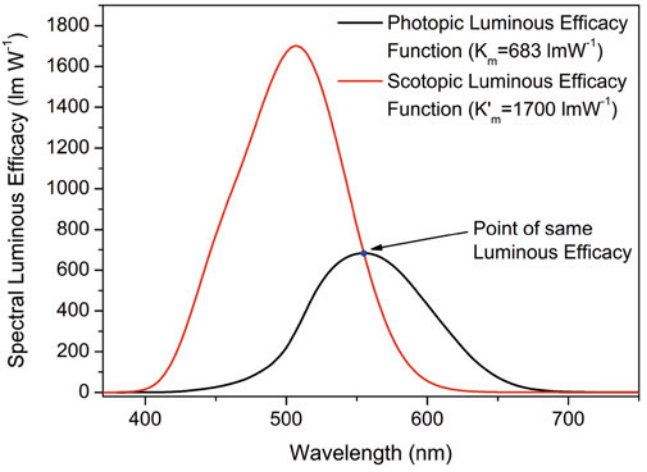

Fig. 3 Response function of a light-adapted (photopic) and dark-adapted (scotopic) average human eye (Goodman et al. 2016; Ohno et al. 2020)

known as the photopic response. This photopic luminous efficacy function, V(λ), represents the relative spectral responsivity of an average human eye in a light-adapted vision for a 2° field of view (cone vision) (Rovamo et al. 1996; International Commission on Illumination (CIE) 1983).

The luminous efficacy function being adopted by the CIE in the year 1924 was a major step for scientific measurement of light as per the perception of the average human vision. It will not be an exaggeration in stating that this laid the base of human-observer independent photometric measurements and in true sense provided a physical base to the physiological phenomenon of vision. This function was important not only for detector-based standards but also for the source-based standardization of light measurements. Without this luminous efficacy function, the photometric measurements would have always relied on human observers, which can never provide an absolute measurement with good reproducibility and would have lacked a scientific base. Thus, the V(λ) function gave a precise methodical basis of characterizing the visual impression of the electromagnetic radiation, closely correlating it with the vision of an average human eye stimulated by the radiation. This adoption played a crucial role not only in the field of photometric measurements, but also laid the foundation for the standardization of the CIE color matching functions.

As mentioned earlier, the luminous efficacy curve being discussed is for an average human eye in a bright field of vision. However, the illumination condition strongly affects the responsivity of the human eye. As we all have experienced, when we encounter sudden darkness, our eye requires some time before it can start perceiving the surroundings in the dark. This is the time when our eye adapts to the darkness or technically the responsivity of the natural detector changes. Now, since it is giving stimulus in lower radiant power, the value of luminous efficacy should increase. To provide a physical base for the human vision in the dark (rod-only vision), an efficacy function was defined which is known as the scotopic luminous efficacy function, V'(λ), that gives relative spectral responsivity of dark-adapted vision of an average human eye (International Commission on Illumination (CIE) 1983). The photopic as well as the scotopic luminous efficacy curves are characterized by a similar bell shape (Error! Reference source not found (Goodman et al. 2016; Ohno et al. 2020).). However, the peak of the scotopic luminous efficacy function can be observed to be at a shorter wavelength as compared to that for the photopic luminous efficacy curve. The disparity between the two functions is coined as Purkinje effect (Wyszecki and Stiles 1982) and the level of illumination between brightness (cone dominated vision) and complete darkness (rod dominated vision) is called the Purkinje illumination range or mesopic range (Zwinkels et al. 2010; Goodman et al. 2016).

The following equation is used to derive the photometric parameters by weighing the corresponding radiometric functions with this luminous efficacy function (Ohno et al. 2020):

$$X_V = K_m \int_0^\infty V(\lambda) X_e(\lambda) d\lambda \tag{5}$$

where the symbols represent physical quantities as follows:

X_V: Photometric quantity.

K_m: Maximum luminous efficacy in the photopic regime which is defined at a wavelength of 555 nm and has a value of 683 lmW^{-1}.

$X_e(\lambda)$: Spectral density of the corresponding radiometric parameter.

λ: Radiation wavelength in air.

Toward the end of the twentieth century, the growth of semiconductors made the use of solid-state detectors viable. The responsivity of the detectors now could be tuned by manipulating the material of the detectors and by using various filters. As the responsivity of the detector is tuned to the photopic luminous efficacy function ($V(\lambda)$) for a 2°-Observer, the detector would now become a photometer. A detector without $V(\lambda)$ correction measures radiometric quantity while the one having the $V(\lambda)$ correction can measure photometric quantities.

With this, one candela, now, could be derived from the radiant intensity given in Eq. 3 (obtained using Planck's formula), by weighing it with the luminous efficacy function as discussed in Eq. 5. Thus, using Eqs. 3 and 5, one candela can be defined as:

$$1cd = \frac{K_m}{600000}\int_0^\infty V(\lambda)\frac{2hc^2}{\lambda^5}\left(\frac{1}{e^{hc/\lambda kT_{FP}}-1}\right)d\lambda \tag{6}$$

On the other hand, the maximum photopic luminous efficacy (K_m) may also be determined as the ratio of the photometric quantity of one candela to the integral involving the radiometric quantity. Thus K_m can be mathematically derived using Eq. 6 and expressed as:

$$K_m = \frac{1}{\frac{1}{600000}\cdot\int_0^\infty V(\lambda)\frac{2hc^2}{\lambda^5}\left(\frac{1}{e^{hc/\lambda kT_{FP-1}}}\right)d\lambda}\left[\frac{cd}{m^2\cdot\frac{W}{sr.m^2}}\right] \tag{7}$$

The equation also leads to the value of K_m for photopic vision to be nearly 683 lm/W (Sperling and Kuck 2019). This maximum luminous efficacy is achieved at the wavelength of 555 nm corresponding to the peak of the bell-shaped curve (Fig. 3). In 1977, CIE adopted the value of the peak luminous efficacy of monochromatic radiation of a frequency of 540×10^{12} Hz (wavelength of 555 nm) as 683 lm/W (Resolution 3 of the 16th CGPM 1979).

Candela Based on Human Vision

The mid-1940s witnessed the transition of defining candela using Planckian radiators at a particular temperature and phasing out of the artifact lamps. Till the late 1970s, owing to the definition being based on the Planckian radiator, candela remained to be dependent on the International Practical Temperature Scale (IPTS)

as the realization of the photometric quantity was defined at the freezing point of platinum. However, as time progressed, the IPTS also witnessed its upgradation. During the decade of the 1960s, the freezing point of platinum changed based on the IPTS-68 (Saha et al. 2020). Thus the dependence of candela on the IPTS led to a direct variation in the scale of photometry also. On the other hand, the other disadvantages of the blackbody radiator (as the standard for photometric quantity), especially its challenging and expensive maintenance, were starting to be highlighted (Taylor and Thompson 2008; Parr 2000). Further, excessive divergence in the results for the realization of primary standards initiated a search for an alternate standard, apart from the blackbody (Resolution 3 of the 16th CGPM 1979).

The adoption of the standard value of the peak photopic luminous efficacy by the CIE in 1977 paved the way for a new definition of candela which would be independent of temperature. In 1979, the 16th CGPM adopted the new definition of candela as (Resolution 3 of the 16th CGPM 1979):

> The Candela is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} hertz and that has a radiant intensity in that direction of 1/683 watt per steradian.

The new definition did not depend on any temperature. Further, instead of relying on a broadband source like a blackbody, the new realization of candela was based on a monochromatic radiation. The 540 THz frequency is not only the frequency where the photopic luminous efficacy shows a peak, but a close observation of Fig. 3 would reveal that both the photopic and scotopic luminous efficacy curves intersect at that wavelength of 555 nm (corresponding to 540 THz) and both have the same luminous efficacy there (Fig. 3). It would be interesting to point out here that apart from the photopic and scotopic luminous efficacy curves, all those in the Purkinje illumination range also pass through the same 540 THz frequency and has the same luminous efficacy at the said point (Saha et al. 2020). This shows that the response of an average human eye remains independent of illumination for a radiation of frequency 540 THz. This choice of frequency for defining candela proved to be beneficial as the originally defined K_m value of 683 lm/W could be preserved, which was adopted after a large number of measurements on the blackbody radiator through tedious international measurement campaign (Sperling and Kuck 2019).

The choice of the wavelength and the value of K_m acted as a bridge between the new and old definitions. Hence, on the one hand, it paved the avenue for establishment of candela through the detector-based measurement of optical power, and on the other hand, even with the introduction of the new definition, the standards based on blackbody radiators were not absolutely obsolete. Further, the luminous intensity at different wavelengths could now also be relatively established as the luminous efficacy curve was adopted by the CIE (Parr 2000).

The definition of 1979 was a point wherein the detector-based realization of candela entered the arena and proved to be advantageous over the source-based standard. Though the solid-state detectors now seem to be an easy way for measurement of candela, its realization based on a physical quantity was enabled by the development and advancement of the electrical substitution radiometers. Since light

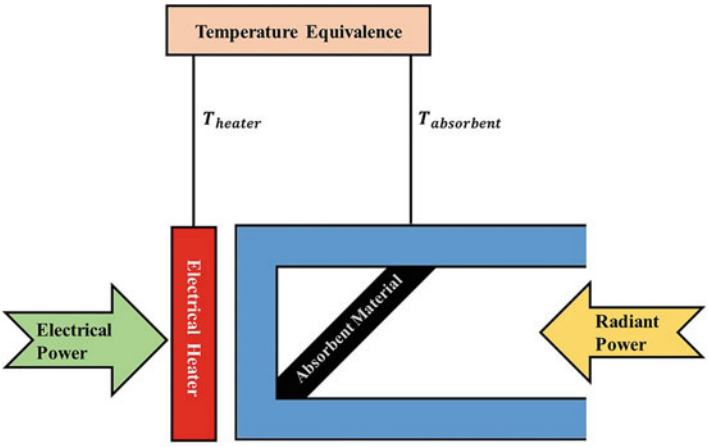

Fig. 4 Schematic of absolute radiometer

is a form of energy, hence an incident radiation, when absorbed by a body, leads to a rise in temperature of the absorbent. The electrical substitution radiometer exploits this principle and quantifies the incident radiant power by comparing it with an electrical power that could lead to the same rise in temperature (Fig. 4). The equivalence of the optical power and electrical power is established through the heating caused by the respective powers. This principle provides an edge to the electrical substitution radiometers, which relies on equivalence of a physical parameter, over the solid-state detectors as they rely on the radiometric response of the material. The electrical substitution radiometers are also known as absolute radiometers as the radiant power is derived in reference to physical laws and the measurements are completely independent of any comparison with other radiant power. As the measurements now depend on the principle of equivalence of temperature caused by two different types of power (radiant and electrical), a low background temperature proves to be helpful in increasing the sensitivity and hence reducing measurement uncertainties. For this reason, the absolute radiometry is done in the cryogenic temperature region which gives the name cryogenic radiometer.

NMIs across the globe initiated and worked to develop and establish cryogenic radiometer for establishing candela during the 1970s to 1980s (Parr 2000; Ohno et al. 2013). The absolute radiometer at room temperature was established at CSIR-NPL, India, in 1988, which was followed by the establishment of the cryogenic radiometer scale in the year 2012 (Zwinkels et al. 2010).

Candela and Defining Constant, *Kcd*

As science and technology progressed into the twenty-first century, the demand of higher accuracy and lower uncertainty emerged. During this time, the scientific measurements and their scope of improvement were strongly pursued at BIPM (*Bureau International des Poids et Mesures* or International Bureau of Weights

and Measures) and NMIs around the world. As the values of fundamental constants used in physics (e.g., speed of light, Planck's constant, etc.) had achieved fairly accurate values, the stage had arrived when the SI base units could be established in terms of the defining constants (Resolution 1 of the 24th CGPM 2011a). Bearing in mind the necessity of stable and self-consistent SI base units that would be practically realizable and be based on fundamental physical constants, CGPM initiated the formal transition of SI units from the beginning of the second decade of twenty-first century (Resolution 1 of the 24th CGPM 2011b). The metrology community agreed to give exact values to the defining constants (without any uncertainty) which would lead to further reduction of measurement uncertainty (Resolution 1 of the 24th CGPM 2011a). Now the definitions of SI units could be independent of processes and artifacts. Thus, in 2018 the SI units were redefined wherein the definitions of all the seven base units were established on the basis of seven defining constants, which were being used as fundamental constants of nature (Resolution 1 of the 26th CGPM 2018). As the new SI units based on fundamental constants of physics were adopted by the 26th CGPM, the luminous efficacy of 540 THz monochromatic radiation was coined as K_{cd}, having a value of 683 lm/W. The definition adopted by the 26th CGPM and implemented from 20th May 2019 may be read as (Resolution 1 of the 26th CGPM 2018; The International System of Units (SI) 2022):

> "The Candela, symbol cd, is the SI unit of luminous intensity in a given direction. It is defined by taking the fixed numerical value of the luminous efficacy of monochromatic radiation of frequency 540×10^{12} Hz, K_{cd}, to be 683 when expressed in the unit lm W^{-1}, which is equal to cd sr W^{-1}, or cd sr $kg^{-1}m^{-2}$ s^3, where the kilogram, metre and second are defined in terms of h, c and $\Delta\nu_{Cs}$."

The new definition establishes Candela on the basis of the constant, K_{cd}, with the unit lm/W, wherein the value of the constant K_{cd} is equal to 683 lmW^{-1} or 683 cd sr $kg^{-1}m^{-2}$ s^3 for 540 THz monochromatic radiation. Thus.

$$1\ cd = \frac{K_{cd}}{683} kg\ m^2 s^{-3} sr^{-1} \tag{8}$$

As the candela depends on other base units, it follows (Saha et al. 2020):

$$1cd = \frac{1}{\left(6.626\ 070\ 15 \times 10^{-34}\right)\left(9\ 192\ 631\ 770\right)^2 683} \left(\Delta v_{Cs}\right)^2 h K_{cd} \tag{9}$$

From Eq. 9, the dependence of the definition of candela on Planck's constant and the ground state hyperfine splitting frequency of the cesium 133 atoms, apart from the K_{cd}, can be inferred (The International System of Units (SI) 2022). Moreover, the measurements in electrical substitution radiometry are based on electrical measurements. Hence, the definition of candela would be prone to variations in the definition of electrical units. However, in the present scenario when the accuracy in the realization of candela is limited by uncertainties of the order of 100 ppm, any practical change in the strategies for realization of photometric and radiometric quantities is hardly expected (Sperling and Kuck 2019; Yadav and Aswal 2020).

Toward Quantum Candela

Photometry has progressed immensely especially through the twentieth century. It has seen the evolution of standards from very basic combustion candles to sophisticated systems like blackbody radiator and cryogenic radiometer. The dawn of the twenty-first century saw the redefinition of candela to be based on K_{cd}. However, the scientific community is still active to reach a more fundamental definition of candela, which would be based on photon. The "quantum candela" is expected to be the future of photometry and would establish its traceability to SI through the quantum regime of the electromagnetic radiation (Mise en pratique for the definition of the candela and associated derived units for photometric and radiometric quantities in the SI 2019). The quantum candela would be established in terms of photon number of known wavelength, thus depending on the particle nature of electromagnetic wave. This has led toward evaluation of the photometric, radiometric, and spectral radiant quantities with reference to photon counts (Sharma et al. 2009; Cheung et al. 2007).

The counts of photon can be related to the radiation power as

$$P = nh\nu = n\frac{hc}{\lambda} \tag{10}$$

where the symbols denote as follows:

P: radiometric power.

n: Number of photons per second.

h: Planck's constant.

ν: Frequency of radiation.

Thus, the dependence of the new quantum candela on the value of Planck's constant, speed of light, and wavelength (or frequency) of radiation leads to its uncertainty to be governed by the uncertainties in the wavelength (or frequency) determination and hence, in turn on the realization of the scale of time, i.e., one second (Cheung et al. 2007). However, since the values of h and c being defining constants have been accepted to be without any uncertainty, the measurement of radiometric power would be having uncertainties that would be contributed by the measurement strategies of the number of photon and on the other hand the wavelength (or frequency) of the light. It is important to point out that the accuracy of frequency measurements limits the precision with which the rate of photon can be measured. At present, the uncertainty in frequency (rate of photon) measurement is 10^{-16}, while the uncertainty in wavelength measurement is 10^{-12} (Sperling and Kuck 2019). Hence, in the current scenario, the measurement of radiometric power cannot be expected to have an uncertainty better than 10^{-12}.

The spectral radiometric parameters would be required to be derived from the corresponding quantities based on photon counts. The equation thus would be (Sperling and Kuck 2019; Zwinkels et al. 2016):

$$X_{e,\lambda}(\lambda) = \frac{hc}{\lambda} n_a(\lambda) X_{p,\lambda}(\lambda) \tag{11}$$

where the symbols represent physical quantities as follows:

$X_{e,\lambda}(\lambda)$: Spectral radiometric parameter.

$X_{p,\lambda}(\lambda)$: Corresponding parameter based on photon number.

$n_a(\lambda)$: Refractive index of air.

The photometric parameters were derived from the radiometric parameter through Eq. 5. In similar lines, for light-adapted vision, a photometric parameter (X_V) would be related to its corresponding quantity defined on the basis of photon number (X_p) by the equation (Sperling and Kuck 2019):

$$X_V = K_m hc \int_0^\infty X_{p,\lambda}(\lambda) \frac{n_a(\lambda)}{\lambda} V(\lambda) d\lambda \tag{12}$$

At present, one candela is defined as that luminous intensity which is perceived by an average human eye when exposed to a radiation of 540×10^{12} Hz frequency having a radiant intensity of 1/683 watt per steradian. Hence, putting the values of the constants in the Eq. 12 gives the number of photons which would be required, from a 540 THz source, every second in a solid angle of one steradian for establishing one candela and it comes out to be 4.092×10^{15} photons/second/steradian (Cheung et al. 2007). Thus defining one candela on the basis of photon number would require a source of photon and a device to count it for emitting and counting photons at a rate of the order of 10^{15} photons per second. Thus, for radiometry and photometry deriving traceability from photon counting, emitters with precise control on the number of photons would be required and simultaneously, devices for accurate counting of the rate of incoming photon would also be necessary. A source, of definite wavelength, which is capable of emitting a definite number of photons which are temporally well separated would be replacing the blackbody and absolute cryogenic radiometer as the standard source when the transition to photon number-based radiometry and photometry becomes a reality. Parallelly, counting system would be necessitated for establishing the single-photon sources as primary standards (CCPR Strategy Document for Rolling Development Programme 2017).

A single-photon source, which emits photons at symmetrically spaced temporal intervals, is usually excited for emission through its triggering by a periodic optical pulse or electronic signal (Vaigu et al. 2017). Fundamental research for absolute source of photon has already gained momentum. Some of the popular methods for achieving definite photon flux are by using spontaneous parametric down conversion (SPDC), quantum dots, attenuated laser beam, and surface acoustic wave (SAW) (Cheung et al. 2007). The method of laser attenuation, which would use multiple attenuators that are calibrated over a multi-order magnitude, can prove to be useful for obtaining multi-photon emission and hence establish a steady photon flux required (Eisaman et al. 2011; Gerrits et al. 2020). In principle, a two-level system that is capable of producing a spontaneous emission can act as a single photon emitter. Such emissions over a wide temperature range (initially cryogenic temperatures to even ambient conditions) have been demonstrated in the solid-state regime using quantum structures (Senellart et al. 2017). The report of acousto-electronic single photon source in the year 2000 (Foden et al. 2000) has been followed by

reports wherein photon emission based on the principle of SAW has been reported, as a lone electron transports in SAW potential through a n-i-p junction and then sees recombination with holes (Hsiao et al. 2020). Apart from the solid-state techniques, single photon source is also realized by the phenomenon of SPDC where photons are produced in pair and are of probabilistic nature (Eisaman et al. 2011). SPDC produces photons, that are correlated and of lower frequency as compared to the parent beam, through interaction of high energy photon with a non-linear medium.

Sourcing of single photon is not, the only important aspect of photon-based realization of photometric and radiometric parameter. Photon counting by single-photon detectors would also be required to be mature before candela can be redefined based on photon counting. In principle, a single-photon detector or a photon counter is based on its ability to detect faint optical pulse (Chunnilall et al. 2014). This incoming optical pulse is efficiently converted into a suitable electronic signal for detection. The "efficiently converted" phrase is of paramount importance in the preceding line. Detection of short-lived faint optical pulse is required for an efficient photon counter. Largely a photon counter has two parts: conversion of the incoming photon to electronic signal and the electronics for using the signal. Currently, both of these aspects enjoy the attention of the scientific community as efforts are being made to achieve a reliable photon counter that may support the definition of quantum candela (Eisaman et al. 2011; Kapri et al. 2021; Kapri et al. 2020).

The realization of photon-based candela may not be that lucid as it sounds from the text and current literature. The practical establishment of quantum candela requires emission and detection of photons in the order of 10^{15} photons per second. Efforts are still required to achieve a reliable system for emitting and detecting photons at this rate (Zwinkels et al. 2010; Sperling and Kuck 2019). Apart from a solution of emission and detection, another important aspect is the determination of pulse frequency as photon counts are deduced from counting of excitation pulses (Sperling and Kuck 2019). However, the NMIs, academia, and the scientific community are relentlessly working toward the realization of quantum candela (Chunnilall et al. 2014; O'Brien et al. 2009; Rodiek et al. 2017).

Candela at Various NMIs

Many NMIs across the globe have realized candela in different ways which is available on the BIPM Key Comparison Database (BIPM-KCDB) website (few are tabulated in Table 1) (BIPM 2022). The measurement capability span of the photometric quantity is currently quite broad among the NMIs, wherein the list of Calibration and Measurement Capabilities (CMCs) at the KCDB database shows that the candela is being realized from as low as 1 m cd to as high as 1000 k cd. Though the traceability is taken from a primary standard but for establishing measurement capabilities for dissemination, NMIs can be seen to prefer standard lamps and photodetectors for establishing candela. There can be a number of ways for establishing traceability to any photometric or radiometric unit from a primary standard. Here we present a typical way of establishing candela with traceability from source- and detector-based primary standards (Parr 2000; Ohno et al. 2013).

(a) Traceability of Candela from Source-Based Standard (Blackbody).

The spectral radiance of the blackbody standard source can be established if the temperature of the Planckian radiator is known (using Eq. 3). The spectral radiance scale can be transferred to a spectral irradiance lamp through a spectroradiometer. If the distance (d) between the radiator source and the spectroradiometer is specifically known, and the radiating area (A_1) can be accurately determined using a precision aperture, then the spectral irradiance of the blackbody source can be deduced as:

$$E(\lambda) = \frac{L(\lambda).A_1}{D^2} \tag{13}$$

where D is a parameter having contributions from distance, area of precision aperture at the source, and the detector aperture and considers the finite size of the apertures (Parr 2000). The standard spectral irradiance lamp can be used to calibrate an illuminance meter. The calibrated illuminance meter, in turn, can be employed to determine luminous intensity of a source if the distance (d) between the two is precisely known.

$$I_v = E_v.d^2 \tag{14}$$

Thus, the scale of luminous intensity is established using a source-based standard, i.e., blackbody.

(b) Traceability of Candela from Detector-Based Standard (Cryogenic Radiometer).

The primary standard detector or the absolute cryogenic radiometer establishes the radiant power of a source. This calibrated radiant power is used to characterize a standard detector, like trap detector, from which the absolute spectral responsivity of a photometer ($s(\lambda)$), having unit of A/W, is deduced. The absolute spectral responsivity scale can then be used to deduce the responsivity of a standard photometer (R_{vf}) by using the equation:

$$R_{vf} = \frac{\int_{\lambda} P(\lambda)\, s(\lambda) d\lambda}{K_m \int_{\lambda} P(\lambda)\, V(\lambda) d\lambda} \tag{15}$$

where, P(λ) denotes the spectral power distribution of the test source. The unit of the R_{vf} is hence derived in A/lm. If the area of detector aperture (A_1) is precisely known, then the responsivity of the photometer for illuminance (R_{vE}), having unit A/lx, can be established as:

$$R_{vE} = A_1.R_{vf} \tag{16}$$

The photometer calibrated for R_{vE} can be used to measure illuminance, from which luminous intensity can be derived if the source-detector distance is known, and the distance is sufficient to assume the source as a point source. If a current (I) is generated by the photometer on being exposed by a point source at a distance d, then the luminous intensity (I_v) of the source can be given by:

$$I_v = r^2 . \left(\frac{I}{R_{vE}} \right) \tag{17}$$

Thus, the scale of luminous intensity can be established deriving traceability from an absolute cryogenic radiometer.

The principles for realization of candela though seems to be simple, but their effective realization may take years, especially in evaluation and making efforts for reduction of uncertainties in the measurements. Apart from the radiometric and photometric quantities, the dimensional parameters like distance and area contribute toward uncertainty at each step. Current supplied to the lamps as well as the measurement of current from a photometer or a detector also plays a role in the uncertainty calculations. Further, the color correction factor, alignment, and parameters of optical components like spectrometer and filters play a key role (Ikonen et al. 1995). The range of uncertainties in candela realization may be anticipated from the data of KCDB database. It can be seen that the uncertainties in realization of candela currently stand in the range 0.4–8.5% for various types of lamps. Presently NPL, UK, and PTB, Germany, have the lowest uncertainty in realizing which stands at 0.4%. This is closely followed by 0.41% for NMI, Australia, and 0.5% for NIST, USA, and NIM, China. The current capability for realization of candela at CSIR-NPL, India, is in the range 1–1000 cd with an uncertainty of 1.4% (100–1000 cd) and 1.5% (1–100 cd), through a set of reference lamps and photometers.

Role of CSIR-NPL, India, in Disseminating Optical Radiation Standards

India, as a country, and the world, as a whole, are looking toward reducing energy consumption and hence its carbon footprint, through a number of green initiatives. With government initiatives, our country is adapting an energy-efficient lifestyle through various programs like Star Labelling Programme and UJALA scheme. These have popularized the energy-efficient LED lights among the masses. Further, the Indian economy being in a growing trajectory and supported by initiatives like "Atma Nirbhar Bharat" and "Make in India" has resulted in India becoming a region of budding industries. These factors have led to the establishment and progress of the LED light manufacturing industries. As demands increased, the industry started to work toward designing new products for domestic as well the international market. Further, the increase in production of LED lamps and luminaires has resulted in imports of raw materials and LED chips and panels. Hence, the beginning and the end of production lines of the lighting industry required reliable photometric measurements for the benefit of the consumers as well as the producers. A reliable testing

of the LED chips is required for deterring poor-quality imports, and at the same time there remains a requirement for qualifying the worthiness of the final product for safeguarding the consumer interest. CSIR-NPL is in the process of establishment of an apex level calibration and testing facility for solid-state light (SSL) sources, particularly for LED-based lighting. Recently, C-type Goniophotometer (LMT GODS-2000) has been installed in the newly created LED Photometry Laboratory. The system primarily measures total luminous flux of a lamp in an absolute manner. The luminous flux is one of the important photometric parameters characterizing a light source. It provides the numeric quantification of the total power radiated in all directions as would be perceived by the human eye. The luminous flux is an important parameter with respect to characterization of light sources for their energy efficiency, as it is used to calculate the luminous efficacy of a lamp. The luminous efficacy, in turn, is used for star labelling of the lighting product. The installed C-type Goniophotometer is a mirror-based Goniophotometer that can measure light sources up to two meters and weighing up to 50 kg. A schematic diagram of the Goniophotometer system is shown in Fig. 5.

The other system that has been installed in the project is the Optical Radiation Test System. It would be used for the measurement of spectral power distribution, radiance, irradiance, radiation exposure, specific effective radiant ultraviolet power, illuminance, and other parameters of LED, LED modules, LED lamps, LED luminaires, fluorescent lamps, HID lamps, halogen lamps for both general lighting services, and special light source. The measurements of the system would facilitate characterization of light source in reference to photobiological safety.

Apart from the LED light industry, illumination industry in general which includes likes of auto lamp manufacturers, operation theater light industry, etc. also require reliable photometric assessment of their products. Moreover, the current pandemic situation has opened the market for home-made and imported UV germicidal irradiation (UVGI) systems, which require proper measurement and characterization for UVGI properties to ensure proper disinfection. Radiometric measurements are required for ensuring the reliability of such UVGI products (Sharma et al. 2022). The industries are supported with these calibrations and testing services through a number of public, private, and internal laboratories. For reliability of these measurements and international acceptance, it is vital to ensure that these

Table 2 Current CMCs of CSIR-NPL, India, in the field of photometry, colorimetry, and radiometry (BIPM 2022)

Sl. No.	Parameters (bumber of CMCs)	Range	Expanded uncertainty at coverage factor of $k = 2$
1	Luminous intensity (2)	1 cd to 10^3 cd	±1.4–1.6%
2	Luminous flux (2)	1 lm to 2×10^4 lm	±1.8–2.0%
3	Illuminance (2)	1 lx to 5×10^3 lx	±1.6–2.0%
4	Luminance (3)	1 cd/m^2 to 10^4 cd/m^2	±1.6–2.0%
5	Correlated color temperature (1)	2000 K to 3000 K	±20 K
6	Spectral irradiance (3)	(wavelength range) 280 nm to 400 nm 400 nm to 800 nm 800 nm to 2500 nm	±1.9–6.0% ±1.9% ±3.3–5.2%
7	Illuminance responsivity (1)	In illuminance range 1 lx to 5×10^3 lx	±1.4%

measurements, from the testing laboratories, have their traceability to the SI units. CSIR-NPL, being mandated to be the NMI of India, plays the role of providing the traceability of SI units for the measurements being carried out by the testing and calibration laboratories.

CSIR-NPL, India, realizes, maintains, upgrades through R&D, and disseminates the standards for photometry and radiometry. The current list of CMCs of CSIR-NPL, India, in the field of photometry, colorimetry, and radiometry is summarized in Table 2. Apart from the parameters mentioned in Table 2, measurement facilities for spectral transmittance and spectral reflectance (diffuse and specular) in the wavelength range 380–780 nm with an expanded uncertainty of ±1.5% at a coverage factor of $k = 2$ are also available (Optical Radiation Standards 2022; Sharma et al. 2010).

Conclusion

Among the seven SI base units, candela is the unit of luminous intensity and is the one used for measurement of light as perceived by the human eye. This is the only SI base unit linked with a physiological perspective of human vision. Over a period spanning over almost two centuries, the measurement of light has evolved from being based on observation to now being derived from the laws of physics. As the society accepted the need for light measurement, its unit travelled also a long way, initially being defined separately by different countries as candlepower, Carcel, and Hefner, which was ultimately unified and became internationally accepted as Candela. Along with the unit, the standards were also evolving. Initially the combustion lamps were being used as standards which later gave way to carbon-filament incandescent lamps to be used as standards for light measurement. As the

technologies developed, the definitions and hence the standards were taken to be based on law of physics. The initial definition of candela to be established from the laws of physics was based on blackbody radiation, and it laid the base of source-based photometry. As the technology for detectors advanced, with the growth of the semiconductors, detector-based photometry gained importance which was quickly followed by the definition of candela being based on monochromatic radiation and the emergence of absolute cryogenic radiometer as the standard. The most recent definition of candela came with the redefinition of the seven SI base units in terms of seven defining constants. Without disturbing the essence of previous description of candela, the new definition defined candela in terms of a defining constant K_{cd}. The time is not far when the current definition would further give way for the quantum realization of candela which has shown a hope of reducing the current level of uncertainties.

Abstract

The mole (symbol: mol) – the unit of the amount of substance – was first realized and redefined with the Avogadro constant in the context of the revision of the base units of the International System of Units (SI) in 2019. The number of entities in 1 mol is equal to the numerical value of the fixed Avogadro constant: 1 mol = $6.02214076 \times 10^{23}$ specified elementary entities. Starting with a historical survey, the realization and dissemination after the revision of the SI is explained with the X-ray crystal density (XRCD) method of the Avogadro project: "counting" silicon atoms in a 1 kg Si sphere. As a key experiment, the determination of the molar mass of silicon – for this purpose highly enriched in the isotope ^{28}Si – with its successive improvements is reported. The aim of this chapter is to provide a state-of-the art and compact description of the mole, its history, changes, and the new definition. Links of the amount-of-substance to

Introduction

The base unit of the amount of substance – the mole (symbol: mol) – is the latest of the seven base units, implemented in the SI, the International System of Units, in 1971, just five decades ago. However, the members of the Meter Convention agreed at that time on a definition linked to another SI unit – the kilogram. The mole was prior to its revision in 2019 linked to the mass of 12 g of the ^{12}C isotope – a certain mass of a certain entity. The term "mole" and its underlying concept have been of extreme importance for chemists and scientists as well as students, teachers, scholars, and others when dealing with chemicals and/or chemical reactions which have to be quantified either for analysis or synthesis or even just for teaching purposes. The principle of the mole enables the chemist to work with a basically infinitely large number of entities (e.g., atoms, molecules, ion, electrons) in a manageable way via the relation between a huge number of microscopic entities and the respective macroscopic portion – accessible via its mass and molar mass. The motivation of this chapter was based on the possible changes resulting in theory and practice from the new definition of the mole after the revision of the SI, which has been released on The General Conference on Weights and Measures (CGPM) at its 26th meeting (BIPM 2018; BIPM) in 2018. In this meeting, the CGPM considered the SI units should be self-consistent, provide long-term stability, and should be described on state-of-the art level physical experiments and respective laws. The SI should be defined based on seven fixed (invariable) defining constants (e.g., the Planck and the Avogadro constant) without associated uncertainties by definition. The new SI should be uniform and should support scientific as well as topics of trade, health, and others. In the new SI, effective from 20 May 2019, additionally, several defining fundamental constants are fixed. The Avogadro constant (symbol N_A) is $N_A = 6.02214076 \times 10^{23}$ mol^{-1}. This numerical value of N_A – among others – has been released in 2017 by the Task Group on Fundamental Constants (TGFC) of the Committee on Data for Science and Technology (CODATA) after a special least-squares adjustment (LSA) of the input values (Newell et al. 2018). The most prominent base unit – the kilogram – mainly triggered the revision of the SI, due to the inadequateness of congruence after comparing the International Prototype of the Kilogram (IPK) with its official copies on a regular basis over the last 100 years showing an increasing mismatch. To remove this last artifact – as an evident driving force as well as the historical attempts to harmonize the definitions of the SI units by introducing a set of invariable and fixed defining constants which

enable the realization and dissemination of the SI units by suitable laboratory experiments – was another important motivation for the revision. One of the initial ideas was given by *Max Planck*, addressing a universal system of constants, which will be discussed later in the context of the historical background and evolution of the mole (Liebisch et al. 2019). Prior to the revision of the SI, numerous institutes, especially national metrology institutes (NMIs) and the International Bureau of Weights and Measures (BIPM), were strongly involved in research and discussions concerning the new definition of this very SI base unit. One outcome was the Ad-Hoc Working Group on the Mole of the Consultative Committee for Amount of Substance: Metrology in Chemistry and Biology (CCQM), paving the way for its redefinition. The key references of the mole in the new SI are given in the SI Brochure and the *Mise en pratique* for the definition of the mole in the SI which were released by the BIPM (BIPM, CCQM; BIPM 2019a, b). After the revision of the SI which entered into force as of 19 May 2021, the revised definition of the mole is:

"The mole, symbol mol, is the SI unit of amount of substance. One mole contains exactly $6.02214076 \times 10^{23}$ elementary entities. This number is the fixed numerical value of the Avogadro constant, N_A, when expressed in the unit mol^{-1} and is called the Avogadro number.

The amount of substance, symbol n, of a system is a measure of the number of specified elementary entities. An elementary entity may be an atom, a molecule, an ion, an electron, any other particle or specified group of particles."

For the understanding of the basic concept of the mole – in the previous and in the new SI – it is necessary to give an overview on the historical background and development. This is done in the following. The ideas and pros and cons of the revision of the mole are addressed briefly, too. Since the mole is now defined via the Avogadro constant N_A, solely

$$1\,\mathrm{mol} = \left(\frac{6.02214076 \times 10^{23}}{N_A}\right) \tag{1}$$

it is now a completely independent and self-consistent SI base unit. Figure 1 shows a photograph of approximately 1 mol of pure silicon as a sphere with natural isotopic composition to visualize this SI unit in the macroscopic world. The sphere, which is used for demonstration purposes only, yields a balance reading of approximately 28 g and has a diameter of approximately 28 mm.

It is one concern of this chapter to explain the current state-of-the art procedures to realize and disseminate the mole. In this context, it must be noted that the planned revision of the SI unit kilogram gave a kind of priming for the revision of the SI in general in 2019. Finally, it was agreed that the artifact-based kilogram was defined via the fixed Planck constant h (Wood and Bettin 2019). Two experimental routes have been developed and asserted themselves: in one of them, the watt balance approach – now called Kibble balance experiment – the Planck constant h can be measured via a comparison of mechanical and electrical power with lowest associated uncertainty u, yielding finally $u_{rel}(h) < 1 \times 10^{-8}$ prior to the revision (Wood and

Fig. 1 A "mole sphere" made of 1 mol silicon with $m \approx 28$ g and a diameter $d \approx 28$ mm on a laboratory balance for the demonstration of the macroscopic meaning of "1 mol"

Bettin 2019; Petley et al. 1987; Gupta 2019). With this primary method at hand, the kilogram can be disseminated using the expression

$$1\,\mathrm{kg} = \left(\frac{h}{6.62607015 \times 10^{-34}}\right)\mathrm{m}^{-2} \times \mathrm{s} \tag{2}$$

The other primary method developed in parallel to realize the kilogram is the x-ray crystal density (XRCD) method. This experimental approach is used to determine the Avogadro constant N_A via "counting" the silicon atoms in a macroscopic single crystalline silicon sphere with a mass of 1 kg (Fujii et al. 2016). This approach has been applied for the first time by the former National Bureau of Standards (NBS, today: National Institute of Standards and Technology, NIST) in 1974, and since the 1980s, the XRCD method has been further developed by PTB and other institutes (Fujii et al. 2016; Deslattes et al. 1974). Initially, the XRCD method aimed at the definition of the kilogram via the Avogadro constant

$$1\,\mathrm{kg} = 10^3 \times \{N_\mathrm{A}\} \times u \tag{3}$$

with the numerical value of the Avogadro constant $\{N_A\}$ and the atomic mass unit u (with u = 1/12 $m(^{12}C)$ prior to the SI revision) (Becker 2003; Bettin et al. 2013). Equation (3) shows that the kilogram can be simply expressed via N_A, too. However, after the SI revision, the kilogram is defined via h. Fortunately, h and N_A can be converted into each other; thus two complementary primary methods were available to realize and disseminate the kilogram. The redefinition was introduced when both methods yielded results for the relevant constants in agreement with each other within a relative measurement uncertainty of 2×10^{-8}, which was one prerequisite of the redefinition of the kilogram and thus of the revision of the SI in 2019 (Stenger and Göbel 2012; Stock et al. 2019).

Consequently, the XRCD method is a primary method for the realization and dissemination of the mole, symbol mol, the SI base unit of the amount-of substance, symbol n, because it yields smallest uncertainties associated with n, it is completely understood, a complete uncertainty budget can be prepared, and an absolute value without the need of any reference standard is needed. Other names for the XRCD method which can be found in the literature are "Avogadro Project" and "Silicon Route" (Becker and Bettin 2011; Andreas et al. 2011; Becker et al. 2003). An overview of the principles of the XRCD method with special focus on the determination of the isotopic composition of silicon is given later. In the "mise en pratique" for the definition of the mole, it is stated that after the revision, any experimental method can be used to realize and disseminate the mole as long as it is traceable to the fixed defining constant (BIPM 2019b). Beside the XRCD method, some more practical methods are presented as well, e.g., the gravimetric approach which is still necessary in the daily life of laboratories using the relation between the macroscopic mass of an entity, its molar mass M, which has to be corrected for by the molar mass constant M_u, and the resulting amount of substance n. Other areas like electrochemistry derive n via the ratio of charge over charge number in electrolysis. The amount of substance is inversely proportional to the fixed Faraday constant times that ratio. Also, equations of state for gases can yield n having information about the pressure/volume and temperature relations. In all methods, the knowledge of the purity of the samples (entities) is one of the main limiting uncertainty contributions. In this chapter, also some typical relations between the amount of substance, the Avogadro constant, and other quantities and constants are reported with special emphasis to any changes prior and after the revision of the SI. One outcome of the revision of the SI is a clear distinction between the quantities amount of substance n and mass m establishing a respective unique feature, because prior to the revision n was dependent from m per definition. Also, after the revision in 2019, the practical measurement results of n are numerically the same as prior to the revision. In the chapter, the need of the redefinition and related changes are highlighted.

Additionally, a reference of the use of the mole and implications after the SI revision also for practical scientists may be used as an amendment for students' textbooks. Meanwhile, several scientific articles and reviews have been published concerning the revision of the mole. Here, only a short selection is cited and references therein are referred to Milton and Quinn (2001), Milton and Mills

(2009), Milton (2011), Marquardt et al. (2017), Güttler et al. (2017, 2019, 2019), Meija (2017), Brown et al. (2021), and Mills et al. (2006).

Brief Historical Survey of the Mole

The historical development of the term "mole" and its later introduction as the seventh SI base unit as well as its underlying quantity "amount of substance" is described in detail in several recent articles and reviews (Milton and Mills 2009; Güttler et al. 2019, 2019). The interested reader is also referred to the article of L. Cerrutti, who gave a comprehensive historical overview on the development and relations of the mole, the Avogadro constant, and the persons who discovered the respective quantities and constants with a variety of original cited research works (Cerrutti 1994). In this context, another comprehensive review article should be mentioned: A detailed review concerning the history, its development, and tools for the determination of the Avogadro constant has been published by P. Becker, initially demonstrating the purpose of the determination of N_A in the interrelation of the revision of the SI (Becker 2001).

Briefly, the concept of the mole started at least with the considerations of the British chemist J. Dalton (1808), who stated that atoms of one element are equal and have a special atomic mass and volume (Dalton 1808). This is in accordance with his "law of multiple proportions" (1803) which states that the combination of elements occurs in a ratio of (small) integers. At that time, there was no possibility for an exact experimental verification of these pioneering ideas which gave them a more axiomatic character. These findings were supported by the Italian scientist A. Avogadro, who published 1811 his hypothesis that presuming constant temperature and pressure, all gases of the same volume exhibit the same number of particles or molecules (Smith 1911). In the first half of the nineteenth century, these pathbreaking ideas almost felt into oblivion. Using the concepts of the atomic weight, in 1858 the Italian chemist S. Cannizzaro set up a list of chemical formulas and relative atomic masses (atomic weights) for all elements known at that time, which establishes the ideas and terms related to atoms, molecules, and atomic weights and later on pushed the development of the periodic table of the elements (Becker 2001). The basic concepts of atomic weights introduced by Cannizzaro gained a widespread attention and later on acceptance at least on the occasion of an international Chemistry meeting in Karlsruhe in 1860, mainly concerned with atomic and molecular theoretical concepts (Cerrutti 1994). The use and application of the atomic and molecular theory accelerates in the late nineteenth century. The concept of the "mole" has been probably first mentioned and applied by the chemist W. Ostwald. In 1893, he published a "Hand- und Hilfsbuch zur Ausführung Physiko-Chemischer Messungen." There, it is written "... let's generally call the weight in grams of a substance that is numerically identical to the molecular weight of that substance, one mole..." (Ostwald 1893). At that time, especially in Germany terms like "gram-molecule," "g-molecule," or "g-mole" circulated in the communities of chemistry and physics. In a publication of 1898, W. Nernst used explicitly the German term "Mol" and

"g-Molekel" as a "chemical mass unit" and in the context of the use of the equation of gases (Cerrutti 1994; Nernst 1893).

In the early twentieth century, the term "mole" already developed a twofold meaning: a description of a number and/or of a mass. A milestone was one of the first experimental determinations of the Avogadro constant by J. Perrin (1909), establishing the number of entities in 1 mol to be referred to as the Avogadro constant (Perrin 1909). Perrin used the expression "gram-molecule" at that time by the postulation that "any 2 g-molecules contain the same number of molecules (which is the number of the Avogadro constant)." Even A. Einstein used the term "gram-molecule" already in 1905 (Einstein 1905). During the next decades, these terms were used in ambiguous meanings. In 1955 U. Stille published a textbook of metrology where the use of the term "mole" was classified in a threefold manner (Stille 1955): The first use of the unit "mole" is that of a chemical mass unit of a special compound or atom (e.g., 1 mol = 28 g silicon). This is the relative atomic mass given in g. The second meaning is a number (of moles) n_{mol} according to the relation $n_{\mathrm{mol}} = N_{\mathrm{ent}}/\{N_{\mathrm{A}}\}$ with N_{ent} as the number of entities (which might be rather large) and $\{N_{\mathrm{A}}\}$ denoting the numerical value of the Avogadro constant (Avogadro number). The third application of the "mole" is the "amount of substance" which means that 1 mol is the amount of substance that contains as many entities as the relative atomic weight of, e.g., an element. Stille has introduced the term "amount of substance" for the first time, which is now commonly used as a key quantity in chemistry with the symbol n.

After progress in mass spectrometric techniques, notably the discovery of the isotopes ^{17}O and ^{18}O by W. F. Giauque and H. L. Johnston, the atomic weights were still based on a historic scale using the isotope ^{16}O as an anchor point with $A_{\mathrm{r}}(^{16}\mathrm{O}) = 16$ (Giauque and Johnston 1929). This was changed in 1959 to $A_{\mathrm{r}}(^{12}\mathrm{C}) = 12$ as a result of long and intense discussions between chemists and physicists (Guggenheim 1961). During the 1950s and 1960s, the concept of the "amount of substance" was then further immersed in the scientific communities, and its special need for chemistry was recognized. In 1971 the mole has been introduced as the seventh SI base unit at the 14th General Conference of the Meter Convention (CGPM) using the amount of substance as the underlying base quantity (CGPM, Resolution 3 of the 14th CGPM 1971; BIPM 1972; Terrien 1972). This step has been prepared by a joint recommendation of several international societies like the International Union of Pure and Applied Chemistry (IUPAC), the International Union of Pure and Applied Physics (IUPAP), and the International Organization for Standardization (ISO). The isotope ^{12}C of carbon was selected as the reference point of the scale of relative atomic weights at that time with $A_{\mathrm{r}}(^{12}\mathrm{C}) = 12$. This led to the old definition of the base unit mole prior to the revision of the SI:

"The mole is the amount of substance of a system that contains as many elementary entities as there are atoms in 0.012 kg of carbon 12. When the mole is used, the elementary entities must be specified and may be atoms, molecules, ions, electrons, or other particles, or specified groups of such particles."

As one outcome of the introduction of the mole as a base unit, in 1993 an international committee – the Consultative Committee for Amount of Substance

(CCQM) – was founded, working on the issues related to this base quantity "amount of substance" (BIPM).

Motivation for and Impact of the Redefinition of the Mole

As outlined, there existed increasing – almost accelerating – efforts for a revision of the SI during the last decades motivated and triggered mainly by the SI base unit of the mass, the kilogram, in its form of a (last) artifact, the International Prototype of the Kilogram (IPK), showing increasing discrepancies with its copies during the last 100 years. The kilogram would preferably be linked to an invariant constant of nature; thus already in 2006, ambitious efforts were undertaken to revise the SI although the prerequisites were not completely fulfilled (Mills et al. 2005). Another – not neglectable – advantage of a definition by an invariant constant of nature is the simple fact that the link to an artifact gets worse due to a stepwise sub-division of each, increasing and accumulating the measurement uncertainty. One main reason for the redefinition of the mole was to establish this SI base unit independently from any other unit as being previously from the unit of the mass – the kilogram. With the new definition of the mole, it is defined by one fixed constant of nature, a fundamental constant: the Avogadro constant N_A with no uncertainty any longer associated with. This fits the new definition of the mole into a set of invariant fundamental constants, independent from any artifact or experiment. For this reason, there is no standard or specification written in the definition about how to realize this base unit using a special experimental route. This can be chosen according to any available state-of-the art experiments when exhibiting the character of a primary method. From the point of view of the involved public – usually non-specialists in fields of metrology – especially teachers, students, and industrial scientists, who rely on the definitions and rules given by, to some extents, outdated textbooks, a more practical definition than the old one relating to 12 g of the carbon ^{12}C isotope, with the 1980 added specification that it referred to atoms in their ground state and at rest would have been desirable. In fact, in the comprehensive IUPAC Technical Report released by Marquardt et al. concerning the redefinition of the mole and related chemical quantities, several surveys were reported concerning the understanding of the definition of the mole of these user groups (Marquardt et al. 2017). Interestingly, the term *mole* is understood by most of them as a number of entities equal to the Avogadro number $\{N_A\}$. This circumstance legitimates the new definition of the mole via the Avogadro constant being closer to the common perception. A central benefit and legitimation for the introduction of the mole as an SI base unit in 1971 and more clearly after its new definition in 2019 is the fact that it presents an independent unit that is not based on artifacts such as the kilogram prototype or on any relation to specific elements or isotopes or any advice on how to realize the units. This unit is directly proportional to a number of entities which have to be defined when discussed. Usually, these elementary entities are "particles" used in chemistry like atoms, molecules, ions, and electrons. With the aid of this special quantity – the mole – scientists, especially chemists, can handle and calculate stoichiometric

relationships and interactions, independently from the mass. Extremely large numbers of these microscopic particles are present in the laboratory scale which usually has a macroscopic dimension. Thus, the Avogadro constant links the microscopic with the macroscopic range, and the mole is the SI base unit needed for this linkage. The mole-principle supported thus the understanding of chemical reactions and the use of stoichiometric relations for many, possibly most, chemists, which also justifies this change introduced by the new definition. The mole is no longer dependent on a material property as its relation to exactly 12 g of the ^{12}C isotope prior to the revision of the SI and even no longer dependent on an artifact, the kilogram via its relation to the mass. The new definition of the mole in terms of a fundamental constant has now a universal character as all the other six SI base units. It must be noted that it was important to take a few requirements into account prior to a new definition. If SI base units are defined via fundamental constants of nature, the set necessary to define them must be as small and exact as possible. It should not be overdetermined and the set of constants must not over-constrain the system. One SI base unit should be defined only by a certain numerically fixed fundamental constant without uncertainty: e.g., the second (hyperfine transition frequency $\Delta\upsilon_{cs}$ of ^{133}Cs), the metre (speed of light in vacuum c), the kilogram (Planck constant h), the ampere (elementary charge e), the kelvin (Boltzmann constant k), the candela (luminous efficacy K_{cd}), and the mole (Avogadro constant N_A). The system of units should be consistent and coherent prior and after the revision. Another central key requirement of a new definition is that the former relationships among the related quantities are untouched. However, some of them will have associated uncertainties after the new definition and have to be determined experimentally (e.g., the molar mass constant M_u, the mass of the ^{12}C isotope $m(^{12}C)$ or the molar mass of the ^{12}C isotope $M(^{12}C)$) and vice versa. As an example, the Avogadro constant N_A has a fixed number without an associated uncertainty after the revision of the SI. The following relation illustrates this change of numbers (and uncertainties) without changing the relation itself:

$$N_A = \frac{M\left(^{12}C\right)}{m\left(^{12}C\right)} \tag{4}$$

Since N_A has now a fixed value ($N_A = 6.02214076 \times 10^{23}$ mol^{-1}) without an associated uncertainty, $M(^{12}C)$ can no longer have a fixed value after the new definition of the mole. Prior to it, the exact relation $M(^{12}C) = 0.012$ kg mol^{-1} without an uncertainty was valid. This implies that the molar mass constant M_u

$$M_u = m_u \times N_A \tag{5}$$

(with the atomic mass constant m_u) which had prior to the new definition the exact value $M_u = 0.001$ kg mol^{-1} (without an associated uncertainty) must have an associated uncertainty after the new definition and therefore a variable numerical value which has to be determined experimentally, too. At present, M_u has the following value: $M_u = 0.99999999965(30) \times 10^{-3}$ kg mol^{-1} with a relative standard uncertainty of $u_{rel}(M_u) = 3 \times 10^{-10}$ (Tiesinga et al. 2021). The numbers

in parenthesis are the standard uncertainties of the last two digits. The atomic mass constant is $m_\mathrm{u} = 1.66053906660(50) \times 10^{-27}$ kg with the relation (Tiesinga et al. 2021)

$$m_\mathrm{u} = 1\,\mathrm{u} = \frac{1}{12} m\left({}^{12}\mathrm{C}\right) \tag{6}$$

Here, u is the unified atomic mass unit and $m({}^{12}\mathrm{C})$ the mass of the ${}^{12}\mathrm{C}$ isotope. Another relation is noteworthy, introducing the dalton (symbol Da with the unit kg)

$$m_\mathrm{u} = 1\,\mathrm{u} = 1\,\mathrm{Da} \tag{7}$$

These considerations yield $M({}^{12}\mathrm{C}) = 11.9999999958(36) \times 10^{-3}$ kg mol^{-1} after the revision of the SI (Tiesinga et al. 2021). Comparing these numbers with those prior to the revision of the SI, it is obvious that the numerical changes are tiny, and in most practical cases, there are no changes in the results noticeable within the limits of the obtained uncertainty. The relation

$$m_\mathrm{u} = \frac{m_e}{A_\mathrm{r}(\mathrm{e})} = \frac{2hR\infty}{A_r(\mathrm{e})\alpha^2 c} = \frac{1}{12} m\left({}^{12}\mathrm{C}\right) \tag{8}$$

shows in more detail which quantities will have an impact on the determination of $m({}^{12}\mathrm{C})$ and thus m_u: m_e is the mass of the electron, $A_\mathrm{r}(\mathrm{e})$ is the relative atomic mass of the electron, R_∞ is the Rydberg constant, α is the fine-structure constant, and c is the speed of light in vacuum. The largest impact on the uncertainty associated with m_u stems from $u_\mathrm{rel}(\alpha) = 1.5 \times 10^{-10}$ (Tiesinga et al. 2021). For comparison, $u_\mathrm{rel}(R_\infty) = 1.9 \times 10^{-12}$, and $u_\mathrm{rel}(A_\mathrm{r}(\mathrm{e})) = 2.9 \times 10^{-11}$ yield additional, but extremely small uncertainty contributions (Tiesinga et al. 2021). The "new" experimentally determined molar mass $M({}^{12}\mathrm{C})$ is obtained combining Eqs. (4) and (8)

$$M\left({}^{12}\mathrm{C}\right) = m\left({}^{12}\mathrm{C}\right) N_A = 12 \frac{2hR\infty}{A_\mathrm{r}(\mathrm{e})\alpha^2 c} N_A \tag{9}$$

Another important fact is that analogue to Eq. (6) prior to and after the revision of the SI also the relation

$$A_\mathrm{r}\left({}^{12}\mathrm{C}\right) = 12 \tag{10}$$

and

$$M\left({}^{12}\mathrm{C}\right) = A_\mathrm{r}\left({}^{12}\mathrm{C}\right) M_\mathrm{u} = 12\, M_\mathrm{u} \tag{11}$$

with the relative atomic mass A_r remain valid and exact. At this point, it is necessary that for the calculation of a molar mass $M(\mathrm{X})$ of an atom or molecule X, the general relation is applied after the redefinition

$$M(\mathrm{X}) = M_{\mathrm{x}} = A_{\mathrm{r}}(\mathrm{X})\, M_{\mathrm{u}} \tag{12}$$

For the mass $m(\mathrm{X})$ of an atom (molecule) X the analogue expression holds

$$m(\mathrm{X}) = m_{\mathrm{x}} = A_{\mathrm{r}}(\mathrm{X})\, m_{\mathrm{u}} \tag{13}$$

For practical purposes, the relative atomic masses A_{r} of the respective isotopes are released and updated from the latest atomic mass evaluation (Wang et al. 2021).

The link between the microscopic and macroscopic world (see Fig. 2) is then given by

$$\frac{h}{m_{\mathrm{u}}} = N_{\mathrm{A}}\, \frac{h}{M_{\mathrm{u}}} \tag{14}$$

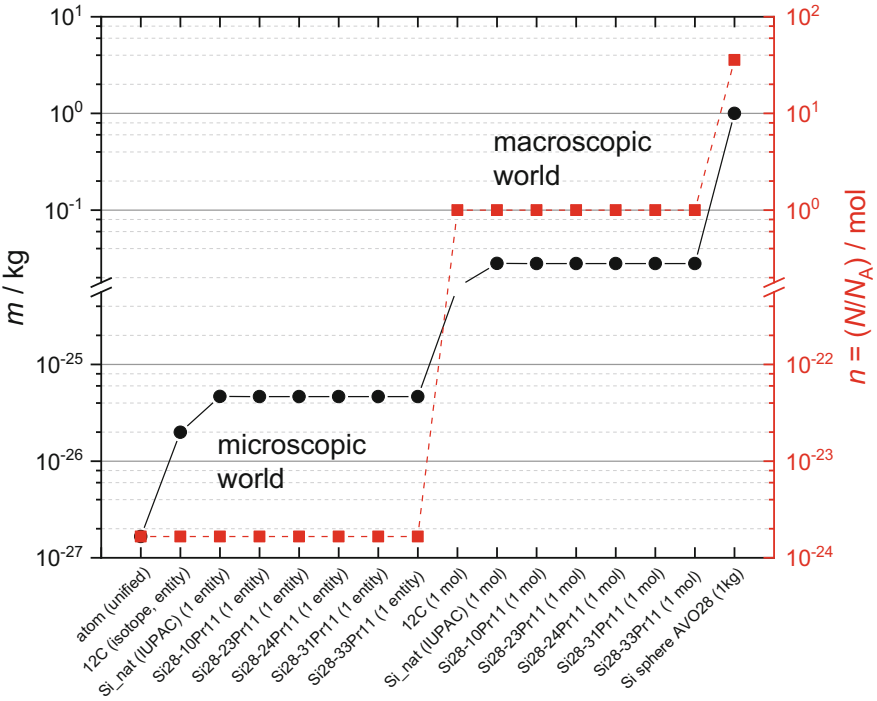

Fig. 2 Comparison of the ranges of microscopic entities and macroscopic bulk material. The mass m (in kg) is visualized vs. the amount of substance n (in mol). The first entity represents the unified atomic mass unit. The subsequent entries relate to the respective bulk single crystalline silicon material (Si_nat: silicon with natural isotopic composition; Si28-Pr11 species denote the respective silicon crystal material highly enriched in ^{28}Si). The plotted masses in the microscopic regime (left hand side) refer to a downscaled mass of the respective material according to one artificial entity of the corresponding macroscopic material. On the right-hand side (macroscopic regime), the respective species of the bulk material are shown (normalized to $n = 1$ mol). Additionally, the amount of substance of a silicon sphere of a hypothetical mass of 1 kg is shown

This relation summarizes clearly, that fixing h and N_A, the third quantity M_u or m_u must be determined experimentally, yielding a value almost equal to that prior to the revision with an associated (most likely very small) uncertainty.

Quantities and Constants Related to the Amount of Substance and Mole

Due to the revision of the SI, the mole is an SI base unit independent from any other base unit. Currently, the XRCD method provides the most exact method for the realization and dissemination of the mole. The amount of substance n of a (pure) substance X is related to its mass m via

$$n(\mathrm{X}) = \frac{m(\mathrm{X})}{A_r(\mathrm{X})\,M_u} = \frac{m(\mathrm{X})}{M(\mathrm{X})} \tag{15}$$

with the general relation

$$n(\mathrm{X}) = \frac{N(\mathrm{X})}{N_A} \tag{16}$$

The relative atomic masses A_r of an isotope of an atom (element) or a respectively composed molecule is available from the regularly updated atomic mass evaluation (AME) tables with associated relative uncertainties usually $<1 \times 10^{-10}$ (Wang et al. 2021). For A_r, the equivalent terms "molecular weight" or "atomic weight" are often used for historical reasons (IUPAC 2007). The A_r are experimentally determined mass ratios, and therefore, they are not depending on the changes of the SI. Every few years, the A_r are updated and completed due to improvements in their experimental realizations. To calculate M(X), it is, however important, to correct M(X) with the valid molar mass constant M_u (Tiesinga et al. 2021). Equations (15) and (16), respectively, compare in a simple manner the practical and theoretical access to the amount of substance n. N(X) denotes the number of elementary entities of a pure substance X in a sample; thus N can be classified as a particle number. However, counting the number of entities and yielding N is not possible using a standard experimental setup. Thus, in practice, in chemistry laboratories, Eq. (15) is applied using a balance, determining n gravimetrically – or less precise volumetrically, if the densities are available.

A practicable relation to determine the amount of substance n(X) in a chemical laboratory is

$$n(\mathrm{X}) = \frac{m(\mathrm{X})}{A_r(\mathrm{X})\,M_u} = \frac{m(\mathrm{X})}{M(\mathrm{X})} = \frac{w(\mathrm{X})m}{M(\mathrm{X})} \tag{17}$$

Having a sample with a macroscopic mass m, the mass $m(\mathrm{X})$ of the substance of interest X in this sample is yielded by the knowledge of its mass fraction $w(\mathrm{X})$. Another common and implemented problem is that a substance treated in a laboratory is never 100% pure. If the purity of a substance is known, Eq. (17) must be multiplied with a "purity coefficient" f with $f < 1$. In metrology, the quantities used must be traceable to the SI. According to Eq. (17) the amount of substance n is still traceable to the SI base unit mass. Commonly used and derived quantities of the amount of substance n are: the amount-of-substance fraction x (unit: mol/mol), the amount of substance concentration c (unit: $\mathrm{mol/m^3}$, in the older literature called "molarity"), and the amount of substance content (unit: mol/kg) (Milton and Quinn 2001; IUPAC 2007). It must be mentioned that this practical method of the gravimetrical determination of $n(\mathrm{X})$ in case of high purity substances suffers from the uncertainty of the mass determination (the balance and the weighing process). Then, $u_{\mathrm{rel}}(n(\mathrm{X}))$ is often $>1 \times 10^{-5}$. In summary, the mole as an SI base unit links chemistry with the SI. This means, the traceable and comparable quantifications are ensured globally and over time. Table 1 contains several quantities related to the amount of substance and molar mass: constants, numerical values, uncertainties, and their relations used in chemistry.

XRCD Method

Currently, the x-ray-crystal-density (XRCD) method serves as a primary method in metrology as the state-of-the art experiment for the realization – and after the SI revision – for the dissemination of the SI base units mole and kilogram (BIPM 2019a, b). The XRCD method, also known as "silicon route" or "Avogadro experiment," is a set of several combined experiments aiming at the measurement of the Avogadro constant N_{A} by "counting" the silicon atoms in a chemically pure silicon single crystalline sphere with a mass of approximately 1 kg (Gupta 2019; Fujii et al. 2016). This "Avogadro Project" has been operated by the International Avogadro Consortium (IAC), consisting of several national metrology institutes (NMIs) and research facilities from all over the world. Initially, the XRCD method has been developed to provide a primary method for the realization of the SI base unit of the mass, the kilogram, complementary to the development of the Kibble balance (Becker 2003). The origin of the XRCD method is based on the pioneering work of *Bonse* and *Hart* in the mid-1960s, who developed the first X-ray interferometer used for the measurement of the lattice parameter a in a silicon crystal (Bonse and Hart 1965). In 1974, Deslattes et al. published the first application of the XRCD method for the determination of N_{A} using single crystalline silicon with natural isotopic composition yielding a relative uncertainty of $u_{\mathrm{rel}}(N_{\mathrm{A}}) = 1.05 \times 10^{-6}$ (Deslattes et al. 1974, 1976). In 1981, Becker et al. presented a new method to determine the lattice parameter in silicon, resulting in an Avogadro number increased by $\Delta_{\mathrm{rel}}(N_{\mathrm{A}}) = +5.4 \times 10^{-6}$ (Becker et al. 1981). This large change in N_{A} initiated the "Avogadro Project" aiming initially at the redefinition of the kilogram on the basis of N_{A} four decades ago. For the determination of N_{A} via "counting silicon atoms" – the

Table 1 Quantities and constants related to the amount of substance and molar mass

			Former SI		New SI			
Quantity or constant (symbol)	Description	Unit	Numerical value	Uncertainty	Numerical value	Uncertainty	Relation	Remark[a,b]
N	Number of entities (particles)	1		Yes		Yes	$N = n \times N_A$	[c]
n	Amount of substance	mol		Yes		Yes	$n = N \times N_A^{-1}$	
N_A	Avogadro constant	mol^{-1}	$6.022140\,857 \times 10^{23}$	74×10^{-9}	$6.022140\,76 \times 10^{23}$	No		[d,e]

number N – in a single crystalline sphere, the lattice parameter a, the volume V of the sphere, its mass m, density ρ, and molar mass M have to be determined with lowest measurement uncertainties possible. The number of silicon atoms in a unit cell is 8:

$$N_{\mathrm{A}} = \frac{8\,V\,M}{a^3\,m} = \frac{8\,M}{\rho\,a^3} = \frac{N}{n} \tag{18}$$

The mass of the electron m_{e} can be calculated using

$$m_{\mathrm{e}} = \frac{2\,R_\infty\,h}{c\,\alpha^2} \tag{19}$$

with the fixed Planck constant h, the Rydberg constant R_∞, the speed of light in vacuum c, and the fine structure constant α. This way, N_{A} can be expressed via

$$N_{\mathrm{A}} = \frac{M_{\mathrm{u}}\,A_{\mathrm{r}}(\mathrm{e})}{m_{\mathrm{e}}} = \frac{c\,\alpha^2}{2\,R_\infty\,h}\,A_{\mathrm{r}}(\mathrm{e})\,M_{\mathrm{u}} \tag{20}$$

with the relative atomic mass of the electron $A_{\mathrm{r}}(\mathrm{e})$, and the molar mass constant M_{u} (Fujii et al. 2016).

After the revision of the SI with a fixed value of N_{A}, the amount of substance n can be obtained from this relation via

$$n = \frac{8\,V}{a^3}\,\frac{2\,R_\infty\,h}{c\,\alpha^2}\,\frac{1}{A_{\mathrm{r}}(\mathrm{e})\,M_{\mathrm{u}}} = \frac{8\,V}{a^3}\,\frac{1}{N_{\mathrm{A}}} \tag{21}$$

Equation (18) is a somewhat simplified expression for N_{A}, because several changing material properties of the single crystalline silicon have to be corrected for. Impurities (mainly carbon, oxygen, and nitrogen) and vacancies in the crystal lattice have to be quantified. Surface contaminations (oxide layers, etc.) have to be detected, quantified using x-ray fluorescence (XRF), x-ray photoelectron spectroscopy (XPS), and ellipsometry. Thus, the exact macroscopic mass of a silicon sphere is given by

$$m = \frac{2\,h\,R_\infty}{c\,\alpha^2}\,\frac{M}{A_{\mathrm{r}}(\mathrm{e})}\,\frac{8\,V}{a^3} - m_{\mathrm{deficit}} + m_{\mathrm{SL}} \tag{22}$$

The term m_{deficit} includes the point defects (impurities, vacancies) in the crystal lattice, and m_{SL} is the mass of the surface layer.

Although the realization of n according to Eq. (21) is based on the measurement of the sphere volume V and the lattice parameter a only, the respective silicon sphere must be characterized completely beforehand with regard to its isotopic composition (molar mass M) and mass or density. However, since a and M are considered as long-term stable quantities, it will be sufficient to re-measure the surface conditions and the diameter (and thus the volume) for the dissemination of n using a silicon sphere. Briefly, the main experiments are summarized. The lattice parameter a (with the

dimension of a length) describes the distance of lattice planes in a "perfect" single crystal. In the x-ray interferometer (XINT), three lamellas with {220} orientation were cut from the initial silicon single crystal ingot, thus representing the material property itself. The first lamella is necessary to split the X-ray bunch into two beams. The second lamella acts like a mirror, reflecting the two beams, which are recombined in the third analyzer lamella. The latter is moveable perpendicular to the X-ray beam. This induces a periodic change of the intensity of the transmitted x-rays correlated with the diffracting-plane spacing period. An optical interferometer measures the movement of the third lamella yielding the period of the X-ray interference fringes representing the lattice spacings. The measurement of the fringe period is finally related to a wavelength standard. The lattice parameter a must be measured at the same ambient conditions (temperature and pressure) as the volume of the sphere. The volume V in Eq. (22) of a "perfect" sphere can be determined by measuring the mean diameter of the sphere. This is one reason why a sphere was used as a macroscopic artifact in the XRCD method. Moreover, a spherical shape is less sensitive towards potential damage. Currently, two similar but different experimental setups are used to determine V using an optical sphere interferometer. In the PTB setup, the sphere is located in the center of two spherical etalons (reference surfaces). The sphere can be moved up and down and no rotation of the sphere is required. Thus, the diameter can be measured from numerous positions ($>$10,000) around the sphere simultaneously. However, the determination via the mean diameter requires an almost perfectly round shape of the sphere, with a roundness deviating only a few nanometers. The distance between the two etalons is measured with and without the sphere in the laser beam of the interferometer. When tuning the optical frequencies, the fractional interference orders of the beam are measured using the concept of phase shifting interferometry (Fujii et al. 2016). The other setup used at the National Metrology Institute of Japan (NMIJ) operates a sphere interferometer with flat reference surfaces, where the sphere is rotated for the determination of the volume. In these setups, the sphere is located in a temperature-controlled vacuum chamber to avoid influences of the refractive index of ambient air. Parallel to the volume measurement, the surface conditions of the sphere have to be monitored, because changing surface layers cause a phase retardation of the reflected beam in the interferometer. Therefore, the surface conditions of the sphere – for mass and optical corrections – are determined with complementary surface analytical techniques: spectroscopic ellipsometry (SE), X-ray reflectometry (XRR), X-ray fluorescence analysis (XRF), and x-ray photoelectron spectroscopy (XPS). For the realization and dissemination of N_A, the macroscopic mass m of the sphere is determined with lowest associated uncertainty using high-resolution mass comparator balances with a nominal load of 1 kg. Measurements in vacuum do not require additional air buoyancy and sorption effect corrections. The mass resolution is in the range of 100 ng which is 1×10^{-10} on a relative scale in case of a 1 kg sphere. Relative uncertainties of mass determinations are in the 10^{-9} range. For comparison purposes, the density ρ is measured using hydrostatic weighing techniques. However, the improved surface quality of the spheres enabled a density determination via diameter and mass measurements with a reduced uncertainty compared to direct

density measurements (Fujii et al. 2016). "Counting" silicon atoms in a sphere assumed a perfect crystal in both geometry and composition. However, at least due to the production process, tiny amounts of point defects (chemical impurities and vacancies) cannot be excluded and have to be determined experimentally for subsequent correction. For this purpose, Fourier transform infrared absorption spectroscopy (FTIR) is applied. For the enriched Si sphere (example: Si28kg01a) the main impurities are carbon ($N/V = 0.89(14) \times 10^{15}$ cm^{-3}; $x = 17.8(2.8) \times 10^{-9}$ mol/mol); oxygen ($N/V = 0.132(21) \times 10^{15}$ cm^{-3}; $x = 2.64(42) \times 10^{-9}$ mol/mol); vacancies ($N/V = 0.33(11) \times 10^{15}$ cm^{-3}; $x = 6.6(2.2) \times 10^{-9}$ mol/mol) (Güttler et al. 2019). The determination of the molar mass M is outlined in a separate section, due to its particular initial uncertainty contribution which has been reduced by several orders of magnitude using new theoretical and experimental mass spectrometric techniques. Prior to the revision of the SI, three main results of N_A with successively reduced uncertainties have been reported by the IAC using the XRCD method: $u_{rel}(N_A) = 3 \times 10^{-8}$ (2011) (Andreas et al. 2011), $u_{rel}(N_A) = 2.0 \times 10^{-8}$ (2015) (Azuma et al. 2015), and $u_{rel}(N_A) = 1.2 \times 10^{-8}$ (2017) (Bartl et al. 2017).

Silicon Crystal Production

The realization and new definition of the mole required the successful application of the XRCD method using a pool of macroscopic silicon spheres highly enriched in ^{28}Si with high chemical purity and an almost perfect single crystalline structure. Prior to 2007, N_A has been determined using Si spheres with a natural isotopic composition ending with $u_{rel}(N_A) = 3 \times 10^{-7}$, which was at least one order of magnitude too large for a planned redefinition of the kilogram and the mole (Becker et al. 2003; Pramann et al. 2020). Simulations predicted that artificially enriched silicon consisting of the main isotope ^{28}Si exclusively will enable a reduced uncertainty $u_{rel}(N_A) < 2 \times 10^{-8}$. The main challenge at that time was the production of a silicon sphere highly enriched in ^{28}Si. A crystal with a mass larger than 1 kg was needed also providing samples for molar mass and purity measurements as well as parts for the construction of the lamellae of the x-ray interferometer and others. Under the custody of the IAC, a project was started in 2004 to produce a large silicon crystal (mass of the crystal ingot approximately 5 kg) with an amount-of-substance fraction of $x(^{28}\text{Si}) > 0.999\ 9$ mol mol^{-1} yielding two spheres with a mass of 1 kg each (Becker et al. 2006). The first silicon crystal enriched in ^{28}Si has been produced in 2007, ready for the characterization with the XRCD method. For comparison purposes and the planned subsequent dissemination of the kilogram and the mole, additional silicon spheres highly enriched in ^{28}Si were necessary. Thus, in two side projects starting in 2012, a cooperation between PTB and Russian companies and research institutes and the German Leibniz Institute for Crystal Growth (IKZ) was aimed at the production of ten even higher enriched silicon spheres (Abrosimov et al. 2017). The crystal production is illustrated in Fig. 3.

Briefly, silicon with natural isotopic composition was shipped to Russia for the production of high purity silicon tetrafluoride (SiF_4). In cascades of gas centrifuges,

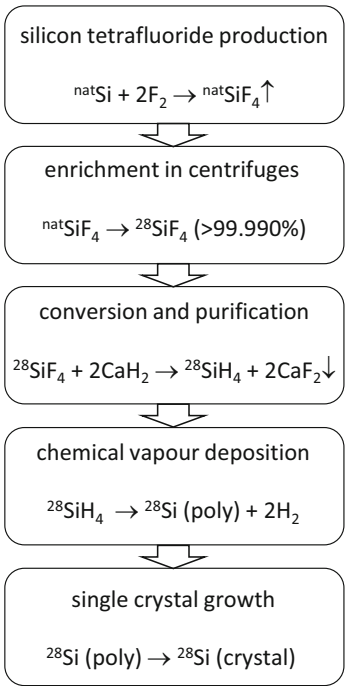

Fig. 3 Steps of the production of silicon crystals highly enriched in ^{28}Si. ^{nat}Si denotes silicon with natural isotopic composition

^{28}Si in SiF_4 was enriched up to $x > 0.999\,99$ mol mol^{-1}. After the conversion of SiF_4 into silane SiH_4, including several rectification and purification steps, SiH_4 was deposited in a pyrolytic (chemical) vapor deposition process yielding polycrystalline silicon, highly enriched in ^{28}Si. The polycrystalline rod was then processed into a single crystalline ingot using a float zone technique at the IKZ in Germany. Finally, the spheres and additional parts and samples were cut from the ingot at PTB. In an improved manufacturing chain, the spheres have a surface roughness smaller than (0.20 ± 0.02) nm and a deviation from perfect spherical shape smaller than (50 ± 10) nm (Fujii et al. 2016). Figure 4 shows the main steps of the crystal and sphere production.

Molar Mass of Silicon Determined Using the Virtual-Element-IDMS Method

Although the first large silicon crystal highly enriched in ^{28}Si has been successfully produced in 2007, a new unexpected problem has been imported in this context: The molar mass M(x) is usually best determined via isotope ratio mass spectrometry by the measurement of isotope ratios of the material x. In case of silicon, M can be expressed by the general relation

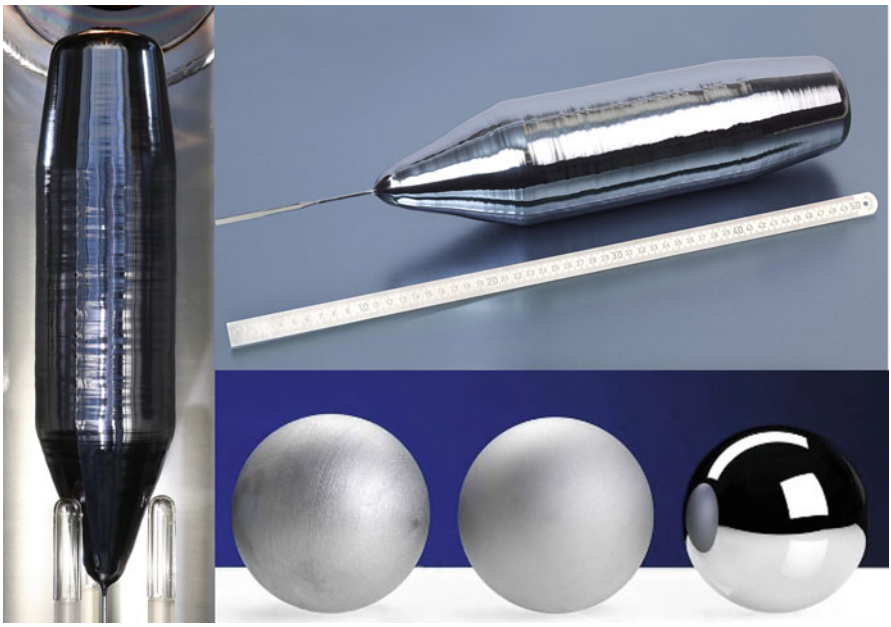

Fig. 4 Steps of the production of silicon crystals and spheres highly enriched in ^{28}Si. (Left) A silicon single crystal ingot (length ≈ 50 cm, mass ≈ 5 kg) produced in a float zone process. (Top) Si crystal prior to cutting. (Bottom) Sphere after cutting towards polishing

$$M = \sum_{i=28}^{30} \left[x\left({}^{i}\mathrm{Si}\right) \times M\left({}^{i}\mathrm{Si}\right) \right] \tag{23}$$

with the amount-of-substance fractions $x({}^{i}\mathrm{Si})$ of the silicon isotopes ^{28}Si, ^{29}Si, and ^{30}Si and the molar masses $M({}^{i}\mathrm{Si})$ of the respective isotopes. The $x({}^{i}\mathrm{Si})$ are accessible by the measured and mass bias corrected isotope ratios R

$$x\left({}^{i}\mathrm{Si}\right) = \frac{R_i}{\sum_{j=28}^{30} R_j} \tag{24}$$

Isotope ratios are usually determined using the most abundant isotope as the denominator. In fact, the new silicon material was enriched in ^{28}Si by almost 100% ($x(^{28}\mathrm{Si}) > 0.999\ 95$ mol mol^{-1}). This would yield ratios $x(^{29}\mathrm{Si})/x(^{28}\mathrm{Si}) \approx 4 \times 10^{-5}$ mol/mol and $x(^{30}\mathrm{Si})/x(^{28}\mathrm{Si}) \approx 1 \times 10^{-6}$ mol/mol in case of the first enriched silicon crystal. The large deviation of these ratios from unity results in uncertainties associated with the molar mass, orders of magnitudes too large to be applicable for the realization of N_A with an associated uncertainty $< 2 \times 10^{-8}$. To overcome this problem, at PTB *Rienitz* et al. have developed and improved a new method to determine the molar mass M of enriched silicon using a principle called Virtual-

Element Isotope-Dilution-Mass Spectrometry (VE-IDMS) (Rienitz et al. 2010; Mana et al. 2010). This approach was adopted to and modified from the classical isotope dilution mass spectrometry (IDMS) technique – a primary method in metrology in chemistry (De Bièvre 1990; Heumann 1992). In this context, it must be noted that the artificial and high enrichment of the silicon results in large efforts to be made to avoid contamination with silicon having a natural isotopic composition which is almost ubiquitous. Care must be taken to avoid this kind of contamination using silicon-free materials as good as possible. The advantage of the inductively coupled plasma mass spectrometry (ICP-MS) is the use of liquid samples which simplifies the preparation of blends and also the measurement of blank solutions in the same way as the sample solutions enabling the subsequent correction of contaminants.

The VE-IDMS method treats the silicon material highly enriched in ^{28}Si as theoretically consisting of ^{29}Si and ^{30}Si only (configuring a "new" virtual element VE) in an excess matrix of ^{28}Si. The ^{29}Si and ^{30}Si isotopes in the new crystal material were initially not desired, but due to technical reasons in the enrichment process, a tiny portion of these "impurities" were always abundant in the crystal and thus had to be determined as accurate as possible. In the VE-IDMS method, the ^{28}Si isotopes are first completely excluded, and mainly the ratios $x(^{30}\mathrm{Si})/x(^{29}\mathrm{Si})$ are measured in the sample x and in a blend bx prepared from the sample and a "spike" material y (which is the same element (silicon) with an almost inverted isotopic pattern). In the spike material the ^{30}Si isotope is highly enriched; however, the knowledge of the exact enrichment is not necessary. Additionally, the masses m_x and m_{yx} (mass of solid sample and spike components in the blend bx) have to be known exactly. The molar mass M is obtained via the VE-IDMS equation

$$M = \frac{M\left(^{28}\mathrm{Si}\right)}{1 + \frac{m_{yx}}{m_x} \cdot \frac{M\left(^{28}\mathrm{Si}\right)\cdot(1+R_{x,2}) - M\left(^{29}\mathrm{Si}\right) - R_{x,2}\cdot M\left(^{30}\mathrm{Si}\right)}{R_{y,3}\cdot M\left(^{28}\mathrm{Si}\right) + M\left(^{29}\mathrm{Si}\right) + R_{y,2}\cdot M\left(^{30}\mathrm{Si}\right)} \cdot \frac{\left(R_{y,2} - R_{bx,2}\right)}{\left(R_{bx,2} - R_{x,2}\right)}} \tag{25}$$

Additionally, the masses m_x and m_{yx} (mass of solid sample and spike components in the blend bx) have to be known. The isotope ratios in the respective materials and blends in Eq. (25) are $R_{j,2} = x_j(^{30}\mathrm{Si})/x_j(^{29}\mathrm{Si})$ and $R_{j,3} = x_j(^{28}\mathrm{Si})/x_j(^{29}\mathrm{Si})$ (Pramann et al. 2011a, 2014, 2015). Figure 5 shows the principle of the VE-IDMS method for the determination of the molar mass of enriched silicon.

The experimental details applied to several different silicon crystals highly enriched in ^{28}Si are given elsewhere (Pramann et al. 2011a, b, c, 2014, 2015, 2017; Pramann and Rienitz 2019; Rienitz and Pramann 2020). In the meantime, the VE-IDMS method has been successfully applied by several other national metrology institutes (NMIs), and an interlaboratory comparison (CCQM-P160) has been conducted (Yang et al. 2012; Narukawa et al. 2014; Vocke et al. 2014; Ren et al. 2015; Rienitz et al. 2020).

Parallel to the challenge of the determination of M with smallest measurement uncertainty, one experimental problem always accompanied with isotope ratio (R) measurements is the occurrence of biased isotope ratios, usually called "mass bias." The measured isotope ratios have to be corrected for using calibration K factors.

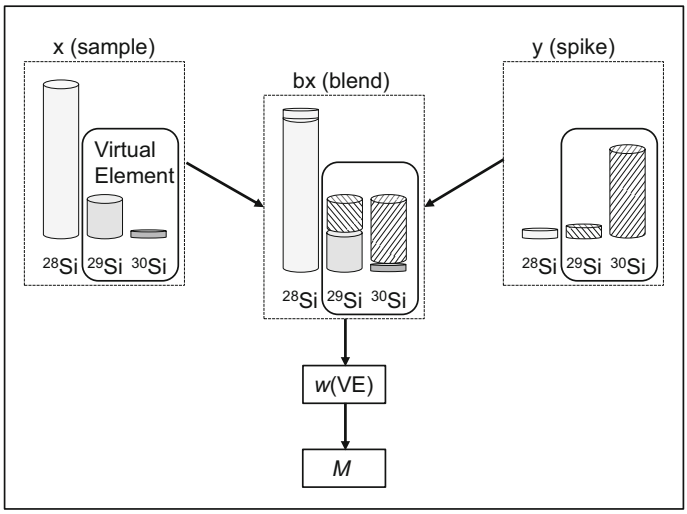

Fig. 5 Principle of the VE-IDMS method. The ^{28}Si signal is mainly ignored in the isotope ratio measurements. The sample x of the enriched silicon material is blended with another silicon material highly enriched in ^{30}Si (spike material y) yielding a blend bx with an adjusted ratio $x(^{30}\mathrm{Si})/x(^{29}\mathrm{Si}) \approx 1$. The mass fraction of the sum of ^{29}Si and ^{30}Si (the virtual element VE or "impurity") and subsequently the molar mass M of the silicon with all three isotopes can be calculated. According to Eq. (25) it is not necessary to determine the respective amount-of-substance fractions $x(^{i}\mathrm{Si})$; however they can be retraced, if necessary

Since there exists no reference material for enriched silicon, an analytical closed-form procedure has been developed in a cooperation of the Istituto Nazionale di Ricerca Metrologica (INRIM, Italy) and PTB (Mana and Rienitz 2010). In this method, gravimetrically prepared blends consisting of the parent materials are used. This enables the experimental determination of K factors without the need of iterative processes yielding an associated measurement uncertainty. Briefly, in case of the silicon isotope ratios $R_j(^{30}\mathrm{Si}/^{29}\mathrm{Si})$ and $R_j(^{28}\mathrm{Si}/^{29}\mathrm{Si})$, the relation between the "true" (corrected) R_j^{true} and measured isotope ratios R_j^{meas} is given by

$$R_{j,2}^{\mathrm{true}} = K_2 \cdot R_{j,2}^{\mathrm{meas}} \quad \text{with} \quad R_{j,2}^{\mathrm{meas}} = \frac{I_j\left(^{30}Si\right)}{I_j\left(^{29}Si\right)} \quad \text{and} \quad j \in \{x, y, \mathrm{bx}\} \tag{26}$$

$$R_{y,3}^{\mathrm{true}} = K_3 \cdot R_{y,3}^{\mathrm{meas}} \quad \text{with} \quad R_{y,3}^{\mathrm{meas}} = \frac{I_y\left(^{28}Si\right)}{I_y\left(^{29}Si\right)} \tag{27}$$

with the measured ion signals I_j (voltages at the respective detectors). Two blends b1 and b2 are necessary and sufficient for the determination of K_2 and K_3. In b1, the parent material z highly enriched in ^{29}Si together with material y (highly enriched in ^{30}Si) are mixed, whereas in b2 silicon with natural isotopic composition (material w) is blended with material z. The application and improvement of the combination of

the VE-IDMS method and the closed-form gravimetric K factor determination has established a primary method for the determination of the molar mass of silicon highly enriched in ^{28}Si. During the last decade, the uncertainty $u_{\mathrm{rel}}(M)$ associated with the molar mass M has been reduced by almost three orders of magnitude from 3×10^{-7} down to 8×10^{-10} as a function of both the high enrichment and the new methods (Güttler et al. 2019; Rienitz and Pramann 2020). This strong reduction in measurement uncertainty yields to the best of the authors' knowledge the most precise measurement results in chemistry so far, necessary for the revision of the SI in 2019.

Dissemination of the Mole

The ways for the practical realization of the SI base unit mole are described in the *Mise en Pratique*, an appendix of the SI brochure acting as an official guide which is released by the Consultative Committee for Amount of Substance – Metrology in Chemistry and Biology (CCQM) of the International Committee for Weights and Measures (CIPM) (BIPM 2019a, b). As both a condition and a consequence of the revision of the mole and the kilogram, the fundamental constants N_{A} and h have been assigned to fixed numerical values without any associated uncertainties. The most accurate and precise way to disseminate the mole is via the XRCD method using a characterized silicon sphere highly enriched in ^{28}Si. This method serves as a primary method considering the enriched spheres as primary standards. Equation (21) summarizes the quantities which have to be determined with lowest associated uncertainties for the current dissemination and realization of the SI base unit mole.

The determination of the lattice parameter a and the volume V (via diameter measurements) as well as surface analysis have to be performed, once a sphere has been characterized with regard to the main quantities like the molar mass, crystal purity, mass, and density according to Eq. (18). Equation (21) demonstrates the "island position" of the mole as a discrete independent SI base unit, which is defined by a certain number of a considered entity (atoms, ions. . .). In practice however, it is still common to realize the amount of substance via the mass of a primary sphere and subsequent comparison with the respective entity using Eq. (22).

For practical purposes some more routine procedures are necessary which can be also adopted from industrial laboratories. PTB has developed a concept of three different categories of silicon spheres which can be distinguished via their purity, surface quality, and isotopic composition which causes three ranges of uncertainties associated with the respective masses (Knopf et al. 2019). This concept is a consequence of the few available ^{28}Si spheres which are extremely expensive due to a time-consuming high level production. Thus, silicon spheres in part commercially manufactured with natural isotopic composition can be used as transfer standards for dissemination purposes. Three categories of silicon spheres will be used for the dissemination: first, the primary standard "^{28}Si" spheres, which are highly enriched in ^{28}Si, enabling the smallest relative uncertainty of $u_{\mathrm{rel}}(m) = 2 \times 10^{-8}$ associated with m (roughness ≤ 0.3 nm). These special spheres were manufactured at PTB. The

next level of uncertainty is represented by the so-called "quasi-primary" spheres ("$^{nat}Si_{qp}$") with $u_{rel}(m) = 3 \times 10^{-8}$ (average roughness ≤ 0.5 nm) which are also manufactured at PTB. Finally, the third category of silicon spheres is called "secondary" silicon spheres ("$^{nat}Si_{sc}$"). These industrially produced spheres can be used for practical (industrial) applications with $u_{rel}(m) = 3 \times 10^{-8}$ (average roughness ≤ 1 nm). The XRCD method thus describes the top-level method for the realization and dissemination of the SI base unit mole when expressing the amount of substance n with lowest associated uncertainty. In common practical (laboratory) applications, more convenient and common experimental methods are used with the drawback of larger uncertainties.

The typical and most common method to determine the amount of substance n in chemical laboratories is using a balance. This is called the "gravimetric-approach" (instead of the volumetric treatment of substances). Simply, a gravimetric determination of n is achieved by Eqs. (15) and (16), and n(x) can be easily accessed using the molar mass M(X) and the mass m(x) of the sample X. The product of the relative atomic mass A_r(X) and the molar mass constant M_u yields M(X). Often, the mass fraction w(X) of the substance X must be accessible, if X is part of a mixture and not a pure substance.

The amount of substance n can be accessed in gases in the simplest case using the ideal gas equation

$$n = \frac{pV}{RT} = \frac{pV}{N_A kT} \tag{28}$$

p is the gas pressure, V is the volume, T is the temperature, and R is the molar gas constant $R = k\,N_A$ (with the fixed Boltzmann constant k). Generally, the uncertainty associated with n is also a few orders of magnitude larger than $u_{rel}(n)$ obtained via the primary realization method using the XRCD method which is a consequence of the uncertainties of the respective input parameters p, V, and T.

In electrochemistry, the amount of substance n is accessible by charge transfer processes at electrodes. The amount of substance n can be visualized directly by the charge Q according to

$$n = \frac{Q}{zeN_A} = \frac{Q}{zF} \tag{29}$$

with the charge number z, the elementary charge e, and the fixed Faraday constant $F = e\,N_A$. Another example for the determination of n is provided by coulometry where a current I is measured in a time interval

$$n(\mathrm{A}) = \frac{1}{z \times F} \int I \mathrm{d}t \tag{30}$$

Besides these formal and defining methods for the realization and dissemination of the SI unit mole and the underlying constantly used quantity "amount of substance" n, the practical methods used in research laboratories as well as in industry

should be highlighted. The practical realization and dissemination of the mole, traceable to the International Systems of Units – the SI – is done using primary standards with a certain value (e.g., mass fraction w, amount concentration c) and an associated uncertainty (which in case of primary standards should be as small as possible). For practical purposes, a dissemination chain from the "highest metrological level" primary standard (usually provided by a national metrology institute NMI) down to a standard released to the respective end user is established. The "primary standards" provided by an NMI have to be characterized by primary measurement procedures (Milton and Quinn 2001). In case of the amount of substance n, not only the value of n but also the kind of entity X have to be specified. The amount of substance is a key quantity in metrology in chemistry, because its practical dissemination must be facilitated for every entity (substance) X which is required. After a careful characterization with regard to its purity, usually a liquid solution of a dissolved element is gravimetrically prepared and characterized by a primary measurement method. Here, primary ratio measurements like isotope dilution mass spectrometry (IDMS) represent the state-of-the art methods with lowest associated uncertainties in analytical chemistry (De Bièvre 1990; Heumann 1992; Sargent et al. 2002). Taking copper (X) as an example, the practical way for the dissemination of the amount of substance n(X) is as follows: A national standard (a "reference point") – usually a mono-elemental solution – is gravimetrically prepared from a high purity copper salt or copper metal sample (with precedingly determined purity) dissolved in a high purity acid (compare Fig. 6). For elements,

Fig. 6 Visualization of the traceability chain of the amount of substance n with the SI base unit mole (1 mol represented here by a sphere made of 28 g silicon) of a certain element (here, copper). High purity solid Cu granules (in the storage bottle), sometimes available as a certified reference material, are converted by gravimetric preparation into liquid primary solutions (ampule in the background)

these mono-elemental solutions represent the link to the mole. The uncertainties associated to the amount of substance include the mass, the purity, and the molar mass of the respective element in the solution as well as the contributions due to the preparation. Whereas the uncertainty of the purity of the respective material expressed as a mass fraction w is in a range $\leq 5 \times 10^{-5}$ g/g, the relative expanded uncertainty ($k = 2$) associated with the mass fraction w of an element is $\leq 10^{-4}$ g/g in case of a primary solution (Matschat et al. 2006). These primary solutions are used in primary measurements for the characterization of secondary solutions (also known as transfer solutions) establishing a traceability chain towards calibration laboratories. The relative uncertainties associated with the transfer solutions are in the range of $\approx 2 \times 10^{-3}$ g/g. Generally, the uncertainties associated with the content (mass fraction) of these national standards (primary solutions) are unaffected by the revision of the SI because the impact of the uncertainties associated with the molar masses needed for the gravimetric preparation is in the range of 10^{-10}, relatively, and can thus be neglected in most cases. A schematic of the traceability chain is shown in Fig. 7. In order to maintain the quality of the dissemination chain, the international comparability, and to prove the ability of the realization on the primary level, international comparisons are carried out with focus on important public areas like clinical chemistry, environmental protection, climate control, and related topics. The worldwide umbrella organization in metrology, the "Metre Convention" has set-up 1993 the "Consultative Committee for Amount of Substance: Metrology in Chemistry and Biology" (CCQM) which acts as an official board for metrology in chemistry. The main task of the CCQM is the establishment and maintenance of international traceability structures in chemistry. These tasks are further fostered by regionally operating metrology organizations like EURAMET (European Association of National Metrology Institutes) or SIM (America), APMP (Asia), COOMET (Euroasia), AFRIMETS (Africa), and GULFMET (Golf region) and also other organizations that support a metrology-based infrastructure for measurements in

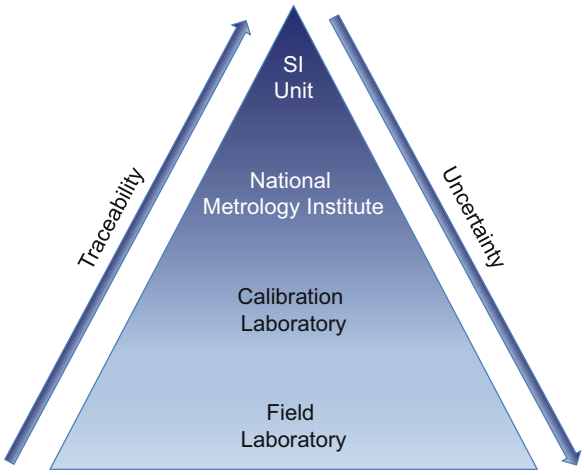

Fig. 7 Schematic traceability chain: Amount of substance n with the SI base unit mole is provided by a National Metrology Institute (NMI) and is disseminated towards accredited calibration laboratories and subsequently to laboratories in the field to ensure the traceability of routine measurements

chemistry such as Eurachem (a network of European organizations of metrology in chemistry), and on an international level, the CITAC (Cooperation on International Traceability in Analytical Chemistry).

Conclusion

After the admission of the SI base unit mole in 1971 which was then related to the SI base unit mass via a "certain" amount (12 g) of a "certain" entity (namely, the ^{12}C isotope), the revision of the SI in 2019 results in a complete independent definition: the mole as the base unit of the amount of substance n is now defined via the Avogadro constant N_A, a fixed fundamental physical constant, solely: "The mole, symbol mol, is the SI unit of amount of substance. One mole contains exactly $6.02214076 \times 10^{23}$ elementary entities. This number is the fixed numerical value of the Avogadro constant, N_A, when expressed in the unit mol^{-1} and is called the Avogadro number. The amount of substance, symbol n, of a system is a measure of the number of specified elementary entities. An elementary entity may be an atom, a molecule, an ion, an electron, any other particle or specified group of particles." This chapter provides the reader with a concise overview about the history, the development and need, as well as the realization, dissemination, and impacts on practical scientific life of the "youngest" SI base unit. For more specific information, a number of reviews are given. A focus in this presentation is the application of the mole in chemistry, and the consequences are shown after the revision of the SI. To understand the turning away from a definition via the relation to an artifact – the former International Prototype of the Kilogram – the XRCD method was presented in more detail, especially the chemical part which is the determination of the molar mass and isotopic composition of the silicon material used. Here, the Virtual-Element IDMS method and the respective closed-form calibration factor method are emphasized as two key approaches enabling the determination of the respective quantities with so far smallest measurement uncertainties which were a prerequisite for the revision of the mole. Both the advantage and the challenge of the new definition of the mole will be that in the future this SI unit might be realized and disseminated via any appropriate experiment with measurable quantities traceable to the SI and considerable low associated uncertainties. The need for related experimental results with lowest possible uncertainties requires thus the maintenance and improvement of existing and developing of future experiments.

Abstract

As the global implementation of new technologies continues to progress, one should hope that a more universal accessibility to the quantum SI is established. This chapter intends to give historical context for the role of the quantum Hall

effect in metrology, including a basic overview of the effect, supporting metrology technologies, and how the research in this field has expanded the world's general capabilities. The present-day era of resistance metrology, heavily dominated by the transition from using gallium-arsenide-based devices to graphene-based ones, will be summarized in terms of how the new 2D material performs, how the world has started to implement it as a resistance standard, and how the corresponding measurement infrastructure is currently adapting to the new standard. In the third section, emerging technologies based on graphene will be introduced to give a brief overview of the possible expansion device capabilities. These ideas and research avenues include p-n junction devices, quantum Hall array devices, and experimental components of ac metrology and the quantum ampere. The chapter then concludes by discussing the possible limitations of graphene-based technology for resistance metrology and looks to explore topological insulators as one potential candidate to, at the very least, supplement graphene-based QHR devices for resistance and electrical current metrology.

Historical Context

Introduction

To fully appreciate the impacts that the discovery of the quantum Hall effect (QHE) had on electrical metrology, it may benefit the reader to cultivate a general understanding of the phenomenon (Von Klitzing and Ebert 1985; Von Klitzing et al. 1980). For the purposes of this handbook, a basic overview will be given. The QHE may be exhibited by a two-dimensional (2D) electron system when placed under a strong magnetic field perpendicular to the plane of the system. These conditions lead to quantization, or discrete energy states for charged particles in the magnetic field. These energy values, determined by solving the Schrödinger equation, are known as Landau levels. In precise measurements, one defines the quantized Hall resistance R_{xy} as the measured voltage, perpendicular to the direction of the applied current, divided by that same current. The characteristic longitudinal resistivity ρ_{xx} goes to zero as R_{xy} approaches a quantized value over a range of magnetic field strength (nominally, a QHE plateau).

Since the discovery of the QHE at the start of the 1980s, the electrical metrology community has sought to implement a resistance standard based on the theoretical relation: $R_{\mathrm{H}}(\nu) = R_{xy}(\nu) = h/\nu e^2$, where ν is an integer related to the Landau energy level, and h and e are the Planck constant and elementary charge, respectively. In 1990 the QHE was assigned a conventional value as an empirical standard based on the determination of fundamental constants through experiments such as the calculable capacitor, which uses the Thompson-Lampard theorem (Thompson and Lampard 1956) to experimentally realize the unit of impedance, the farad, as defined by the International System of Units (SI). When the redefinition of the SI occurred in 2019, the constants h and e were assigned globally agreed-upon exact SI values such that the electrical units of the ohm, volt, and ampere are defined by relation to these fundamental constants. Interestingly, the electrical quantum standards of resistance and voltage now realize the SI unit of mass, the kilogram, through the exact value of

h and an experiment called the Kibble Balance (Kibble 1976; Schlamminger and Haddad 2019). Within the redefined SI, many other fundamental constants are exact or have greatly reduced uncertainties (Tiesinga et al. 2021). For instance, the von Klitzing constant is now exact, calculated from h/e^2 ($R_K = 25\,812.807\,45\ldots\,\Omega$).

Before the QHE, resistance metrologists would employ standard resistors made from copper-manganese-nickel and similar stable alloys. These standards behaved differently in locations around the world due to variation of their nominal resistance (Witt 1998), and this robust, time-independent definition based on the ratio of fundamental constants has developed to allow expansion of the focus of the field.

Predecessors for Quantum Hall Standards

Quantum Hall standards began their journey shortly after the QHE was discovered. Some of the earliest devices were based on silicon metal–oxide–semiconductor field-effect transistors (MOSFETs). For Si systems, the electric field needed to define the energy state of electrons in two dimensions was generated by a planar metallic voltage gate separated from the surface of the semiconductor by an insulating oxide layer. In work performed by Hartland et al., a cryogenic current-comparator (CCC) bridge with a precise 1:1- or 2:1-ratio was used to compare two quantized Hall resistances, one from the MOSFET and the other from a gallium arsenide (GaAs) heterostructure, which employs layers of semiconductors to create a 2D quantum well (Hartland et al. 1991). Both QHE devices were operated at the same temperature and magnetic field, but on different Landau levels. The critical components of the CCC were immersed in liquid helium at 4.2 K and were shielded from external magnetic fields using superconducting lead foil and low-temperature ferromagnetic alloy (Hartland et al. 1991).

This work focused on comparing the quantized Hall resistance (QHR) of the GaAs/AlGaAs heterostructure (measured at the $\nu = 2$ plateau, or $h/2e^2$, which is approximately 12.9 kΩ) to that of the silicon MOSFET device (measured at the $\nu = 4$ plateau, or $h/4e^2$, about 6.45 kΩ). The deviations from the expected ratio of 2:1, summarized in Fig. 1, are represented as Δ_{24} and the ratio of the winding ratio allows two resistances to be compared while canceling out the multiplicative factor of 2 between them. These results suggest that the two QHR values agree within 2 $[1-0.22(3.5)\times 10^{-10}]$, where the uncertainty is in parentheses. Given the novelty of the QHE at the time, this type of experiment was effective in supporting the notion of representing the plateaus as based on the fundamental constants.

One of the disadvantages of MOSFETs was the high magnetic field required during an experiment. Laboratory magnetic fields of the time typically yielded a resistance plateau that was only quantized over a narrow range of magnetic field. As seen in (Hartland et al. 1991), the Si MOSFET device required 13 T to access its $\nu = 4$ plateau, and currents above 10 μA would cause the QHE to break down, or lose its precise quantized value. These devices did not stay long in favor since GaAs-based devices quickly demonstrated more optimal behavior (Cage et al. 1985; Hartland 1992). In GaAs-based devices, a 2D layer of electrons forms when an electric field forces electrons to the interface between two semiconductor layers (the other, in this case, being AlGaAs). For many devices with this type of interface, the layers were

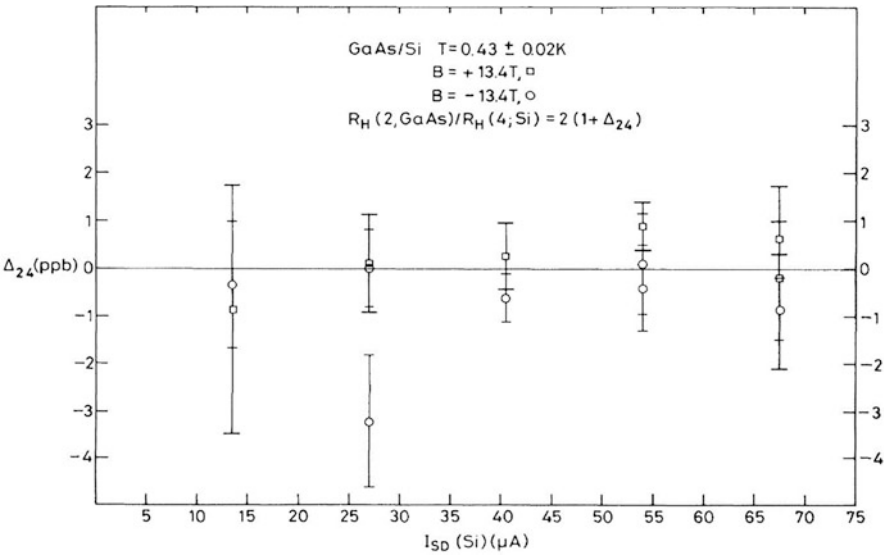

Fig. 1 Measurements of Δ_{24} expressed in parts per billion (ppb, or nΩ/Ω) for the direct comparison of the GaAs-based device (at the $\nu = 2$ plateau) and the Si MOSFET device (at the $\nu = 4$ plateau). These data are shown as a function of the applied current through the Si MOSFET device, and the error bars represent a 1σ random error of the average of Δ_{24}. (Reprinted figure with permission from (Hartland et al. 1991). Copyright 1990 by the American Physical Society)

grown via molecular beam epitaxy (Tsui and Gossard 1981; Hartland et al. 1985). Similar heterostructures were developed in InGaAs/InP, which were obtained via metal-organic chemical vapor deposition (Delahaye et al. 1986).

These early GaAs-GaAlAs heterostructure devices were grown with excellent homogeneity and exhibited high mobilities (on the order of 200 000 $cm^2V^{-1}s^{-1}$) at 4 K. The success of this material in providing highly precise quantized resistances led in 1990 to the definition of the $R_{K\text{-}90}$ representation of the ohm as recommended by the Consultative Committee for Electricity (CCE) (Taylor 1990). For another 20 years, technologies continued to improve, allowing both GaAs-based resistance standards and cryogenic measurement methods to offer increased sensitivity and precision (Jeckelmann et al. 1997; Williams 2011).

During the 1980s, metrologists at national metrology institutes (NMIs) utilized these high-quality devices to confirm the universality of the von Klitzing constant R_K over the course of many experiments. An example of the use of GaAs-based devices for metrology can be seen in Cage et al. (1985), where the authors looked to adopt GaAs as a standard used to maintain a laboratory unit of resistance. The work again demonstrated the universality of the QHE and showed the viability of the device as a means to calibrate artifact standards. The devices were grown by molecular beam epitaxy at an AT&T Bell Laboratory facility in New Jersey (Cage et al. 1985) and had dimensions as shown in the inset of Fig. 2. The magnetic field sweep data for the Hall and longitudinal voltages are also shown in Fig. 2a. The second part of the

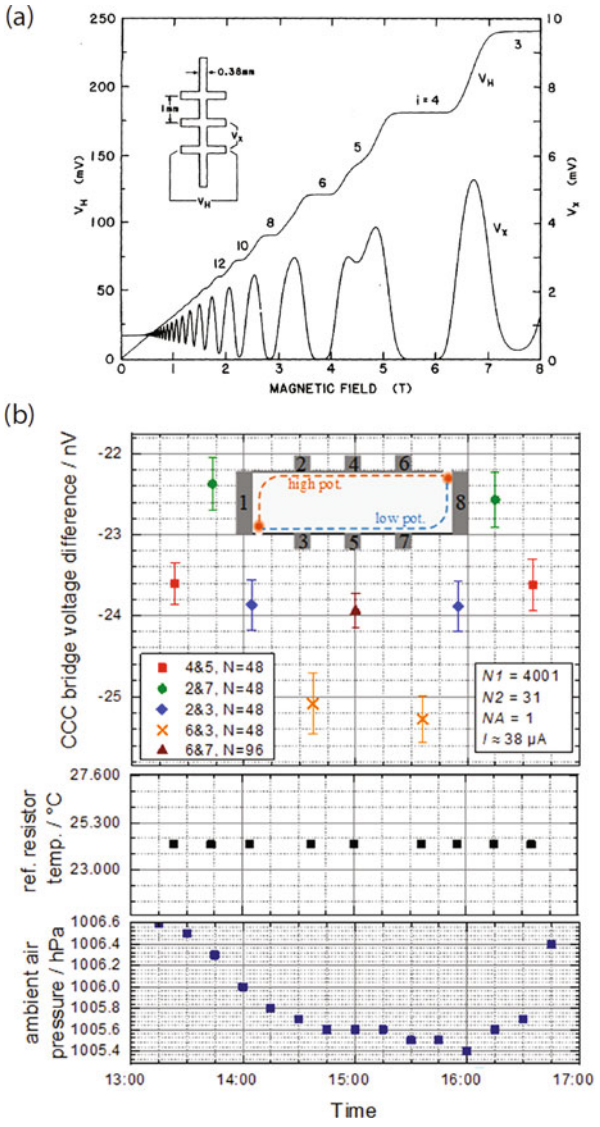

Fig. 2 (**a**) Hall and longitudinal voltage measurements from a magnetic field sweep of a GaAs-based device. The temperature was 1.2 K and the applied current was 25.5 µA. © 1985 IEEE. Reprinted, with permission, from (Cage et al. 1985). (**b**) A practical example of the final high accuracy device characterization procedure prior to calibration at a fixed *B*-field where the deviation from $R_K/2$ is expected to be below 1 nΩ/Ω. The characterization procedure of the device (CCC bridge voltage difference) involves a series of CCC measurements at diagonally and orthogonally aligned Hall contact pairs with the primary purpose of identifying instabilities over time as well as asymmetries in the device properties. The quantity *N* describes the number of measurement cycles in the CCC measurement. The error bars represent type A expanded measurement uncertainties ($k = 2$). To identify instabilities related to the room-temperature reference resistor, the ambient air pressure and the reference resistor temperature are recorded simultaneously as one characterizes the QHR device

experiment involved transferring the QHE value through 1:1 comparisons to a set of 6453.2 Ω resistors, and from there to the US ohm, maintained with a group of resistors at the 1 Ω level (Hamon 1954). Comparisons were done using a direct current comparator (DCC) resistance bridge and reconfigurable series-parallel resistor networks at several resistance levels (Cage et al. 1985).

Before a QHR device can be utilized for calibration, it needs to pass a characterization procedure. The main purpose here is to identify instabilities over time as well as asymmetries in the device properties for different combinations of contacts. The systematic series of CCC measurements shown in Fig. 2b involves various combinations of orthogonally and diagonally aligned pairs of Hall contacts inside the device. It is performed at the same fixed *B*-field intended to be later used for the calibration procedure in which the QHR will be the reference. The suitable *B*-field, where the deviation from $R_K/2$ is expected to be on the level of 1 nΩ/Ω, is typically identified prior to this procedure by characterizing the longitudinal resistivity ρ_{xx} at several points within the resistance plateau.

A series of eight symmetrically arranged Hall measurements at five pairs of Hall contacts (see inset in Fig. 2b) are applied in the following order: (1) contacts 4 and 5, (2) contacts 2 and 7, (3) contacts 2 and 3, (4) contacts 6 and 3, (5) contacts 6 and 7, (6) contacts 2 and 3, (7) contacts 2 and 7, (8) contacts 4 and 5. Whereas the contact pairs 2 and 7 (and 6 and 3) are diagonally aligned and thus have a longitudinal resistance component, the other contact pairs 4 and 5, 2 and 3, and 6 and 7 are orthogonally aligned Hall contacts. Therefore, in the case where a device exhibits equal quantization in all regions, the Hall resistances and corresponding bridge voltages at the Hall contact pairs 4 and 5, 2 and 3, and 6 and 7 should be the same within the expanded uncertainties. Since the remaining contact pairs 2 and 7 (and 6 and 3) have a longitudinal component across the full accessible length of the device, they should deviate from the previous three pairs according to their longitudinal resistance component. The results of the practical example, plotted in Fig. 2b, represent a typical pattern of such a measurement series. The difference voltage in nV represents average data derived using a CCC in a series of current-reversed measurements. The measured bridge voltage difference can be used to calculate the value of the unknown resistor if the reference resistor value, winding ratio, and compensation network configuration are known quantities (Götz et al. 2009).

In the case of instabilities in the QHR device or the reference resistor, the measurement results can be asymmetrically distributed or not be reproducible over time within the expanded uncertainties. Additionally, the noise and uncertainty figures of the individual measurements should be similar for all pairs of contacts. A typical expanded ($k = 2$) type A uncertainty of a CCC bridge voltage in a QHR versus a 100 Ω measurement is below 0.5 nV after 48 measurement cycles. To be able to identify instabilities caused by the reference resistor, it is recommended to simultaneously record the ambient pressure and resistor temperature during the measurement as shown in the bottom panels of Fig. 2b. The final dc calibration procedure in which the QHR is used as a reference is typically realized by using the center Hall contact pair 4 and 5.

Expansion of QHR Device Capabilities

QHR devices soon became the norm in the electrical metrology community, with many of the NMI efforts implementing the new standards based on GaAs devices (Small et al. 1989; Cage et al. 1989; Delahaye and Jeckelmann 2003; Jeckelmann and Jeanneret 2001). Compared to the part-per-million or larger changes that occurred over the years before 1990 in many NMI ohm representations based on standard resistors, better agreement was obtained (by an order of magnitude) between the various worldwide NMIs in later resistance intercomparisons. However, to calibrate standards at resistance levels far removed from the QHR value, several stages of resistance ratio scaling were required and the uncertainty increased with each stage. The next natural step for metrologists was to examine whether or not these QHR devices could accommodate other values of resistance so that the calibration chain could be shortened. More advanced experiments and models were developed by studies of QHE behavior and showed how this may be accomplished by constructing quantum Hall array resistance standards (QHARS) (Oe et al. 2013; Poirier et al. 2004; Ortolano et al. 2014; Konemann et al. 2011).

For instance, in Oe et al., a 10 kΩ QHARS device was designed and consisted of 16 Hall bars, providing a more easily accessible decade resistance value compared to previous work (Oe et al. 2013). The nominal value of the device was about 34 nΩ/Ω from 10 kΩ (based on R_{K-90}). The design and final device can be seen in Fig. 3. The device was measured using a CCC to compare the device against an artifact calibrated using another well-characterized QHR device. In this case, a 100 Ω

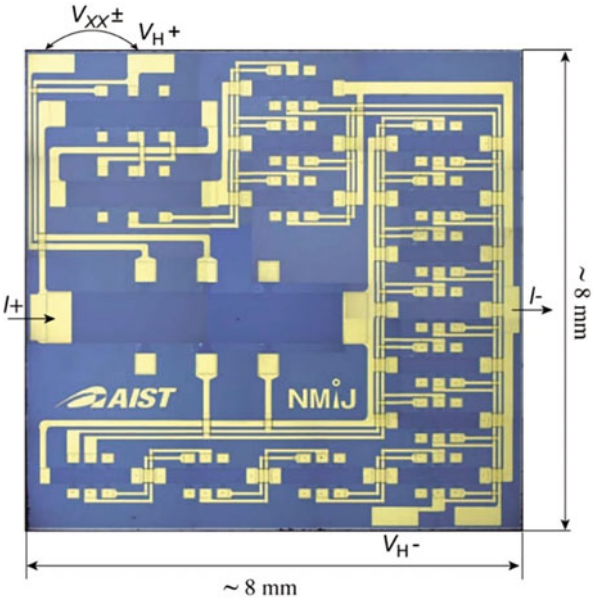

Fig. 3 A 10 kΩ QHARS device is shown with 16 Hall bars. The chip has lateral dimensions of 8 mm per side and was fabricated to be mounted on a standard transistor outline (TO)-8 package. The contact pads are labeled based on whether they are used for current injection or voltage measurements. (© 2013 IEEE. Reprinted, with permission, from (Oe et al. 2013))

standard resistor was used to verify that the array device agreed with its nominal value to within approximately one part in 10^8. The work also proposed new combinations of Hall bars such that the array output could be customized for any of the decade values between 100 Ω and 1 MΩ (Oe et al. 2013).

In addition to the benefits gained from expanding GaAs-based devices further into the world of metrology using direct current (DC), expansion was also explored in the realm of alternating current (AC). Various NMIs began standardizing impedance by using the QHE in an effort to replace the calculable capacitor, which is a difficult apparatus to construct and time-consuming to operate (Ahlers et al. 2009; Cabiati et al. 1999; Bykov et al. 2005; Hartland et al. 1995; Wood et al. 1997). The QHE still exhibited plateaus even at very high excitation frequencies, as shown in Bykov et al., which described the behavior of the 2D electron system in GaAs-based devices for frequencies between 10 KHz and 20 GHz (Bykov et al. 2005). However, when the applied current was AC, a new set of oscillations dependent on the magnetic field was found. This is relevant for impedance metrology because having a longitudinal resistance very close to zero is one mark of a well-quantized device, and having AC frequency-dependent oscillations would undoubtedly increase the uncertainty associated with the QHR. Challenges in adopting QHR technology still exist today in this branch of electrical metrology.

The Graphene Era Begins

Comparing Graphene to GaAs

At the end of the 2000s, research in 2D materials like graphene became prevalent (Zhang et al. 2005; Novoselov et al. 2005, 2007; De Heer et al. 2007). It was evident that QHR measurements could be graphene-based, with fabrications performed by chemical vapor deposition (CVD) (Jabakhanji et al. 2014), epitaxial growth (De Heer et al. 2007; Janssen et al. 2012) (Fig. 4), and the exfoliation of graphite (Giesbers et al. 2008). Given the many methods of available graphene synthesis, efforts to find an optimal synthesis method for metrological purposes were underway. Exfoliated graphene was widely known to exhibit the highest mobilities due to its pristine crystallinity. It was a primary initial candidate as far as metrological testing was concerned. It was found in Giesbers et al. that devices constructed from flakes of graphene had low breakdown currents relative to GaAs-based counterparts, with currents on the order of 1 μA being the maximum one could apply before observing a breakdown in the QHE (Giesbers et al. 2008).

Among the other forms of synthesis, epitaxial graphene (EG) proved to be the most promising for metrological applications (Tzalenchuk et al. 2010). In their work, Tzalenchuk et al. fabricated EG devices and performed precision measurements, achieving quantization uncertainties of about 3 nΩ/Ω. An example of their measurements is shown in Fig. 5, where (a) is a demonstration of how viable the graphene-based device was to be a suitable QHR standard. It was the start of a new chapter for standards, but additional work was required to exceed the stringent temperature requirement of 300 mK and low current capability of 12 μA, relative to modern day

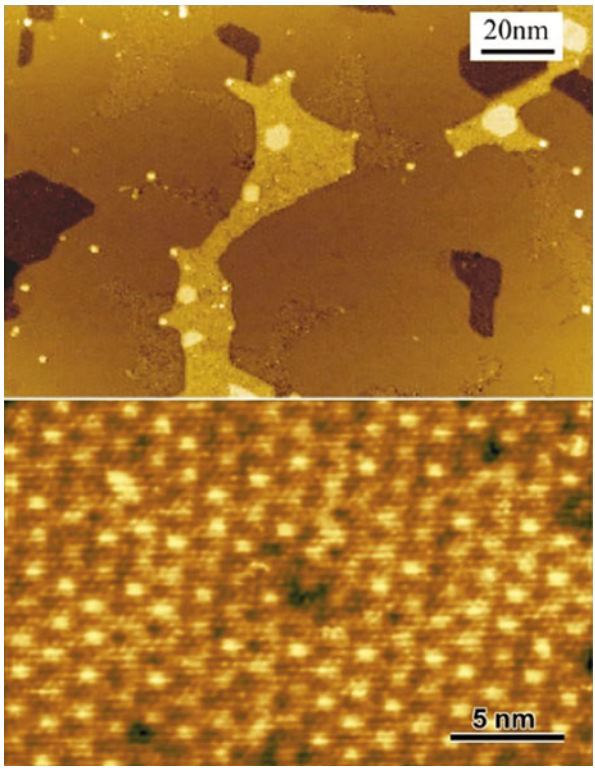

Fig. 4 Scanning tunneling microscopy images (taken at 0.8 V sample bias, 100 pA) show a single layer of epitaxially grown graphene on SiC(0001). The top and bottom panels show two different magnifications of a neighborhood of the grown crystal. (Reprinted from (De Heer et al. 2007))

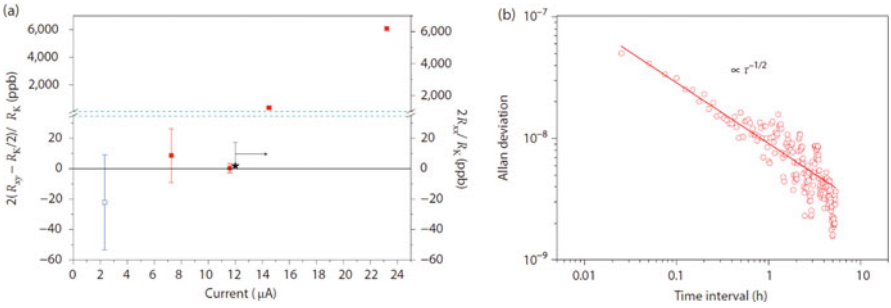

Fig. 5 The Hall resistance quantization accuracy was determined in these measurements. (**a**) The mean relative deviation of R_{xy} from $R_K/2$ is shown at different currents (ppb, or nΩ/Ω) on the right vertical axis. Recall that R_{xy} is nominally measuring the $\nu = 2$ plateau of the QHE. The value of the deviation at the smallest current was measured at 4.2 K (blue squares), and all other measurements were performed at 300 mK (red squares). To achieve the highest accuracies, using an 11.6 μA source–drain current (14 T, 300 mK), at least one of the measurements was performed over 11 h. The right vertical axis shows R_{xx}/R_K, which is represented as the black star along with its measurement uncertainty. (**b**) The Allan deviation of R_{xy} from $R_K/2$ is plotted as a function of time (of the measurement). The square root dependence (as fit by the solid red curve) is indicative of white noise. capabilities (Tzalenchuk et al. 2010). EG graphene as QHR standards soon provided increased current capability and showed impressive plateau width for high and low magnetic field and higher temperatures. EG was also synthesized on SiC via CVD in 2015, showing that graphene could provide standards-quality resistance at temperatures up to 10 K (Lafont et al. 2015). This CVD method relied on the SiC substrate to provide a template for the growth of EG from a gas containing a hydrocarbon precursor.

Establishing Graphene as a Global Resistance Standard

EG has been used as part of the traceability chain of electrical resistance dissemination in the United States since early 2017 (Janssen et al. 2011; Oe et al. 2019; Woszczyna et al. 2012; Satrapinski et al. 2013; Rigosi et al. 2019a). The preceding years from 2010 onward were dedicated to the study of basic fabrication processes and measurement techniques so that EG-based QHR devices could be accepted as the replacement for GaAs-based QHR devices. With optimized EG devices, performance far surpassed that of the best GaAs-based devices. A compilation of these efforts can be linked to multiple institutes (Lara-Avila et al. 2011; Rigosi et al. 2017, 2018, 2019b; Riedl et al. 2010; Janssen et al. 2015; Kruskopf et al. 2016; He et al. 2018). EG-based devices suitable for metrology required high-quality EG to the point of substantial scalability (centimeter-scale) as well as stabilization of electrical properties to have a long shelf life and end-user ease-of-use.

In one example of EG-based QHR development, implemented by two separate groups, devices had become compatible with a 5 T table-top cryocooler system (Rigosi et al. 2019a; Janssen et al. 2015). Janssen et al. first demonstrated this type of measurement with a table-top system in 2015, pushing the bounds of operability to lower fields and higher temperatures. The advantage of such a system also includes the removal of the need for liquid helium, enabling continuous, year-round operation of the QHR without the use of liquid cryogens. The $\nu = 2$ plateau in EG devices is the primary level used to disseminate the ohm, much like for GaAs-based QHRs. In fact, EG provides this plateau in a very robust way and for a large range of magnetic fields because of Fermi level pinning from the covalently bonded, insulating carbon layer directly beneath the conducting graphene layer (Lara-Avila et al. 2011).

For the 5 T table-top system at the National Institute of Standards and Technology (NIST), the EG QHR device plateau value was scaled to a 1 kΩ standard using a binary CCC and a DCC (Rigosi et al. 2019a). The uncertainties that were achieved with this equipment matched those obtained in GaAs-based QHR systems (i.e., on the unit order of nΩ/Ω). The results of some of these measurements are shown in Fig. 6 at three different currents. The limit of nearly 100 μA gives EG-based QHRs the edge over GaAs, especially since these measurements were performed at approximately 3 K. Another example of graphene being established as the new QHR standard comes from Lafont et al., whose work hardened the global question of when graphene would surpass GaAs in various respects (Lafont et al. 2015). An example of this investigation is shown in Fig. 7, where the sample of choice was

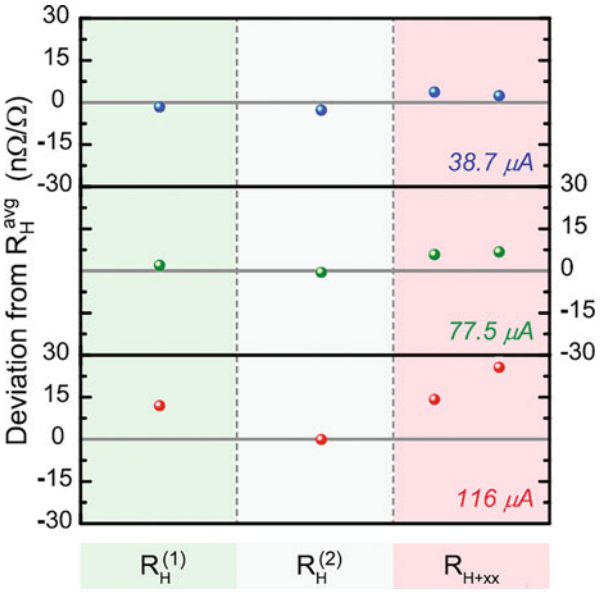

Fig. 6 Binary winding CCC measurements were performed with an EG-based QHR device in a cryogen-free table-top system at 5 T and 3 K. The CCC measurement data are displayed in three rows, with the upper, middle, and lower data corresponding to the source-drain currents of 38.7 μA, 77.5 μA, and 116 μA, respectively. Each column shows a comparison between the resistance of the $\nu = 2$ plateau and a 1 kΩ resistor, with the left two columns representing orthogonal contact pairs ($R_H^{(1)}$ and $R_H^{(2)}$). The third column represents the two diagonal pairs formed by the same contacts as the two orthogonal pairs. It is labelled as R_{H+xx} and indicates the impact of the residual longitudinal resistance. The type A measurement uncertainties are smaller than the data points, and the type B uncertainties are under 2 nΩ/Ω. (© 2019 IEEE. Reprinted, with permission, from (Rigosi et al. 2019a))

CVD-grown epitaxial graphene on SiC. Overall, with the success of the national institute's QHR efforts, the evidence for EG-based devices surpassing GaAs-based QHRs has been widely accepted.

Improvements in Measurement Infrastructure

Given the establishment of better QHR devices for resistance standards, the corresponding equipment and infrastructure with which one can disseminate the ohm had to also improve or at least be shown to maintain its compatibility with EG-based QHRs. The measurement of the ratio between a QHR device and a standard resistor must achieve uncertainties that are comparable to or better than the stability of those resistors. This criterion would support the notion of reliable traceability in that system. Measurements with a longer integration time produce better results because the ratios are well-maintained. The obvious benefits from room-temperature bridge systems like the DCC include an ability to deliver

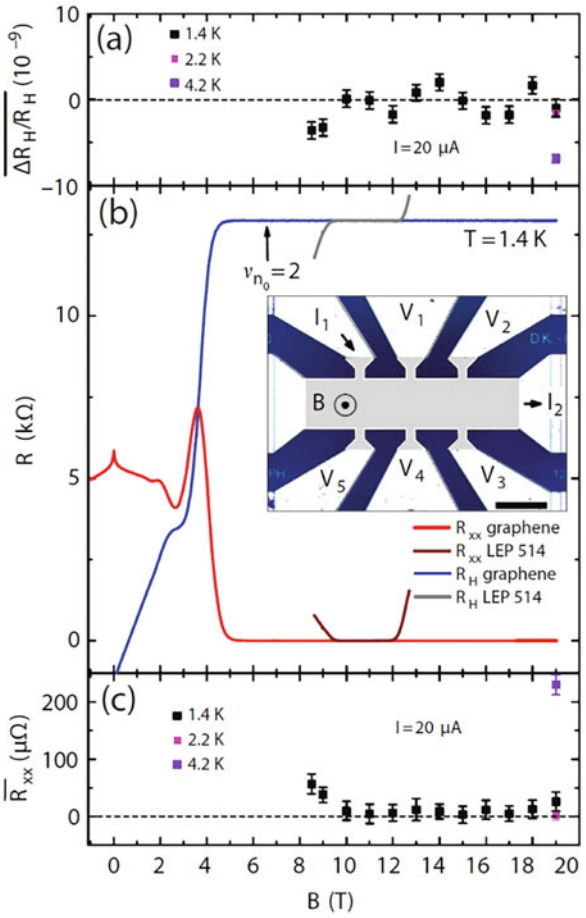

Fig. 7 The magnetic field dependence for Hall resistance in CVD-grown epitaxial graphene is shown. (**a**) The Hall resistance (R_H) deviation is measured on the $\nu = 2$ plateau at 1.4 K (black), 2.2 K (magenta), and 4.2 K (violet). (**b**) R_{xx} and R_H were measured with a source-drain current of 20 μA, with both types of voltages measured using the (V_1, V_2) and (V_2, V_3) contact pads, respectively. The magnetic field was energized to values between 1 T and 19 T for the graphene device (shown by the red and blue curves) and from 8 T to 13 T for the GaAs device (maroon and gray curves). The onset of the Landau level was calculated by using the carrier density at low magnetic fields, which is related to the slope of R_H near zero field. The inset shows an optical image of the device (scale bar is 100 mm). (**c**) Data for precision measurements of R_{xx} are shown at 1.4 K (black), 2.2 K (magenta), and 4.2 K (violet). The error bars represent combined standard uncertainties (1σ). (Lafont et al. (2015) is an open-access article distributed under the terms of the Creative Commons CC BY license, which permits unrestricted use, distribution, and reproduction in any medium)

measurements to laboratories in both NMI and non-NMI settings with greater frequently (year-round) due to their operation not requiring cryogens (MacMartin and Kusters 1966). Additionally, both DCCs and CCCs have been improved so that they are more user-friendly and automated, removing, at least in the case of the DCC,

most of the dependence on specialized knowledge that one normally expects for the more complex cryogenic counterparts (Williams 2011; Drung et al. 2009). Some NMIs have shown that the automated binary-ratio CCCs have type B uncertainties below 0.001 μΩ/Ω, a useful feature when dealing with precise QHR comparisons (Sullivan and Dziuba 1974; Grohmann et al. 1974; Williams et al. 2010). CCC scaling methods can achieve resistance ratios of 4000 or more, enabling measurements for sub-nanoampere current levels, whereas DCCs achieve similar current sensitivity only with larger currents.

The DCC is a room-temperature current comparator, and this simplifies the operation and cost compared to SQUID-based CCC systems. The work by MacMartin and Kusters shows the development of a DCC for comparing four-terminal resistances (MacMartin and Kusters 1966). It works by measuring a current ratio, represented as a turns ratio, that is balanced by detecting magnetic hysteresis in magnetic cores using a modulator. Manual dials allowed the ratio to be adjustable in part-per-million steps. The two current sources in the DCC are isolated so that there is no current in the galvanometer circuit when fully balanced. Their DCC was able to measure and compare the ratio of two isolated direct currents and adjust the ratio to balance the galvanometer. A detailed description provided a discussion of its accuracy limitations (MacMartin and Kusters 1966). In the optimum operating range, the authors achieved accuracies that were better than one part per million. The bridge was designed to accommodate the scaling of resistance standards from 100 Ω to a less than 1 mΩ and can be used for any ratio from 1 to 1000, thus permitting one to calibrate low value resistors and current shunts whose accuracies would be limited only by the level of noise and the stability of the resistor (MacMartin and Kusters 1966). Modern DCC systems are fully automated to control current levels, ratios, and resistance values, and allow scaling of resistance standards from 100 kΩ to below 10 μΩ.

From the previously mentioned work at NIST (Rigosi et al. 2019a), the two bridges demonstrate the applicability of using a modern room-temperature DCC with an EG-based QHR device to obtain uncertainty near 0.01 mΩ/Ω. As shown in Fig. 8a, the DCC measurements extend the range of the applied source-drain currents when scaled from the EG-based QHR device to a 1 kΩ resistor. The inset of Fig. 8a shows how sample heating from a high applied current affects the overall sample temperature. This information was relevant because high currents applied to EG-based QHR devices improves the resolution of the DCC measurements, but will degrade the accuracy of the QHE due to too high a temperature. Ultimately, the work found that table-top systems, in which the QHR is cooled indirectly by conduction and is in vacuum, may limit how much current can be applied (Rigosi et al. 2019a). Larger cryomechanical chillers are designed to immerse the device in a small volume of liquid helium and provide better temperature stabilization by contact with the liquid bath.

As of the present day, CCC bridges outperform DCCs in terms of achievable uncertainties. However, in order to more easily disseminate QHR technology globally, room temperature DCCs are preferred in terms of ease-of-use and fewer resource needs as well as year-round operability. For this reason, a comparison between the two methods was examined and is shown in Fig. 8b, where the number

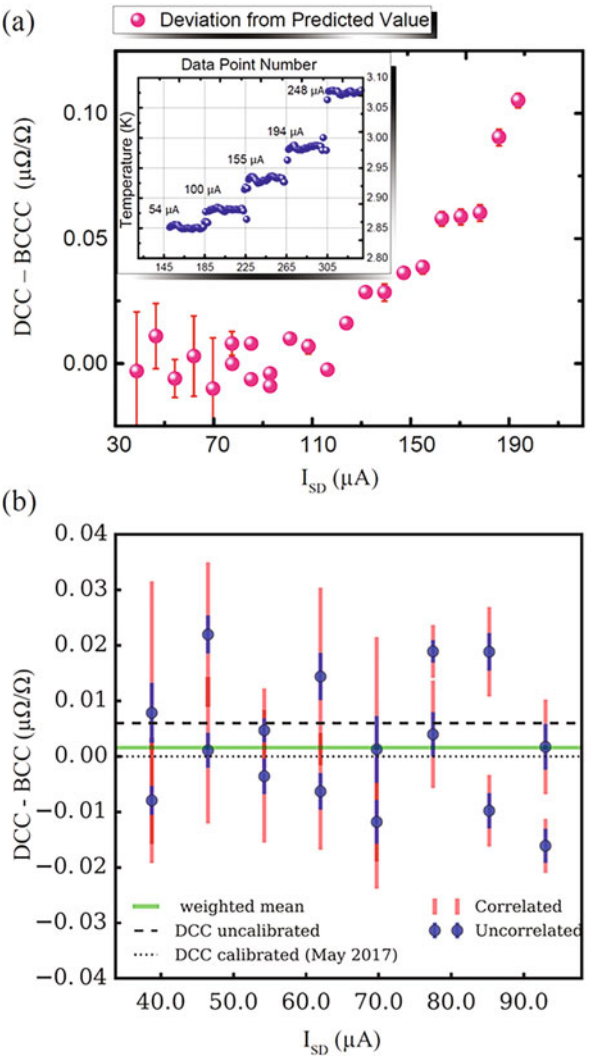

Fig. 8 (**a**) Current dependence data of DCC ratios for a 1 kΩ resistor are shown in magenta, based on the same EG QHR device used with a binary winding CCC (BCCC). The DCC results confirm that the QHR device remains quantized to within 0.01 μΩ/Ω up to approximately 116 μA. Data for higher source-drain currents shows the effect of heating of the sample caused by power dissipation, with temperature data for extended current ranges shown in the inset with blue data points. Some type A measurement uncertainties (in red) are smaller than the data points. (**b**) DCC data for the ratio of the QHR to 1 kΩ are shown for increasing source-drain currents from 38 μA to 94 μA and are normalized to the average results of BCCC scaling (using 38.7 μA and 77.5 μA). The red error bars show the expanded ($k = 2$) with uncorrelated uncertainties whereas the blue error bars show the expanded ($k = 2$) uncertainty reported by the measurement device. (© 2019 IEEE. Reprinted, with permission, from (Rigosi et al. 2019a))

of DCC data points averaged was varied inversely with the square of the applied voltage $V \approx I_{SD} \times R_H$ to obtain a similar type A uncertainty for all values of the source-drain current, with measurement durations ranging from 110 min for the 0.5 V measurements to 24 min for the 1.2 V measurements. Further, in Fig. 8b, the uncertainties indicated in blue were produced by the DCC software. The larger, red error bars are uncertainties that take into account known statistical correlations in the data (Zhang 2006). Potential noise from the cryogen-free mechanical refrigeration system may also interfere to some degree with the balancing algorithm. A similar issue exists for CCC systems, where the additional noise from vibration may

increase noise and may cause the SQUID to lose the delicate balance required to maintain its set point through feedback.

Even though DCCs would make global dissemination easier for some research institutes and smaller NMIs, CCC technology is still important for international metrology at the highest levels. Williams et al. demonstrated a design for an automated CCC in order to perform routine NMI measurements (Williams et al. 2010). Their system uses a CCC in a low loss liquid helium storage vessel and may be continuously operated with isolated supplies coming from the mains power. All parameters were shown to be digitally controlled, and the noise sources present in the system were analyzed using the standard Allan deviation, leading to the conclusion that one may eliminate non-white noise sources simply by choosing the appropriate current reversal rate. New generations of CCC systems with integrated fast ramping current sources, nano-voltmeter, and a compensation network for improved bridge balancing have become widely used at worldwide NMIs (Drung et al. 2009).

As progress continues, NMIs have both anticipated and in many cases achieved these goals for EG-based QHR devices. Lastly, to begin expanding on the functionality of EG-based devices, it would need to be shown that precise resistance scaling could be done to reference resistors from the QHR by using voltages larger than those available in standard DCCs and CCCs. These efforts are underway and hope to eventually accelerate dissemination efforts.

Expanding the Use of the Quantum Hall Effect in Graphene

Assembly of p-n Junctions in Graphene-Based Devices

With EG-based QHR devices established as national standards at several NMIs, as well as the metrology community in agreement that comparisons against GaAs-based QHR devices had been accomplished, the next steps became clearer concerning how the EG-based QHR could be further developed. Unlike the QHR in GaAs, only the $\nu = 2$ plateau is well quantized, and although other Landau levels exist in graphene, they simply do not offer the same level of precision as the $\nu = 2$ plateau (Zhang et al. 2005; Hu et al. 2021). Since the early 1990s, it has been of interest that QHR devices have a means of interconnecting several single Hall bar elements without loss of precision, and this has since been of great research interest. As discussed earlier, this work allowed QHR devices to output more than the single value at the $\nu = 2$ plateau (about 12.9 kΩ) through arrays of devices, using what are described as multi-series interconnections (Delahaye 1993). With graphene, which supports both electron conduction and hole conduction (with positive carrier charge) the first natural question is whether one may use the plateau at $\nu = -2$, in addition to the plateau at $\nu = 2$. This array would avoid the need for manufactured interconnections entirely, using an interface of electronic states internal to the 2D conductor.

This alternative for outputting new quantized values utilizes *p-n* junctions (*pn*Js) to provide useful and controllable values of resistance quantization (Hu et al. 2018a, b; Woszczyna et al. 2011; Rigosi et al. 2019c; Momtaz et al. 2020). Woszczyna et al. approached this issue a decade ago (Woszczyna et al. 2011), noting that since metallic

leads had to cross paths in traditional GaAs-based devices, typical fabrication methods would be overly complicated, having to include some form of multilayer interconnect technology. Any leakage between leads would likely generate an additional Hall voltage, thus becoming a detriment to the achievable uncertainty. Graphene is more accessible for the fabrication of small structures than the GaAs heterostructure interface, where contacts must be alloyed through the insulating surface layer. Charge carrier control by gating offered the opportunity to combine two regions of opposite charge carrier polarity. Rather than requiring interconnections, such a device only needs a set of uniform top gates to modulate regions between the $\nu = -2$ and $\nu = 2$ plateaus. This work demonstrated that *pn*Js were possible and worth exploring as a viable extension for QHR standards.

The fabrication of *pn*J devices larger than the order 100 μm is presently limited by the difficulty of producing of high-quality, exfoliated single-crystal hexagonal boron nitrate (*h*-BN) as an insulating material for top gating. As demonstrated by Hu et al., numerous pnJ's can be fabricated in a single device of size 100 μm or less, rendering it possible to implement reliable top gates for adjusting the carrier density in gated EG-based devices (Hu et al. 2018a). The underlying physics of these *pn*Js makes it possible to construct devices that can access quantized resistance values that are fractional or integer multiples of R_K. Hu et al. made an assessment for one such *pn*J device at the $\nu = -2$ and $\nu = 2$ plateaus (summing to about 25.8 kΩ), with data shown in Fig. 9. A DCC was used to provide turn-key resistance traceability and

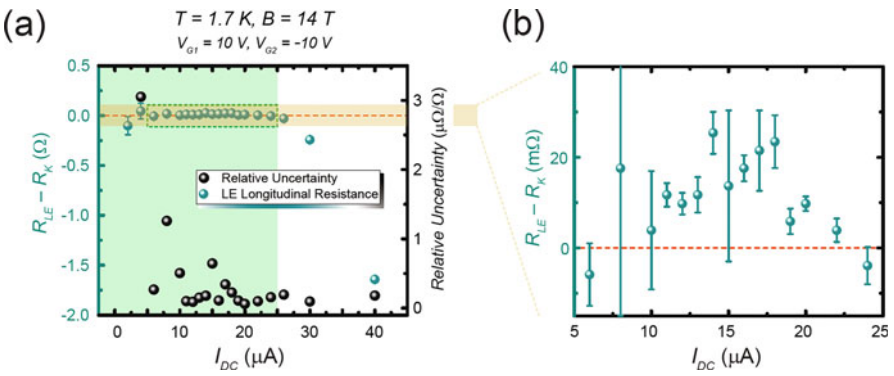

Fig. 9 (**a**) The lower edge (LE) of the device in Hu et al. was compared against a 10 kΩ standard resistor with a DCC to give an assessment of the quality of quantization exhibited by the device. The resistor was selected based on its traceability to a quantum resistance standard at the National Institute of Standards and Technology. The turquoise points show the DCC measurements as deviations from R_K on the left axis and the relative uncertainties of those deviations with DC current. The relative uncertainties improve with increasing current, but the device loses its optimal quantization after the critical current of 24 μA. The shaded green area indicates the well-quantized region. (**b**) The beige shaded area in (**a**) is magnified to show the deviations' error bars as well as the reference to zero deviation, marked as an orange dashed line. The error bars represent a 1σ deviation from the mean, where each data point represents an average of a set of data taken at each value of current. (Hu et al. (2018a) is an open access article distributed under the terms of the Creative Commons CC BY license, which permits unrestricted use, distribution, and reproduction in any medium)

compare against a 10 kΩ standard resistor (see Fig. 9a). The measurement time for each data point with the DCC was 15 min, with an orange shaded region representing Fig. 9b, which clarifies the deviation of the DCC measurements with respect to zero. In Fig. 9a, the right axis is represented by black points and gives the relative uncertainty of each measurement as a function of source-drain current. For this *pn*J device, a precision of about 2×10^7 was achieved as shown in Fig. 9b. Although this may be one or two orders of magnitude below what is possible for a conventional Hall bar device, one must recall that, based on this work, a programmable resistance standard may be built using the demonstrated techniques. Such flexibility and expansion of accessible parameter space could justify its further technical exploration within resistance metrology.

These types of devices are not as well-studied as other conventionally prepared devices, but given their interesting and rather unique properties, *pn*J devices could offer a second, more fundamental path to avoid any resistance from interconnecting metallic contacts and multiple device connections. This possibility is illustrated in a recent experiment by Momtaz et al. and demonstrates how a programmable quantum Hall circuit could implement an iterative voltage bisection scheme, thus permitting the user to access any binary fraction of the $\nu = 2$ plateau resistance (Momtaz et al. 2020). Their proposed circuit designs offer potential advantages for resistance metrology, as summarized here: first, their circuit contains no internal Ohmic contacts, a recurring problem in interconnected QHR circuits. Second, there is a logarithmic scaling of the complexity of the design as a function of the required fractional resolution. This scaling feature is a major advantage compared with a standard QHARS device. The latter might use hundreds of distinct multi-contact Hall bars, whereas a bisection circuit can output a similar number of values while only needing a small number of elements. The approach is thought to match, or become comparable to, the present limits of QHR standards.

The design does have some limitations, as pointed out by Momtaz et al. They noted that, even though the last bisection stages of the device were controlling a finer portion of the output value, each stage still relied on QHE states equilibrating across a junction barrier, emphasizing the importance of the quality of the junction itself. Their preliminary numerical estimates suggest that imperfections in the device would be partially fixable since any absolute errors caused by imperfect mixing would not be amplified through the remaining sections of the device. Nonetheless, this design warrants further study as one way to expand on available quantized resistance outputs.

Using Arrays to Expand the Parameter Space

Recent developments have utilized superconducting materials like NbN and NbTiN to create interconnections compatible with EG-based QHR devices (Kruskopf et al. 2019a, b; He et al. 2021). These metals have high critical temperature (≈10 K) and critical field (≈20 T) so that they may be applied to QHR devices during measurement, as shown by Kruskopf et al. (2019b). They argue that array technology based

on superconducting metals is preferred and can eliminate accumulated resistance and voltage errors at contacts and interconnections. They demonstrated that the application of NbTiN, along with superconducting split contacts, enabled both four-terminal and two-terminal precision measurements without the need for insulated crossovers. The split contacts are inspired by the multiple series approach described by Delahaye (1993), with reduced separation between the interconnections. Since the resulting contact resistances become much smaller than R_K, it becomes straightforward to fabricate series and parallel connections as fundamental device elements. The limits of this technology have not yet been determined, nonetheless, the merits of this technique seem to point to such structures as the next generation of QHR devices.

Another example of array technology that expands on the parameter space comes from Park et al. (2020), where they successfully construct 10 single Hall bars in series with EG on SiC. They operated this device at the $\nu = 2$ plateau near 129 kΩ with precision measurements made using a CCC. While measuring the device at a magnetic field of 6 T and a temperature of 4 K, they were able to achieve a relative uncertainty of approximately 4×10^{-8}, approaching the state-of-the-art for this resistance level. Despite only being able to inject a low double-digit electrical current (in μA), their efforts added support to the notion of expanding QHR values with QHARS devices.

One difficulty that could arise from making these arrays, especially as they increase in lateral size, is how to make their carrier densities uniform. For that, there are two prime examples of accomplishing this task, with both methods being user-friendly and attaining a long shelf life for the device. The first method involves functionalizing the EG surface with $Cr(CO)_3$ (Rigosi et al. 2019b), and what this process enables the user to do is apply heat for a specified time to obtain a predictable carrier density. The advantage is that this process is reversible and may be cycled without damaging the device. One of the features of this method is that storing the device in air for long periods of time simply resets the Fermi level to an energy close to the Dirac point. The same anneal may be applied to reacquire the value of the carrier density. Once in an inert environment or at colder temperatures, the carrier density of the device remains stable. The second method involves a polymer-assisted doping process (He et al. 2018), which allows the user to adjust the carrier density by also using an anneal. This method retains some reversibility as long as the polymer will retain its matrix. Both methods are highly scalable and give extended shelf life to EG-based standards.

With the ability to make very large QHARS devices having controllable and uniform carrier densities, researchers were able to construct a 1 kΩ array based on 13 single Hall bar elements in parallel (Hu et al. 2021). A CCC was used to measure two 13-element arrays. At 1.6 K, the array devices achieved useful quantization above 5 T. One such array measurement is shown in Fig. 10. In this case, the DCC measurements verified that, in the high-field limit, the resistance for both B-field directions approached the value $R_K/26$ (about 992.8 Ω) to better than one part in 10^8 for currents up to 700 μA. As is typical, the CCC ratio uncertainty was below one part in 10^9, and most of the uncertainty had originated from the 100 Ω artifact resistance standards.

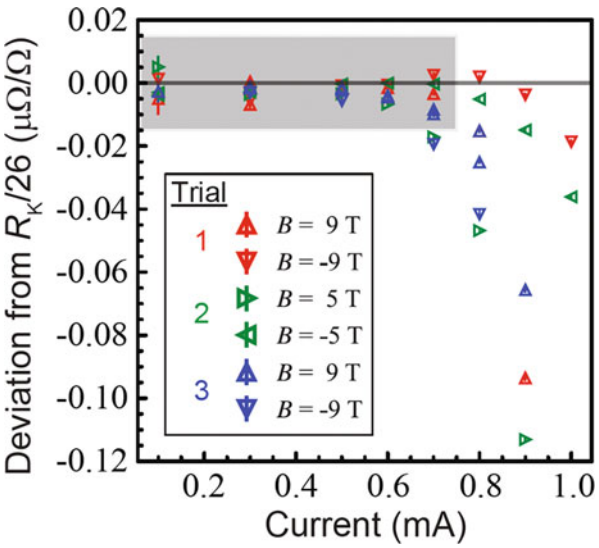

Fig. 10 The $\nu = 2$ plateau was measured at selected values of the magnetic field (B) for device 1 at 1.6 K in a conventional cryostat using a room-temperature DCC. DCC measurements verify that, in the high-field limit, the resistance for both B-field directions approaches the value $R_K/26$ (about 992.8 Ω) to better than one part in 10^8 for currents up to 700 μA, confirming that this array device utilizes highly homogeneous graphene. All expanded uncertainty values given here are for a 2σ confidence interval. (Hu et al. (2021) is an open access article distributed under the terms of the Creative Commons CC BY license, which permits unrestricted use, distribution, and reproduction in any medium)

Recent work by He et al. shows quantum Hall measurements performed on a large QHARS device containing 236 individual EG Hall bars (He et al. 2021). Given the difficulty of verifying the longitudinal resistance as zero for every element, they utilized a direct comparison between two similar EG-based QHARS devices to verify the accuracy of quantization. The design of this array is such that two subarrays with 118 parallel elements are connected in series, having a nominal resistance of $h/236e^2$ (about 109.4 Ω) at the $\nu = 2$ plateau (Fig. 11). The Hall bars were designed to be circular in order to both have a symmetrical design and to be able to fit many devices into a small area (He et al. 2021). The contact pads and interconnections were fabricated from NbN and support currents on the order of 10 mA at 2 K and 5 T. Additionally, a split contact design was implemented to minimize the contact resistance, much like other previously reported work (Kruskopf et al. 2019a, b). The two QHARS devices were compared using high precision measurements, showing no significant deviation of their output resistance within 0.2 nΩ/Ω. Within the next few years, given the increasing complexity of EG-based QHARS devices, even larger and more versatile arrays are expected to make available an abundance of new quantized resistance values.

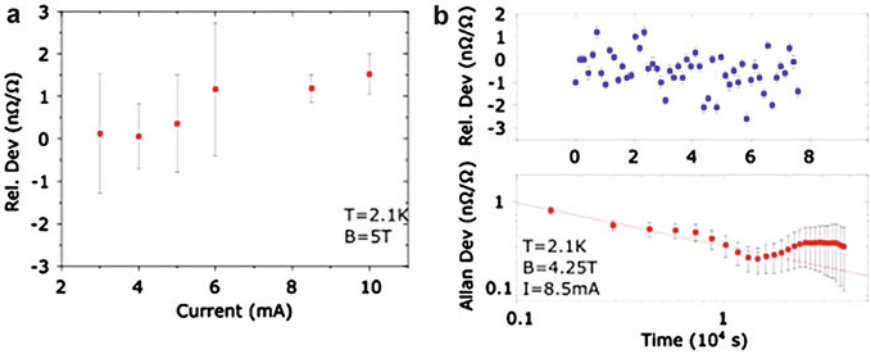

Fig. 11 High bias current measurements on arrays. (**a**) CCC measurements are shown of a direct comparison between subarrays to show that no significant deviation occurs until 8.5 mA. The data consist of the mean of 5–10 CCC readings, each of which is 20 min long. The top graph shows the relative deviation, with error bars of one standard deviation. The bottom graph shows the corresponding Allan deviation. The standard error is limited to 0.25 nΩ/Ω. (He et al. (2021) is an open access article distributed under the terms of the Creative Commons CC BY license, which permits unrestricted use, distribution, and reproduction in any medium)

From DC to AC to the Quantum Ampere

As the *quantum* SI continues to expand in its applications, new research directions are plentiful and of interest to the electrical metrology community. The QHE will continue to be our foundation for disseminating the ohm in the DC realm. The vast improvements in EG-based QHR technology are beginning to inspire efforts to develop more sophisticated devices suitable for AC resistance standards. This subfield of electrical metrology focuses on the calibration of impedance and is conventionally obtained from systems like a calculable capacitor (Thompson and Lampard 1956; Clothier 1965; Cutkosky 1974). Such a system has allowed for the calibration of capacitors, inductors, or AC resistors, which is essentially a measurement of complex ratios of impedance, where the signal phase depends on the type of standard. Historically, the design and operation of this kind of system have been challenging because of unavoidable fringe electric fields, imperfections in capacitor electrode construction, and a long chain of required bridges and standards.

The next step for improving AC standards may be to introduce EG-based QHR devices, as Kruskopf et al. have done recently (Kruskopf et al. 2021). They used a conventional EG-based device to analyze the frequency dependence of losses and to determine the characteristic internal capacitances. The environment of the device included a double shield used as an active electrode, to compensate for capacitive effects, as shown in Fig. 12a. Figure 12b displays the set of magnetocapacitance measurements corresponding to a configuration of the capacitance (Cx) between the active electrode (left side of (a)) and the EG Hall bar between points A and B in Fig. 12a. Cx was compared with a variable precision reference capacitor using a simple configuration used for other traditional measurements (Kruskopf et al. 2021).

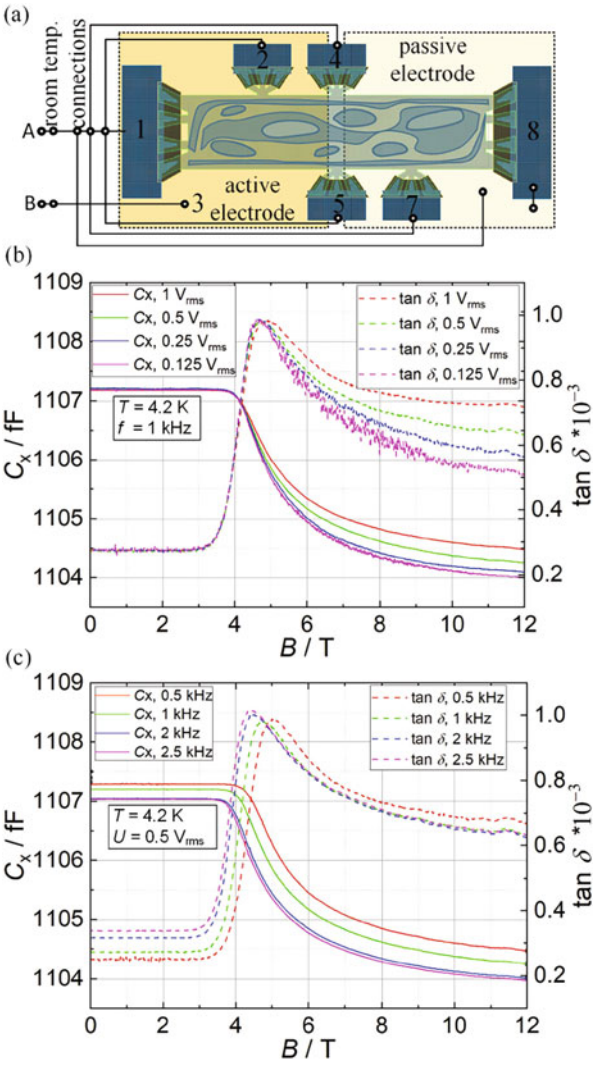

Fig. 12 Magnetocapacitance measurement data of an example device are shown (taken at 4.2 K). (**a**) An illustration captures the various elements of the used magnetocapacitance measurement configuration. As one electrode gets shorted to the labeled passive electrode (pin 8), the other electrode is then used to characterize C and tan(δ). Compressible and incompressible states of the 2D electron system are represented as different colors within the EG Hall bar. (**b**) The capacitance is plotted as a function of magnetic field for a set of different voltages. (**c**) A similar plot to (**b**) is shown for a set of different frequencies. The dissipation factor (tan(δ)) is also plotted representing the losses between the active electrode and the EG Hall bar device. (Kruskopf et al. (2021) is an open access article distributed under the terms of the Creative Commons CC BY license, which permits unrestricted use, distribution, and reproduction in any medium)

Figure 12a shows the passive electrode on right side, shorted to the EG contact, and therefore not contributing to the measurement of *Cx*.

The AC QHR may directly access the units of capacitance and inductance with high precision (Kruskopf et al. 2021; Lüönd et al. 2017). Kruskopf et al. show the voltage and frequency dependencies of the magnetocapacitance in Fig. 12b, c, respectively, along with the associated dissipation factor for an example device. By appropriately modeling the compressible and incompressible states, the observed dissipation factors may be explained rather well. At low magnetic field values, the 2D electron system in the EG is not quantized and is thus accurately representable as

a semi-metal with dominant compressible states. However, when the magnetic field is increased, *Cx* starts to decrease around 4 T and does so by nearly 3 fF in both cases as 12 T is approached. This phenomenon may be due to the increase in incompressible regions that form, which are themselves transparent to electric fields. Furthermore, the dissipation factor is observed to first increase, peaking during the transition region as the resistance plateau in EG forms. As the quantization accuracy improves at higher magnetic fields, the observed dissipative losses decrease again to about tan $(\delta) = 0.0003$. Overall, these are but a few magnetocapacitance measurements that demonstrate the viability of efforts to better understand the physical phenomena driving the observations made in the QHE regime while under AC conditions. This pursuit of AC QHR standards aims to advance how units such as the farad and henry are realized by using fundamental constants instead of dimensional measurements.

In addition to expanding the influence of the QHE to AC electrical metrology, one may also expand into the realms of electrical current and mass metrology by utilizing EG-based QHARS devices. The realization of the quantum ampere lacks accurate traceability to within 10^{-8} despite the various efforts that exist for developing a current source using single-electron tunneling devices (Giblin et al. 2012; Pekola et al. 2013; Koppinen et al. 2012). The alternative route one may take to realizing the quantum ampere is by building a circuit that effectively combines the QHE and a programmable Josephson junction voltage standard. This combination has been recently assembled to attain a programmable quantum current generator, which may disseminate the ampere at the milliampere range and above (Brun-Picard et al. 2016). The work reported by Brun-Picard et al. demonstrates this construction with a superconducting cryogenic amplifier and to measurement uncertainties of 10^{-8}. Their quantum current source, which is housed as two separate cryogenic systems, can deliver accurate currents down to the microampere range. Considering the orders of magnitude involved, this work renders the programmable quantum current generator a pronounced supplement to electron-pumping mechanisms.

Future Improvements and the Quantum Anomalous Hall Effect

Limitations to the Modern QHR Technology

In order to make an accurate assessment of future needs for quantum metrological applications, it would benefit us to know the limits of the current technology, at least to some extent. For instance, it is not known with substantial certainty how high a current could be applied to a single EG Hall bar, or the upper bound on operational temperature for EG-based devices.

There is much research to be conducted on newer technologies that build on the single Hall bar design despite the noted benefits from their development. For instance, the *pn*J devices have conceptual access to different fractional or integer multiples of R_H (or $R_K/2$) as possible resistances, especially if source and drain currents are allowed for more than two total terminals. If one defines q as a coefficient of R_H, then the following relation may be used (Rigosi et al. 2020):

$$q_{M-1}(n_{M-1}) = \frac{q_{M-2}(n_{M-1}+1)}{n_{M-1} + \frac{q_{M-2}}{q^{(0)}_{M-1}}} \tag{1}$$

In Eq. (1), M is the number of terminals in the *pn*J device, n is the number of junctions between the outermost terminal and its nearest neighbor, and $q^{(0)}_{M-1}$ refers to a default value the device outputs when the configuration in question is modified such that its outermost terminal moves to share the same region as its nearest neighbor (meaning that one of the two outermost regions containing any source or drain terminals has both a source and a drain connected to it) (Rigosi et al. 2020). The key takeaway with this algorithm (Eq. 1) is that an incredibly vast set of available resistances becomes hypothetically possible by simple reverse engineering. The algorithm assumes that the Hall bar is of conventional linearity. That is, each *p* region is adjacent to two other *n* regions unless it is an endpoint. The same would hold true when *p* and *n* are swapped. The equation breaks down when the *pn*J device geometry changes to that of a checkerboard grid or Corbino-type geometry. In all of these cases, the available resistances in this parameter space are vastly abundant and will obviously not be a limiting factor for this species of device. Instead, limitations may stem from imperfections in the device fabrication, an almost inevitable manifestation as the device complexity increases (Rigosi et al. 2019c).

In the limit of the purely hypothetical, should the resistance metrology community wish to scale to decade values only, as per the existing infrastructure, then a programmable resistance standard may be able to provide many decades of quantized resistance output by following the designs proposed by Hu et al. (2018a). The proposed programmable QHR device is illustrated in Fig. 13, with each subfigure defining a small component of a total device. When programmed in a particular way, this single device can output all decades between 100 Ω and 100 MΩ, as summarized by Table 1 (where voltage probes are labeled in reference to Fig. 13c).

With all *pn*J devices, better gating techniques are warranted. In the case of top gating, which is the basis for forming the device measured by Hu et al. (2018a), fabrication is limited by the size of the exfoliated *h*-BN flake typically used as a high-quality dielectric spacer. For bottom gating of EG on SiC, as seen with ion implantation (Waldmann et al. 2011), there has not yet been a demonstration of metrologically viable devices, though there may still be potential for perfecting this technique. Since gating is likely to be the largest limiting factor for *pn*Js, one must instead turn to array technology. Although QHARS devices can theoretically replicate *pn*Js, the necessity of an interconnection will ultimately result in a smaller available parameter space. Nonetheless, the output quantized resistance values offered by this technology may still be sufficiently plentiful for future applications in electrical metrology.

When it comes to arrays, there are several types that can take shape for a potential QHR device. There are the conventional parallel or series devices, which are the subject of recent works (Hu et al. 2021; Kruskopf et al. 2019a, b; He et al. 2021; Park et al. 2020). As one departs from this simpler design, the number of potential quantized resistances that become available rapidly increases. Designs with varying

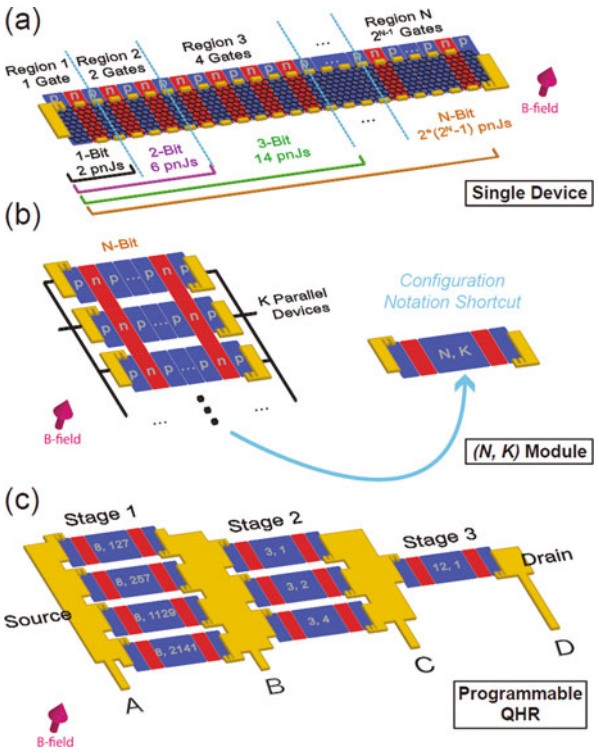

Fig. 13 The proposed device illustrated represents a programmable QHR device for scalable standards. (**a**) An *N-bit* device is illustrated showing how each region is defined and the maximum number of *pn*Js that can be used. (**b**) This device, when connected in parallel with *K* copies of itself, becomes the foundation of the (*N*, *K*) *module*. Each region has a set of gates that extend to all *K* parallel branches. (**c**) The proposed device is illustrated and composed of eight (*N*, *K*) *modules*, four of which are in parallel in stage 1, three of which are parallel in stage 2, and a single *module* in stage 3. All three stages are connected in series and all connections and contacts are proposed to be superconducting metal to eliminate the contact voltage differences to the greatest possible extent. The *modules* in stage 1 are *8-bit* devices with more than 100 parallel copies per *module*, whereas the *modules* in stage 2 are *3-bit* devices with four or fewer parallel copies per *module*. Stage 3 is a single *12-bit* device with no additional parallel branches. These numbers for (*N*, *K*) are required should one wish to reproduce the values in Table 1. (Hu et al. (2018a) is an open access article distributed under the terms of the Creative Commons CC BY license, which permits unrestricted use, distribution, and reproduction in any medium)

topological genera, as shown in Fig. 14, along with the predictive power of simulations like LTspice, Kwant, or traditional tight-binding Hamiltonians, allows the designer to customize devices accordingly. Depending on the genus and final layout, QHARS devices can still be metrologically verified by means of measuring a specific configuration and its mirror symmetric counterparts. In that sense, future QHARS devices whose longitudinal resistances cannot be checked must either be compared with a duplicate of itself, or must have appropriate symmetries such that a

Table 1 This shows all possible resistance decades achievable with the proposed programmable QHR device in Fig. 13

Resistance	Stage 1	Stage 2	Stage 3	Voltage probes used	Deviation from decade value
100 Ω	00010010 00011001 00001001 00010001	None	None	*A, B*	0.714 μΩ/Ω
1 kΩ	10001001 10001011 10000111 10010001	None	None	*A, B*	0.108 μΩ/Ω
10 kΩ	00110001 00100111 00110011 00111100	011 010 010	None	*A, C*	14.8 nΩ/Ω
100 kΩ	00111101 00111101 00111100 00111110	010 010 010	000000000011	*A, D*	0.043 nΩ/Ω
1 MΩ	00101011 00100001 00110101 00110000	010 001 001	000000100110	*A, D*	0.0243 nΩ/Ω
10 MΩ	01011110 01011001 01010011 01001100	110 101 110	000110000010	*A, D*	0.346 pΩ/Ω
100 MΩ	01110111 10001001 01101101 01100111	100 011 011	111100100001	*A, D*	1.21 nΩ/Ω

The values listed in this table are described in more detail in Hu et al. (2018a) and can achieve values of seven decades of resistance. Each module in each stage is assigned a binary string. As long as the exact configuration is used, the measured voltage between the two probes will measure a near-exact decade value, to within a deviation defined in the rightmost column. Hu et al. (2018a) is an open access article distributed under the terms of the Creative Commons CC BY license, which permits unrestricted use, distribution, and reproduction in any medium

same-device comparison can be made. For instance, a square array could be the subject of a two-terminal measurement using same-sided corners. This configuration would have a four-fold symmetry which can be measured and compared to verify device functionality. All types of arrays would be thus limited by the EG growth area, which at present has been optimized by the use of a polymer-assisted sublimation growth technique (Kruskopf et al. 2016). The total growth area may be the most demanding limiting factor for this species of device. Nonetheless, one can hope that the latter technique, and any similar technique to be developed, will enable homogeneous growth on the wafer scale such that the whole EG area retains metrological quality.

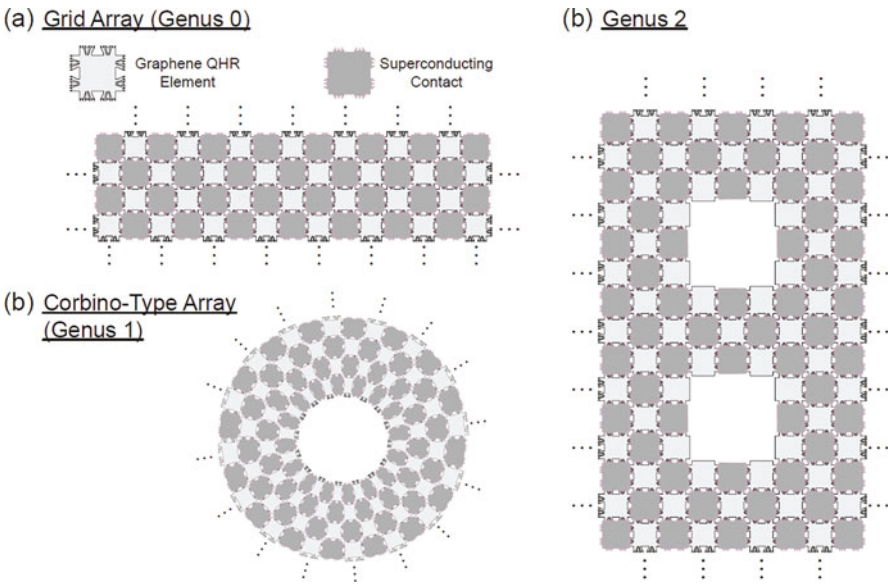

Fig. 14 Hypothetical array designs of varying topological genera. Determining the predicted value of output quantized resistance between any pair of contacts can be done with various modeling techniques done for similar systems. (**a**) The use of superconducting contacts enables the design of larger and more complex arrays, provided the EG QHR elements are small enough. For genus 0, grid arrays can take on user-defined dimensions. (**b**) Corbino-type geometries could also be implemented, and these are just examples of genus 1 topologies. (**c**) A final example of array type comes from those that have a genus 2 topology. Even more customized designs are possible and not well-explored

The Quantum Anomalous Hall Effect

Regardless of EG device size, the magnetic field requirement will always be a limit. This is inherently tied to the band structure of graphene. In addition to this limitation, there are at least two others that prevent SI-traceable quantum electrical standards beyond the ohm from being user-friendly and more widely disseminated, which at present, confines their global accessibility to mostly NMIs. These other limitations include the sub-nA currents obtained from single electron transistors (in the case of the quantum ampere) and the Josephson voltage standard's aversion to magnetism, complicating the use in a single cryostat with a QHR device to create a compact current standard. Ongoing research on magnetic topological materials has the potential to avoid compatibility problems.

The physical phenomenon underpinning this research is the quantum anomalous Hall effect (QAHE). This effect yields a quantized conductance in magnetically

ordered materials at zero applied magnetic field. Certain types of material display a quantized resistance plateau at zero-field suitable for metrology measurements, as has been shown in some recent work (Fox et al. 2018; Götz et al. 2018). The QAHE is a manifestation of a material's topologically nontrivial electronic structure. The QAHE, along with the Josephson effect and QHE, is a rare example of a macroscopic quantum phenomenon. There are several types of materials that exhibit the QAHE, with many being classified within the following categories: magnetically doped topological insulators (TIs), intrinsic magnetic TIs, and twisted van der Waals layered systems.

Fox et al. explored the potential of the QAHE in a magnetic TI thin film for metrological applications. Using a CCC system, they measured the quantization of the Hall resistance to within one part per million and, at lower current bias, measured the longitudinal resistivity under 10 mΩ at zero magnetic field (Fox et al. 2018). An example of the data they acquired is in Fig. 15a, b. When the current density was increased past a critical value, a breakdown of the quantized state was induced, and this effect was attributed to electron heating in parallel bulk current flow. Their work furthered the understanding of TIs by gaining a comprehension of the mechanism during the prebreakdown regime, including evidence for bulk dissipation, thermal activation and possible variable-range hopping. A concurrently reported work by Götz et al. also looked to present a metrologically comprehensive measurement of a TI system (V-doped $(Bi,Sb)_2Te_3$) in zero magnetic field (Götz et al. 2018). When they measured the deviation of the quantized anomalous Hall resistance from R_K, they determined a value of 0.176 μΩ/Ω ± 0.25 μΩ/Ω. An example of their data is shown in Fig. 15c. The steps both works made are vital to our eventual realization of a zero-field quantum resistance standard.

One of the remaining major limitations, besides finding a TI material system with a large band gap, will be to lift the stringent temperature requirements, which are currently in the 10 mK to 100 mK range. Fijalkowski et al. show, through a careful analysis of non-local voltages in devices having a Corbino geometry, that the chiral edge channels closely tied to the observation of the QAHE continue to exist without applied magnetic field up to the Curie temperature (≈20 K) of bulk ferromagnetism in their TI system. Furthermore, it was found that thermally activated bulk conductance was responsible for quantization breakdown (Fijalkowski et al. 2021). The results give hope that one may utilize the topological protection of TI edge channels for developing a standard, as has been demonstrated most recently by Okazaki et al. (2021). They demonstrate a precision of 10 nΩ/Ω of the Hall resistance quantization in the QAHE. They directly compared both the QAHE and QHE from a conventional device to confirm their observations. Given this very recent development, more efforts are expected to follow to verify the viability of TIs as a primary standard for resistance. In the ideal case scenario, TI-based QHR devices will make disseminating the ohm more economical and portable, and will, more importantly, serve as a basis for a compact quantum ampere.

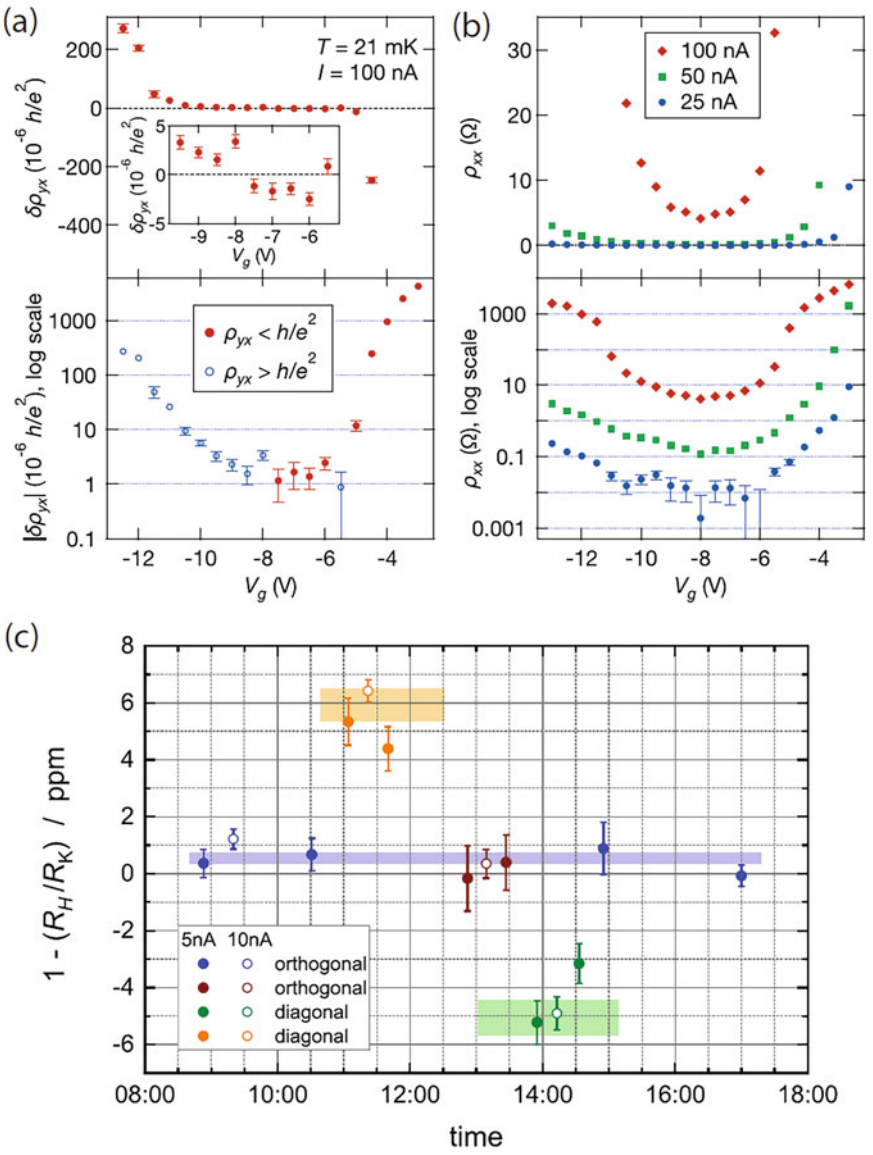

Fig. 15 (**a**) CCC data are shown for measurements of ρ_{yx} in an example device using a 100 nA current at 21 mK. The plateau in the upper panel shows the deviation from R_K for a range of gate voltages. The inset shows a magnified view of the Hall resistance deviations in the center of the plateau ($\nu = 1$). The bottom panel shows the logarithmic behavior of the deviations as one departs from the optimal gate voltage. (**b**) ρ_{xx} of the same device was measured as a function of gate voltage for three different bias currents. The data show strong current and gate voltage dependence, as displayed on a linear and log scale in the top and bottom panels, respectively. At 25 nA, with the gate voltage near the center of the plateau, the resistivity nearly vanishes and the measurements approach the noise floor. All error bars show the standard uncertainty and are omitted when they are

Conclusion

As the global implementation of new technologies continues to progress, one should hope to see a more universal accessibility to the quantum SI. This chapter has given historical context for the role of the QHE in metrology, including a basic overview of the QHE, supporting technologies, and how metrology research has expanded these capabilities. The present-day graphene era was summarized in terms of how the new 2D material performed compared with GaAs-based QHR devices, how the world began to implement it as a resistance standard, and how the corresponding measurement infrastructure has adapted to the new standard. In the third section, emerging technologies based on graphene were introduced to give a brief overview of the possible expansion of QHR device capabilities. These ideas and research avenues include *pn*J devices, QHARS devices, and experimental components of AC metrology and the quantum ampere. The chapter then concludes by discussing the possible limitations of graphene-based technology for resistance metrology and looks to explore TIs as one potential candidate to, at the very least, supplement graphene-based QHR devices for resistance and electrical current metrology.

It has become evident throughout the last few decades that the quantum Hall effect, as exhibited by our modern 2D systems both with and without magnetic fields, has the marvelous potential to unify the components of Ohm's $V = IR$ relation. That is, to bring together all three electrical quantities allowing several traceability capabilities will undoubtedly improve electrical metrology worldwide. Throughout all the coming advancements, it will be important to remember that these milestones should keep us motivated to continue learning how to better enrich society with the quantum Hall effect:

> It is characteristic of fundamental discoveries, of great achievements of intellect, that they retain an undiminished power upon the imagination of the thinker. – Nikola Tesla, 1891, New York City, New York

Acknowledgments The authors wish to acknowledge S. Mhatre, A. Levy, G. Fitzpatrick, and E. Benck for their efforts and assistance during the internal review process at NIST. Commercial equipment, instruments, and materials are identified in this chapter in order to specify the experimental procedure adequately. Such identification is not intended to imply recommendation or endorsement by the National Institute of Standards and Technology or the United States government, nor is it intended to imply that the materials or equipment identified are necessarily the best available for the purpose.

Abstract

After the redefinition of the International System of Units (SI), it has been realized that the pascal, the SI unit of pressure, can be calculated more accurately because, according to ideal gas law, the pressure depends on temperature, gas number density, and few fundamental constants like Boltzmann's constant, the universal gas constant, and Avogadro's number. Among those, the temperature is redefined by evaluating the thermal energy. The fundamental constants are already calculated using quantum electrodynamics (QED) with the utmost accuracy. Therefore, the precise measurement of pascal depends majorly on gas number density, which

can be computed using optical techniques. Quantum calculations involve calculating pressure using optical methods, also known as the quantum realization of pascal. This chapter reviewed the optical techniques for measuring pressure using refractometry proposed by various national metrology institutes.

Keywords

Pascal · Traceability · Calibration · Metrology · Refractometry

Introduction

One of the most often observed physical phenomena in daily life, pressure is essential to many physical functions, such as human physiology, weather forecasting, civil aviation and space travel, earth core exploration, deep ocean research, heavy engineering, the power plant industry, etc. The development of mercury manometers by Italian scientist and mathematician Evangelista Torricelli in 1643 is the tale of barometric pressure and the first vacuum measurements. Some of the earliest barometric measurements were performed by carrying a liquid-filled mercury manometer to a mountain and periodically measuring the height of the mercury column as they moved toward the peak of the mountains. It was observed that the lower the mercury column height, the higher the altitude, and the higher the mercury column height, the lower the barometric pressure. One of the pressure units is torr, which is equal to 133.322 Pa and is still widely used on many vacuum gauges; it was named in honor of Torricelli and is ostensibly equal to 1 mm of mercury column height. Since Torricelli's time, mercury manometers have gradually improved based on a more accurate and precise resolution of column heights. The National Institute of Standard and Technology (NIST), USA, invented a device called the ultrasonic interferometer manometer (UIM) in 1975 (Heydemann et al. 1977) that uses pulsed ultrasound to precisely measure the column heights in a 3 m tall mercury liquid-column manometer within the resolution of 10 nm. These UIM pressure uncertainties are at par or better than any existing primary pressure standards. The National Physical Laboratory of India (NPLI) developed a comparable UIM system in 1982 (Kumar et al. 2019; Thakur et al. 2021). Various NMIs have phased out the UIM due to Mercury's neurotoxic nature and the instruments' huge, heavy, and complicated design. Even though digital pressure transducers, which rely on variations in the resistance, capacitance, or frequency of mechanically strained diaphragms, have replaced mainly mercury manometers used by various research and industry, they still require a UIM to complete the traceability chain. Different regulatory bodies prohibit the purchase and use of mercury-containing items due to mercury's position as neurotoxic and environmentally unfriendly. The National Metrology Institutes (NMIs) and the international metrology community are now working toward pascal's quantum realization, and other NMIs are joining the hunt for the most effective optical approaches for realizing pressure. In addition to making all quantum-based pressure realizations and measurements immediately traceable to the SI, further advancement will put an end to mercury's four-century hegemony in

pressure metrology. In quest of a more accurate, mercury-free, and physics-based method of realizing pressure than using a physical item. An alternate measuring technique is made possible by the relationship between pressure p and energy density. The relationship (1) is true for an ideal gas (the ideal-gas law),

$$p = \left(\frac{N}{V}\right) k_B T \tag{1}$$

where N is the number of particles filling volume V, k_B represents the Boltzmann constant, and T represents the ambient temperature.

By using gas refractivity, one may determine a gas's number density, $\rho_N = N/V$; in this case, the equation for pressure is $p \propto (\eta - 1)k_B T$, where η and $(\eta - 1)$ stand for the gas's refractive index and refractometry, respectively. The refractive index of a medium, which alters an electromagnetic (EM) wave's frequency in the presence of gas as opposed to a vacuum, is where the name "refractometry" originates (Pendrill 2004). The pressure is computed based on fundamental constants such as the Boltzmann constant, the Avogadro number, and frequencies.

The revised definition of Kelvin based on fundamental constants states that it deals with the quantity of thermal energy $k_B T$ (Fischer 2015). Since thermal energy can now be computed with the highest degree of precision thanks to Eq. (1) and Kelvin's redefinition, the only important variable left to determine pressure or temperature is the gas number density (ρ_N). Due to the interaction of gas molecules with laser light, or EM radiation, the most accurate way to calculate gas number density is by optical methods. Depending on the range of the measuring pressure, it may be obtained via dispersion, absorption, fluorescence, or any other light-matter interactions. The EM wave resonates with one of the gas molecules' quantum states in the event of the absorption condition.

NIST started an entirely new optical pressure standard that connects the pascal to quantum calculations of helium's refractive index. A gas's density, which relies on temperature and pressure, determines its refractive index. Calculations for atomic helium will enable us to connect pressure, refractive index, and temperature with an accuracy greater than 1 ppm. Quantum mechanics explains the precise link between these variables. Based on the atomic characteristics of helium, we can accurately measure temperature and refractive index to estimate the pressure and convert the instrument into the main pressure standard. On the other hand, if other methods can precisely measure pressure, the thermodynamic temperature may be calculated by measuring the refractive index. With the use of laser interferometry, it is possible to measure the refractive index with precision far greater than previously conceivable. Photons interact at the quantum level, causing light to move through gases more slowly than it does in a vacuum, which makes it possible to estimate the pressure of a gas. When a length is measured by laser interferometry, the presence of a gas, such as helium, makes the measurement appear somewhat longer than it would in a vacuum. The apparent difference would consequently enable us to calculate the refractive index if we could compare two equal lengths in gas and vacuum.

Fixed Length Optical Cavity

A fixed-length optical cavity (FLOC) was devised, constructed, and tested by the NIST team in order to accurately determine the refractive index. The FLOC comprises two Fabry–Perot (FP) cavities, each composed of a set of mirrors atop a spacer built of ultralow-expansion (ULE) glass (Avdiaj et al. 2018) to prevent variations in interferometer length with temperature. The most common FP cavities have lengths ranging from a few tens to hundreds of millimeters. In a vertical FP cavity, the lower chamber is kept at vacuum, while the upper cavity is filled with gas. The length between the two cavities changes based on the gas's refractive index, density, and atomic or molecular characteristics. First-principles calculations were used to determine the atomic characteristics of helium; therefore, the measurement of refractivity results in a determination of density, which then yields a determination of pressure.

The reference cavity is kept vacuum-sealed to reduce noise and other systematic errors, which helps to increase precision. The reference cavity, which can be seen in the schematic of FLOC Fig. 1a, is a hole bored through the glass block and sealed at each end with mirrors. The top cavity, by contrast, has a slit to readily enable gas to flow in and out. In addition, a vertical tube enables us to connect the reference cavity with the vacuum-pump (Fig. 1a). To increase temperature stability and guarantee that the gas species is known and, thus, has a known refractivity, the glass cavity is housed inside a leak-proof metal chamber. Quantum mechanics may be used to determine the refractivity and virial density coefficients for gases with simple electron structures and few isotopes, such as helium (Puchalski et al. 2016). This calculation can produce refractivity with better than 1 ppm of error. The refractivity values for additional gases such as N_2, Ar, and O_2 can be measured or estimated, but with far greater uncertainty. FLOC was designated as the principal realization of pressure, since pressure computation only requires temperature and refractivity. They were able to calculate nitrogen's refractivity $\eta - 1 = (26485.28 \pm 0.3) \times 10^{-8}$ at $p = 100.0000$ kPa, $T = 302.9190$ K, and $\lambda_{vac} = 632.9908$ nm (Egan et al. 2015), which outperforming mercury manometers (Egan et al. 2016). The NIST team (Egan et al. 2016) also independently measured the Boltzmann constant using helium's predicted refractive index. At low pressures, the FLOC has less uncertainty

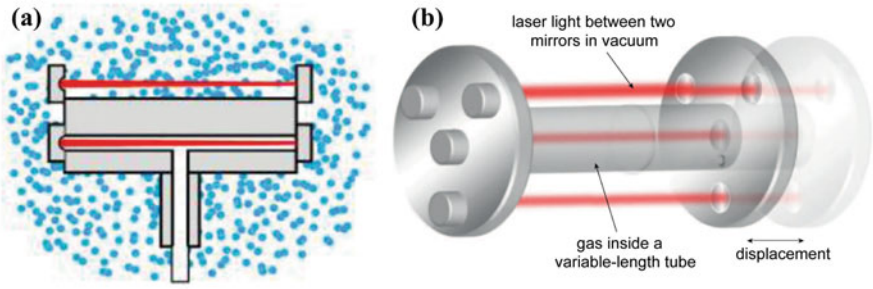

Fig. 1 Schematic of (**a**) FLOC (dots represent gas molecules) and (**b**) VLOC (Ricker et al. 2018)

than a mercury manometer, and at pressures higher above the operating range of manometers, the FLOC will reach parts-per-million uncertainties.

Although creating such a major pressure standard at NIST was a wonderful thing, it was also necessary to figure out how to transfer its better precision to sites outside the standards lab. As a result, NIST also created a FLOC that is less complicated and will provide more sensitivity than the existing pressure standards in a much more compact form factor. Because it is more refractive than helium and 100 times less susceptible to impurities, nitrogen (N_2) is used as the working medium in the transportable FLOC standard. Fixed-length cavities are desirable as pressure standards because they may be constructed from materials with little temporal instabilities and will provide a threefold reduction in measurement errors over current commercial technologies for vacuum pressures as low as 1 Pa. Although the FLOC is the primary, there are two significant flaws that must be taken into consideration when doing a high precision measurement. The first is the deformation of the glass as a result of pressure. As you exert force on the exterior surfaces, the glass is compressed in volume. The reference cavity is at a different pressure than the glass, which results in non-uniform forces that cause the glass to bend non-uniformly in addition to the bulk compression. Each glass cavity has a unique set of distortions, but the correction may be estimated empirically and rectified with a degree of error. The second problem is that glass may bulge as a result of helium absorption. The absorption can be tracked through time and extrapolated back to zero with adequate interferometer data, although there is some uncertainty involved. Overall, a FLOC standard may reach a nitrogen uncertainty of 9 ppm (Egan et al. 2016), although this might be further decreased with improved index determination. Additionally, using various gases with known refractive indices at the same pressure would be the ideal way to evaluate pressure distortions. Gas species won't affect the distortions, which may be solved to estimate the error's size. Better refractivity measurements result in better pressure standards because if the refractivity is not established properly, this might add ambiguity.

Variable Length Optical Cavity

It is obvious that the FLOC's aberrations would restrict its effectiveness for doing a high-accuracy measurement of refraction. Similar in operation to the FLOC, a different idea known as the Variable Length Optical Cavity (VLOC) has important distinctions that make it possible to quantify refractivity. First, as illustrated in Fig. 1b, the VLOC contains four chambers, three of which are spaced equally apart from the center cavity. While the surrounding cavities will be vacuum-sealed, the middle cavity, also known as the measuring cavity, will be exposed to a gas at a constant pressure. The exceptionally robust monolithic platforms on which the mirrors at either end of the device are constructed ensure that the movement of one mirrored end-piece causes equals displacements in the inner and outer interferometers. Three interferometers are placed in a vacuum to measure and regulate angular tilts when the end-piece is moved, which is required to prevent Abbe errors.

With the help of the VLOC, it is possible to test the refractivity at one cavity length, modify the cavity's length, and then measure the refractivity at a second length. Both lengths will exhibit the same systematic errors, such as distortions, helium absorption or bending. In order to get the refractive index, we must subtract the two measurements as follows:

$$\eta = \frac{OP_2 - OP_1}{L_2 - L_1}$$

where numerator and denominator on the right side of the above equation are given by displacement and optical path, respectively, and L represents the cavity length.

The refractive index of helium may be determined using the VLOC, and the value can then be converted to N_2 using a piston gauge. The piston gauge had been employed to create a steady pressure, starting from helium and subsequently in N_2. As a result, the helium's quantum traceability may be utilized to determine N_2's refractivity, so creating quantum traceability through the refractometry. This experimentation only has to be carried out once, and then any refractometer may be used to determine pressure and obtain traceability via the quantum fundamental quantities of the gas because the refractivity is an unchanging attribute of the gas. The VLOC should be able to estimate refractometry of helium with 1 ppm of uncertainty or less (Stone et al. 2014), which will significantly lower the uncertainties for nitrogen-based pressure determination using FLOC. In order to employ other inert gasses in a FLOC, refractivity data for those gases will also be accessible.

Several challenging conditions must be addressed to construct a VLOC for measurement to 1 ppm. The gas must, first and foremost, be highly pure. For gases like helium, whose refractive properties range greatly, the purity must be more than 50 ppb. The second crucial criterion is that the cavity must be built to alter lengths. Cavities that stretch 15 cm are ideal, since the longer the movement, the better resolution. The mirrors cannot be impacted by the movement, which is the last significant restriction. It is not possible to utilize alternative mirrors or switch out components since you want the mirrors to be the same at both places. Without adding faults exceeding the system's dimensional tolerance of 3 picometers (pm), it is almost hard to add something to change the path length. By 3 pm, the movement cannot transmit any pressures that would change the dimensions.

The VLOC built at NIST is the first of its type in the world and was built in accordance with the above description to achieve the uncertainty objective of 1 part per million (ppm). To avoid stress on mirrors, the design has a neutral axis mount and can compress from 30 cm to 15 cm. The complete apparatus will be evacuated to a vacuum of 10^{-5} Pa within a vacuum chamber. The linear stage is moved by a hand crank, which compresses a bellows with a 15 mm diameter to contain the measuring gas. The bellows' purity is guaranteed by employing a steady stream of pure helium that has undergone cryostat purification, preserving all metal seals, and using ultrahigh purity tubing. It will be possible to switch between helium and other gases using a commercial pressure balance that can deliver stability of better than

0.5 ppm. Various NMIs have been working on creating the optical interferometer manometer (OIM) for pascal realization utilizing laser refractometer alongside NIST.

Development of Pressure Standard at NMIs

National Institute of Standard and Technology (NIST)

The foundation of method, which uses a dual FP cavity refractometer and gas refractivity to measure pressure, is described in Egan et al. (2015). By silicate-bonding, ends of FP cavity in ULE spacer, mirrors were being attached. In order to determine the optical paths in both cavities, a He-Ne laser must be dither locked to both the cavities at resonance. The optical length is given by the formula ηL, where L is the physical distance between the mirrors. Initially both the cavities kept at vacuum but in one of them gas is filled such as that the cavity kept at vacuum and pressure are known as reference and measurement cavities, respectively. A gas refractivity is determined by computing the optical path between both the cavities and using the Lorentz-Lorenz equation and gas laws relate the pressure to gas refractivity in a linear fashion. As demonstrated in Fig. 2 with the actual image of the FP cavity inset, the laser refractometer created by NIST provides one of the most precise realizations of the pascal available anywhere in the world. Each refractometer system's FP cavities, fabricated of glass from various sets and have marginally dissimilar designs or dimensions (different compressive distortion terms), have a few minor differences. Additionally, the mirrors in each system are made from various coating runs and have a reflectivity of 99.8% and 99.7%.

The relation between pressure, density, and temperature for non-ideal gas is given by Eq. (2) (Moldover 1998),

$$P = k_B T\left(\rho_N + B_\rho {\rho_N}^2 + C_\rho {\rho_N}^3 + - - - - -\right) \tag{2}$$

where B_ρ and C_ρ are virial coefficients.

The Pascal is expected to switch the current apex level pressure standard UIM (Heydemann et al. 1977; Kumar et al. 2019) for pressure measurements less than 180 kPa since the thermal energy $k_B T$ can be estimated with an error of 1 ppm (Fischer 2016). Refractometry should be monitored with the least uncertainty, and the associated cavity's distortion throughout the experiment should be taken into account, which is the sole challenge in achieving pressure from OIM.

The technique of an OIM depends on fundamental physical quantities, i.e., frequency change of EM waves, which is steady with the Pascal's quantum realization, to calculate the pressure. This can be done by first calculating the refractometry, which can be done by calculating the polarizability. In order to capture pressure with an uncertainty below 1 ppm, theoretical calculations involving atomic characteristics, such as polarizability, were done at the relativistic and QED levels (Puchalski et al. 2016).

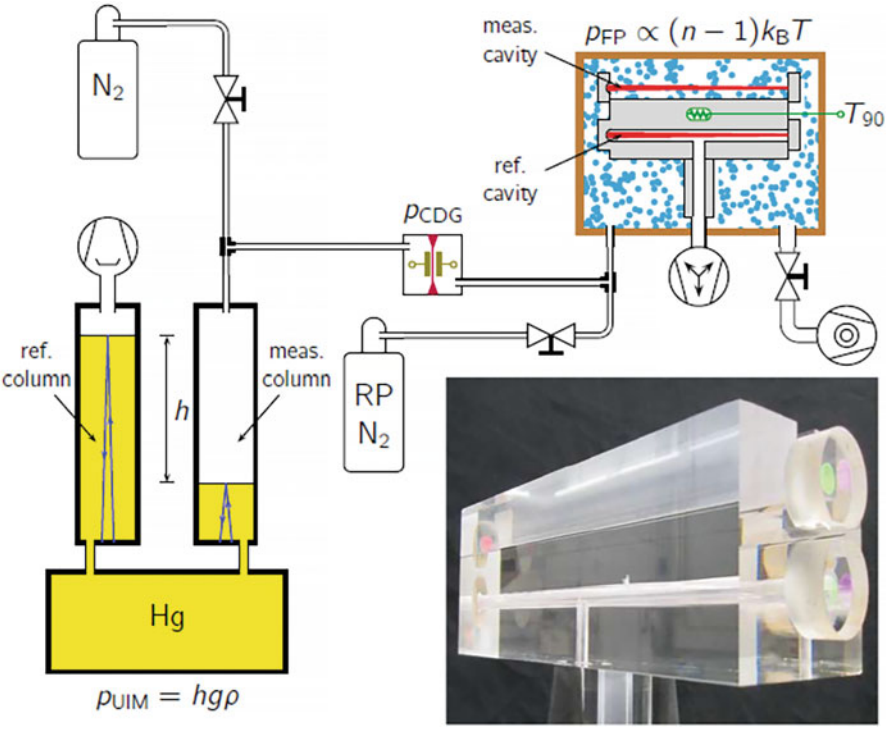

Fig. 2 Schematic of comparison setup of OIM and UIM with the inset of real picture of FLOC (Egan et al. 2016; Ricker et al. 2018)

Any inert gas that is appropriate for measuring the refractive index, such as He, N_2, Ar, or any other, may be selected. Due to the fact that it is absorbed by the FP cavity formed of ultralow expansion glass (ULE), helium gas exhibits one drawback when used as the testing gas for pressure computation utilizing OIM (Avdiaj et al. 2018). The ULE chamber served as a refractometer to determine the gas' refractometry. Figure 1 depicts the actual OIM chamber manufactured by NIST in the USA. The chamber contains two FLOCs, one at the top exposed to the gas input and pertinent vacuum system, known as the measurement cavity, and the other at the bottom linked to the vacuum pump.

A laser whose wavelength is fixed to an FP cavity at resonance. The servo modifies the laser's frequency f to preserve the cavity's resonance if the gas density (i.e., pressure) varies. The refractive index is determined by a change in frequency, as shown by the equation below,

$$n - 1 = \frac{\Delta f}{f} + n d_m p + d_r p \tag{3}$$

The effective fractional frequency can be calculated using Eq. (4),

$$\frac{\Delta f}{f} = \Delta\nu_{FSR}(1+\epsilon_\alpha).\frac{\frac{f_i - f_f}{\Delta\nu_{FSR}} + \Delta m}{f_f + \nu_f} \tag{4}$$

where f laser's frequency in vacuum and Δf is the difference in frequency between the measurement and reference cavities. One can calculate the free spectral range (FSR) by computing the frequency difference between measurement and reference cavities.

The effective fractional frequency is dependent on FSR of the measurement cavity $\Delta\nu_{FSR}$ with mirror phase shifts correction $(1 + \epsilon_\alpha)$, beat frequencies when both the cavities are kept at vacuum (f_i) and pressure (f_f); and resonant mode number change (Δm) of the measurement cavity.

Starting with f_i, one gets f_f, by filling the measuring cavity with gas. When the bulk modulus compresses, the cavity length changes from the initial (L_i) to final (L_f), resulting in the first distortion term, $d_m p = (L_i - L_f)/L_f$. The reference cavity's mirror bending and bulk modulus compression result in the second distortion factor, $d_r p = (\nu_i - \nu_f)(1 + \epsilon_\alpha)/(f_i + \nu_f)$, whose resonance frequency shifts from initial ν_i to final ν_f.

Under applied pressure, the vacuum and reference cavities deform. The deformation occurred in the cavities because of the existence of bulk modulus . Thus, the consequences of the distortion are neutralized.

The Lorentz-Lorenz equation (Born and Wolf 1980; Pendrill 1988, 2014), which is provided by Eq. (5) for an ideal gas, is used to determine refractometry,

$$\frac{\eta^2 - 1}{\eta^2 + 2} = \frac{4\pi}{3}(\alpha + \chi)\rho_N = A_R\rho_V \tag{5}$$

where χ and α are the magnetic susceptibility and dynamic polarizability, respectively, A_R is the molar dynamic polarizability or virial coefficient or molar refractivity (Egan and Stone 2011), and ρ_V is the mass density.

For a non-ideal or real gas, Eq. (5) can be rephrased as given below,

$$\frac{\eta^2 - 1}{\eta^2 + 2} = A_R\rho_V + B_R{\rho_V}^2 + C_R{\rho_V}^3 + - - - - - \tag{6}$$

B_R *and* C_R are temperature dependent virial coefficients.

The term $\frac{\eta^2-1}{\eta^2+2}$ reduces to $\frac{2}{3}(\eta - 1)$ at lower pressure.

Equation (6) can be rewritten as,

$$\eta - 1 = \frac{3}{2}A_R\rho_V + \frac{3}{2}B_R{\rho_V}^2 + \frac{3}{2}C_R{\rho_V}^3 + - - - \tag{7}$$

Since by perceiving Eqs. (3) and (7), refractometry $(n - 1)$ can be inscribed in the terms of pressure (p),

$$\eta - 1 = c_1 p + c_2 p^2 + c_3 p^3 + - - - - \tag{8}$$

Where

$$c_1 = \frac{3}{2k_BT}A_R, c_2 = \frac{3}{8(k_BT)^2}\left(A_R^2 - 4A_RB_P + 4B_R\right),$$

$$c_3 = \frac{3}{16(k_BT)^3}\left(5A_R^3 - 4A_R^2B_P + 4A_RB_R + 16A_RB_P^2 - 16B_PB_R - 8A_RC_P + 8C_R\right)$$

For suitability, disregarding higher orders in Eq. (8),

$$\eta - 1 \approx c_1 p$$

A dual FP chamber refractometer may now detect pressure generated by the FLOC thanks to a final series reversion (Egan et al. 2016),

$$p_{FP} = \frac{1}{c_1 - d_m - d_r}\left(\frac{\Delta f}{f}\right) - \frac{c_2 - c_1 d_m}{(c_1 - d_m - d_r)^3}\left(\frac{\Delta f}{f}\right)^2 + \frac{2(c_2 - c_1 d_m)^2 - c_3(c_1 - d_m - d_r)}{(c_1 - d_m - d_r)^5}\left(\frac{\Delta f}{f}\right)^3 - - - - \quad (9)$$

Equation (9) is used by the NIST's fixed-length OIM to measure pressure, and it produced an expanded uncertainty of $(0.002\ Pa)^2 + (8.8 \times 10^{-6}p)^2)^{0.5}$. The atomic or molecular characteristics of the gases employed in the FP cavities are the focus of the OIM. The Boltzmann constant, the Avogadro number, and frequencies serve as its foundations. OIM may be used to realize Kelvin as well.

One of the drawbacks of the NIST-made OIM is that the mode order m varied drastically per 0.9 kPa of pressure range (Egan et al. 2016).

Istituto Nazionale di Ricerca Metrologica (INRIM)

A refractometry-based OIM (Mari et al. 2019) in the 1 kPa to 120 kPa range was also created by INRIM, an Italian NMI. The optical system's response has first been assessed by assessing its sensitivity for N_2 and air, in the form of relationship between a change in pressure and the quantity of interferometric fringes recorded. The interferometer has then undergone geometrical characterization to provide an absolute measurement of the gas's refractive index, enabling an optical measurement of the gas pressure. Two capacitance diaphragm gauges (CDGs) that determine pressure values in the range of 1 kPa – 120 kPa and the standard have been compared.

Method and System

The suggested approach is an alternative Pascal realization method that makes use of FP cavities and is established on the evaluation of a gas's refractive index using a homodyne Michelson interferometer (Egan et al. 2015). He-Ne laser having wavelength (≈633 *nm*) is frequency-stabilized and used as the light source. It is connected

to a fiber that ends with collimeter and maintains polarization and incidents the light into the cavity. A homodyne Michelson interferometer having fixed arms is depicted schematically in Mari et al. (2018). The measurement arm basically comprises a dual mirror assembly which is evident of the reflection of bean between A and B (Pisani 2009; Mari et al. 2014), whereas the reference arm incidents the laser light to the mirror M_R. Depending on the angle between B and A and incidence angle on A, the double mirror multiplication setup enables the collection of an N-count of reflections (Pisani 2009). The beam splitter "BS" is used to combine the interference-producing reference and measurement beams. A high-speed camera's CMOS sensor "D" picks up the interference fringes, which appear as a dark or bright pattern after passing through a polarizer "P." The program administers the data collection and analysis for the experiment. Mirrors A and B are produced of ULE ceramic glass (Manufacturer: Clearceram) and attached to a circular plate made of the same material with a nominal diameter of 160 mm using the "hydroxide bonding" process, effectively acting as a single glass block, in order to make the interferometer as temperature stable as feasible. The mirrors had the following nominal measurements: width, height, and thickness given by 70 mm, 20 mm, and 10 mm, respectively. They adhered at an angle of around 0.4° (Mari et al. 2018). The plate has a circular pumping hole and is mounted on proper kinematic spherical supports to lessen mechanical strains and vibrations during the pumping or gas input operation. The plate is placed within the chamber V_1 made of stainless steel having height and internal diameter of 62.5 mm and 180 mm, respectively. This chamber is where the standard pressure p is produced, and it is where all the interferometer's other optical components are bonded. According to (Mari et al. 2014), an in-depth description of interferometer functioning is given. A double-knife CF40 flange-encased exchangeable conductance that connects V_1 to a pumping system is sandwiched between the conductance and the pumping system and a KF40 butterfly valve.

Three ports of the V_1 have a barometer placed on them that is calibrated against the INRIM HG5 main standard (Alasia et al. 1999) and two CDGs. V_1 is injected at an initial absolute pressure p_0 of around 0.1 Pa at the start of operation. The reference refractive index at p_0 is given by $\eta_{vac} \approx 1$. The gas is then inserted into the calibration compartment till the chosen nominal value is obtained, and wait for adequately enough time for stabilizing the temperature, then the standard pressure p is observed in V_1. One can calculate the final refractive index at pressure p using Eq. (10),

$$\eta = \eta_{vac} + \frac{\phi \frac{\lambda}{2}}{L} \approx 1 + \frac{\phi \frac{\lambda}{2}}{L} \tag{10}$$

where L is the interferometer's vacuum imbalance, or the difference in optical paths between the reference and measurement arms of the interferometer, and ϕ is the fringe counts observed between reference pressure p_0 and measured pressure p. The relationship between the molar density ρ_N and refractive index (Pendrill 1988, 2014) provided by the equation is established using the Lorentz-Lorenz equation (5).

Equation (11) yields the standard pressure p while excluding terms of higher order,

$$p = \rho_N RT\left(1 + B_\rho \rho_N\right) \tag{11}$$

T is the measured temperature at p in V_1.

Interferometer's Unbalance Measurement

Through a focused experiment shown in Fig. 3, an amplitude modulated fiber coupled diode laser having wavelength ≈ 640 nm, frequency f_M using a bias-T on the bias current to produce a synthetic wave with wavelength Λ and group velocity v_g, the interferometer's unbalance was determined using (12).

$$\Lambda = \frac{v_g}{f_M} \tag{12}$$

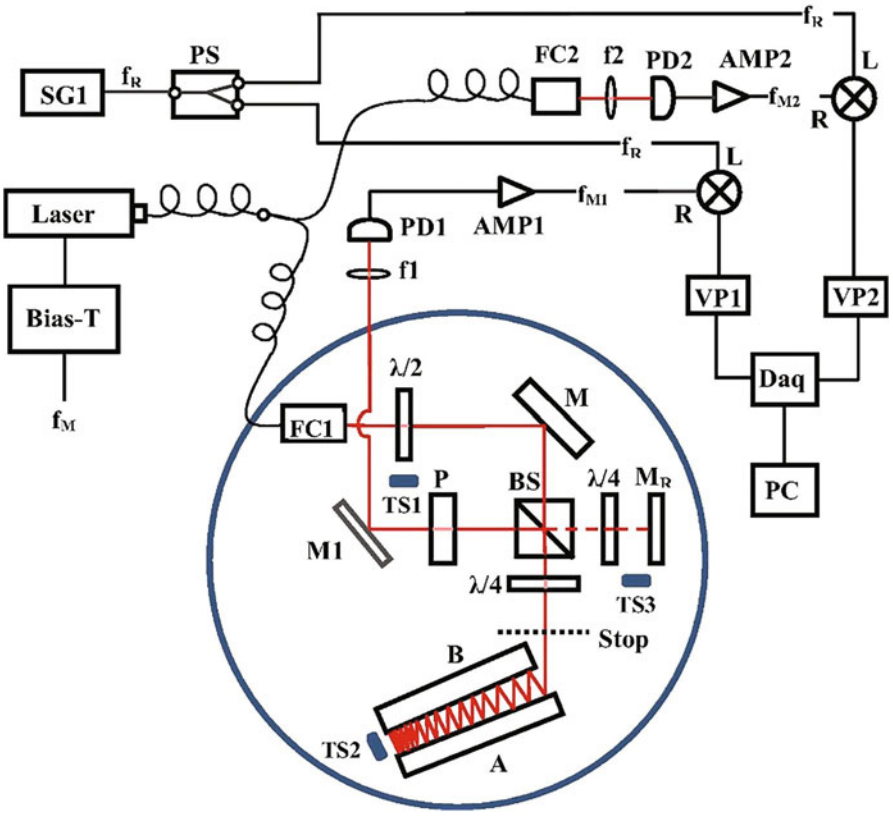

Fig. 3 Labeled diagram of the experimental assembly for path difference of the interferometer; M1: deflection mirror; voltage preamplifier: VP; power splitter: PS; signal generator: SG1; lens: f; fiber coupler: FC; amplifier: AMP; photo-detector: PD; AMP; mixer channels: R, L (Mari et al. 2019)

The laser emits two rays of radiation; one beam is incident to the photodetector PD2, which produces the reference ray at f_{M2}, and the other ray is thrown into the interferometer's input port. The interferometer's output port's photodetector PD1 produces the measurement signal at f_{M1}, which is the first measurement point. It is often easy to determine the optical path in terms of Λ obtained from the phase difference between the two signals f_M from the two photodetectors.

By adjusting the synthetic frequency f_M at the appropriate time, the uncertainty is removed because the measured phase only provides information about the excess fraction of wavelength. The superposition of the interferometer's two arms' beams, which PD1 was able to detect. To effectively detect the interferometer's imbalance or the relative differences between the two arms, they assessed the phase difference between the two signals (PD1 and PD2) by alternately blocking either of the two arms of the interferometer.

With frequencies of around GHz, which correspond to synthetic wavelengths of about tens of mm, we may reach a precision of fractions of mm. The resolution of the measurement falls as the modulation frequency f_M is increased. The signals from PD1 and PD2 are then combined with a signal at $f_R = f_M + 100$ kHz to perform a super-heterodyne down conversion at $f_{sh} = 100$ kHz. The down-conversion of the signal to the super-heterodyne frequency at 100 kHz preserves the signal's phase information at the order of GHz. The data at 100 kHz are recorded in Daq card and phase difference is evaluated using a computational method.

The imbalance L for several synthetic frequencies was measured between 0.7 and 1.3 GHz (Mari et al. 2019). Every point is the consequence of the variation in route lengths during an interval of a few minutes. After accounting for group velocity, the interferometer's resultant imbalance length in vacuum is $L = (1.4717 \pm 0.0002)$ m, with repeatability – measured as the standard deviation of the mean – contributing the majority of the uncertainty. The repeatability has been assessed using a number of normality tests. For instance, the Shapiro-Francia and Kolmogorov-Smirnov tests both produced p-values larger than 0.90, confirming the null hypothesis of normal distribution at the 0.05 level of significance. The incomplete elimination of common mode effects, for instance, because of fiber length changes during the minutes of measurements, may be the source of the data's dispersion.

Pressure Measurement by Optical Technique

This optical system's two potential methods for measuring pressure are outlined. First, the "sensitivity approach" which requires frequent calibration using a pressure reference standard, permitted the use of the device as an optical pressure sensor. Through the geometrical calibration of the interferometer arms, the second approach, known as the "absolute refractive index approach," permitted the use of the instrument as a pressure standard.

Sensitivity Approach

The initial step to detect and compute the sensitivity (S) using optical system's response (Mari et al. 2018), which is given by the ratio $\Delta p/\phi \approx p_s/\phi$, where Δp is the difference between the pressure p_s (usually from 120 to 130 kPa) and p_0 is the

reference pressure, and ϕ is the total number of fringes counted in the pressure difference Δp; p_s was obtained using barometer which is calibrated against INRIM primary standard HG5 (Alasia et al. 1999). An adjustable valve to control the leak was installed in series with the exchangeable conductance and adjusted to achieve an input time of V_1 of ≈ 5 minute. This allowed the pressure to change from p_0 to p_s while minimizing mechanical stress on the system and negating the opening change in temperature that would have happened in the situation of a rapid pressure deviation (Jousten et al. 2014; Jousten 1994), at standard temperature $T_{st} = 20$ °C, the findings of the S values for N_2 gas and ambient. The S value and associated standard uncertainty were determined to be (78.718 ± 0.014) Pa/fringe for N_2 and (80.322 ± 0.030) Pa/fringe for air, respectively. The uncertainty was calculated while also taking into consideration the pressure transducer's long-term stability. The findings of the sensitivity tests for N_2 and air are consistent with those of Table 1's data in Pendrill (2004). The last column shows the ratio percentage from each variance to total variance.

It is important to note that the established structure might be used as a pressure "sensor" in the sensitivity approach as early results, using the appropriate normalized sensitivity of each gas S_{gas} at T_{st} to acquire its associated pressure value p_j by counting the corresponding number of fringes ϕ_j arose between the p_0 and p_j at the temperature T_j:

$$p_j = \phi_j S_{gas} \frac{T_j}{T_{st}} \tag{13}$$

It may be assumed that ϕ_j has no effect of thermal expansion of ULE glass. The acquired findings further demonstrate the inherent stability for long span of the entire apparatus when used as a sensor because the interferometer was kept in the same settings.

Absolute Refractive Index Approach

To create and quantify standard pressure p, the second part of the investigation outlined above was then put into action. The interferometer's L-unbalance must be

Table 1 Uncertainty budget for N_2 gas at p= 100176 Pa (sensitivity approach) (Mari et al. 2019)

Input x_j	Value	Uncertainty source	$u(x_j)$	$c_i\, u(x_j)/p_j$	% Variance
S (Pa/fringes)	78.718	Stability, repeatability calibration uncertainty	0.014	1.82×10^{-4}	74.6
ϕ_j (fringes)	1271.76	Systematic effects, repeatability	0.05	3.93×10^{-5}	3.5
T_j (K)	293.342	Temperature gradients in chamber V_1, repeatability, calibration uncertainty	0.029	9.88×10^{-5}	21.9
Combined relative standard uncertainty ($u_c(p_i)/p_i$)				2.1×10^{-4}	100

determined, which calls for the specialized experimental setup seen in Fig. 3 and is a necessary prerequisite for this approach to be used rigorously. A sequence of data were recorded at a notional pressure of 120 kPa for 24 weeks after the imbalance L was determined so as to describe the OIM. The measured ϕ_j and T at optical pressure p and barometer pressure p_b and hence η and standard pressure p by Eqs. (10) and (11), respectively, with B_ρ acquired from (Egan et al. 2016; O'Connell 1981).

The outcomes p were contrasted with the calibrated barometer's pressure measurement p_b (standard uncertainty ≈ 5 Pa). The relative differences values obtained from the barometer and optical system at 120 kPa lie from -7.0 x 10^{-5} to +9.4 x 10^{-5} which is below the uncertainty bar limit or relative standard uncertainty of 1.7×10^{-4}.

Uncertainty Budget

Sensitivity Approach

Uncertainty was evaluated using model equation given by (13) in the sensitivity method example; Table 1 provides a summary of the corresponding uncertainty budget. The technique described in Mari et al. (2014) is used to count the interference fringes ϕ_j that occurred between the pressure at which the reference pressure was first set p_0 under vacuum and the pressure at which the interference occurred (p_j). Presently, there is 0.05 fringes of standard uncertainty. PT100 sensors were used to evaluate the temperature T_j. Calibrating, repeating, and accounting for temperature gradients within volume V1 result in a standard uncertainty of 0.029 K. However, as a first approach, the "sensitivity method" enables coverage of the pressure varies from 1 to 120 kPa with a relative standard uncertainty of 2.1×10^{-4} at standard barometric pressure. Table 1 makes it abundantly evident that the component owing to gas sensitivity determination has a significant impact on the combined standard uncertainty.

Absolute Refractive Index Approach

Equations (5, 10, 11) may be used to create the model Eq. (14) to calculate the uncertainty for the "absolute refractive index approach."

$$p = \frac{\left(1+\frac{\phi\lambda}{2}\right)^2 - 1}{\left(1+\frac{\phi\lambda}{2}\right)^2 + 2} \frac{RT}{A_R} \left(1 + B_i \frac{\left(1+\frac{\phi\lambda}{2}\right)^2 - 1}{\left(1+\frac{\phi\lambda}{2}\right)^2 + 2} \frac{1}{A_R} \right) \tag{14}$$

Table 2 summarizes the uncertainty budget associated with the model Eq. (13) for $p = 100164$ Pa. This discovery must be regarded as the first introductory step in the direction of a pascal realization optically because the obtained pressure standard has a relative standard uncertainty of 170 ppm at standard barometric pressure. It is simple to infer from Table 2 the key advancements required to achieve the desired uncertainty of 5 ppm: The measurement of the interferometer's imbalance L and the

Table 2 Uncertainty budget at $p = 100164$ Pa (Mari et al. 2019)

Input x_i	Value	Uncertainty source	$u(x_i)$	$c_i\, u(x_i)/p_i$	% Variance
T_i (K)	293.124	Temperature gradients in chamber V_1, calibration uncertainty, resolution, repeatability	0.029	9.89×10^{-5}	32.5
A_R (m^3/mol)	4.44585×10^{-6}	Mole refractivity (Egan and Stone 2011)	6 x 10^{-11}	-1.35×10^{-5}	0.6
ϕ (fringes)	1274.82	Systematic effects, repeatability (Mari et al. 2014)	0.05	3.92×10^{-5}	5.1
λ (nm)	632.9908	Laser wavelength (Jousten et al. 2014) (Stone et al. 2009)	9.5×10^{-13}	1.50×10^{-6}	0.0
L (m)	1.4717	Repeatability, calibration uncertainty, stability, resolution	0.0002	-1.36×10^{-4}	61.5
B_ρ (m^3/mol)	-5.95×10^{-6}	(Egan et al. 2016; O'Connell 1981)	2.4×10^{-7}	9.87×10^{-6}	0.3
Combined relative standard uncertainty ($u_c(p_i)/p_i$)				1.7×10^{-4}	100

temperature measurement within the calibration container V_1 are the two factors that contribute most to the combined standard uncertainty $u_c(p)$ in the current experimental setup.

The biggest challenge may be obtaining an accurate measurement of temperature because it necessitates further research to modify the system's current plan and design a thermal management and experimental setup that can achieve an uncertainty of the order of 0.3 mK while also considering the inhomogeneity of the temperature inside V_1. As per the computing the imbalanced L of the interferometer with an accompanying uncertainty of roughly 3 m, a different method might be used (van den Berg et al. 2015). Additionally, this aim will necessitate alterations to the optical setup in order to increase the thermal and mechanical stability of the numerous constituents. It will be essential to increase the signal-to-noise ratio, lessen the impact of the interferometer's non-linearities, build a more complicated compensating algorithm, and minimize the measurement of fringes ϕ (Gregorčič et al. 2009). Then, helium could be used because its refraction index can be determined by first principles with least uncertainty and its molar refractivity can be evaluated with higher accuracy, making it possible to compare the results of "first principles calculations" with the measurement made by the OIM to assess the effect of pressure on thermomechanical deformations of the dual mirror multiplication setup (Stone and Stejskal 2004; Schmidt et al. 2007; Moldover et al. 2014).

In order to account for the non-ideality of gas, the mathematical model represented in Eq. (13) must be updated. To do this, Eqs. (5) and (11) must be amended to include larger terms of refractivity and density virial coefficients, as detailed in (Pendrill 2004; O'Connell 1981; Achtermann et al. 1991).

National Metrology Institute Japan (NMIJ)

The OIM, which NMIJ created, can constantly evaluate an 18 kPa pressure range (Takei et al. 2020). The light source was a Littrow external cavity diode laser (ECDL) having a large adjustable frequency range, as opposed to a He-Ne laser. Because instead of a cavity with two optical routes, one optical path cavity was used for this investigation. One flat and one convex mirror, or two convex mirrors, can be employed in optical pressure measuring devices. The below equation provides the vacuum resonance condition of FP cavities.

$$\nu_{0,m} = \frac{c}{2L}(m + \gamma) \tag{15}$$

where $\gamma = \frac{1}{\pi}\cos^{-1}\sqrt{\left(1 - \frac{L}{R_1}\right)\left(1 - \frac{L}{R_2}\right)}$

Here R_1 and R_2 are the curvature radii of each mirror, c is the light speed, and γ is the ratio of the spatial to longitudinal modes of the cavity. The resonance criteria for a gas-filled at p is

$$\nu_{p,m} = \frac{c}{2\eta_p L}(m + \gamma) \tag{16}$$

If m does not change for gas and vacuum modes, then the refractive index at pressure p (η_p) is given by Eq. (17),

$$\eta_p = \frac{\nu_{0,m}}{\nu_{p,m}} \tag{17}$$

When m changes between vacuum and gas mode with the quantity Δm, it is essential to evaluate the FSR, $\nu_{FSR} = c/2L$, separately in a vacuum. While calculating η_p, the Δm is compensated and Eq. (17) is rewritten as Eq. (18),

$$\eta_p = \frac{\nu_{0,m} + \Delta m \times \nu_{FSR}}{\nu_{p,m+\Delta m}} \tag{18}$$

Thus Eq. (18) can be used to calculate η_p for the FP cavity to further evaluate the pressure.

Experimental Setup

Figure 4 displays a picture of the FP cavity that was employed in this work. Two mirrors with a 99.7% reflectivity were optically connected to a spacer constructed of ULE glass ceramic (Manufacturer: CLEARCERAM-Z) (http://www.ohara-inc.co.jp/en/product/electronics/clearceram.html). A finesse of approximately 1000 indicates that the full width at half maximum of the resonant peak is one thousandth of the full scale range. One mirror had a flat surface, and the other had a concave surface with a curvature radius of 75 cm. The length of cavity was around 5 cm, making the

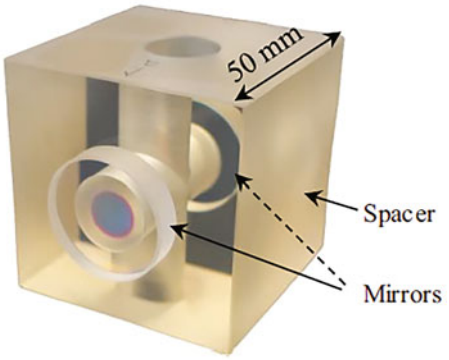

Fig. 4 Real picture of FP cavity having length of 5 cm (Takei et al. 2020)

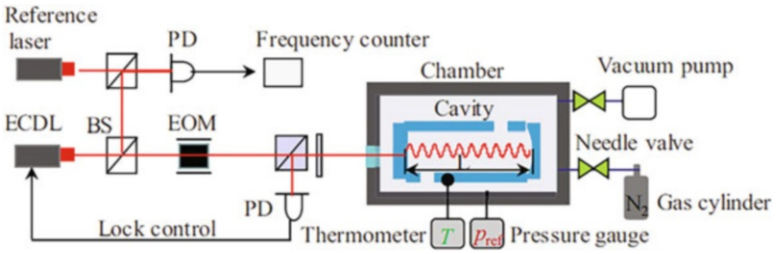

Fig. 5 Labeled diagram of OIM setup by NMIJ (Takei et al. 2020)

ν_{FSR} around 3 GHz. The hole was positioned within the vacuum compartment (Fig. 5). Sufficiently high thermal conductive metal aluminum was used to make the chamber in order to keep a consistent temperature within. The conduits that were joined to the chamber's exterior wall were also circulating water that was kept at a consistent temperature. According to the standard deviation, the thermal stability on the hollow surface was around 1 mK over a day. The cavity's temperature was considered to be the gas temperature. A calibrated pressure gauge was used to measure the pressure after the insertion of N_2 gas simultaneously to compare the readings obtained using the optical pressure measuring device (PACE1000, GE) in a pressure range of 130 kPa. This pressure gauge was calibrated with against a reference gauge with in the pressure range of 10–130 kPa with the standard uncertainty falls between 1.5 and 1.7 Pa.

An ECDL (manufacturer: New Focus 6005 Vortex, Newport) having a wavelength ≈ 632.99 nm in the variable range used as the light source for the optical pressure monitoring device. Using the Pound-Drever-Hall method, it was possible to determine the difference between the resonance and laser frequencies (Drever et al. 1983). A photodetector (PD) detected the laser beam that was reflected from the FP cavity after electro-optic modulator (EOM) modulates it at 15 MHz. Demodulating the signal from the PD yielded the frequency difference (i.e., the error signal). A proportional-integral controller transmitted the noise signal return to both ports to

adjust the frequency of the laser beam. One port was used to adjust the semiconductor chip's current, which has a quick reaction time but a limited range of adjustment. The other port was used to tune the piezo voltage, which has a sluggish reaction but a broad adjustable range, to change the diffraction grating's angle. In order to determine n_p, the laser's locked frequency was recorded. Beam splitters were used to combine a portion of the unmodified ECDL and I_2 stabilized He-Ne laser beams. A PD picked up the merged laser beam. Then this signal from PD resembles the difference between the two laser frequencies (i.e., beat frequency), which was further evaluated by a frequency counter having a gate time of 0.5 s. The ECDL's absolute laser frequency, which served as the reference frequency for the I_2 stabilized He-Ne laser, was calculated from the beat frequency. This optical pressure monitoring structure's constantly computable range is its major characteristic. The ECDL has an adjustable frequency range of more than 120 GHz. The detector and frequency counter frequency ranges are DC to 12 GHz and 0.25 GHz to 14 GHz, respectively. The continuous measuring range in the optical pressure evaluation setup with constant m is around 18 kPa since a change in pressure of 1 Pa resembles to a shift in frequency of roughly 1.3 MHz for N_2.

Discrete Pressure Measurements

Pressure was applied to both the internal and external side of the FP cavity during gas filling, which caused a little shortening of the cavity length. Even though this article merely provides a straightforward Eq. (18) for calculating refractive index η_p, the degree of deformation must be taken into account in reality. A calibrated gauge was used to compare the pressure points obtained from NIML's OIM for whole pressure range starts from vacuum to barometric pressure in order to quantify the deformation. Without altering the laser's frequency, m was varied throughout the trials at pressures of 10, 30, 50, 80, and 100 kPa.

At vacuum of 1 mPa, the resonant frequency $\nu_{0,\ m}$ was obtained. Resonant frequency $\nu_{p,\ m\ +\ \Delta m}$ was recorded when N_2 gas was filled to the specified pressure p by switching the resonance order from m to $m + \Delta m$. The resonant frequency was then measured once again when the pressure was changed to the subsequent set values. The temperature, frequency, and pressure were taken for every set of pressure values for 10 min at consecutive gaps of 8 s, and the obtained data points were utilized for the computations that followed. Five times this sequence of studies was carried out.

Using Eqs. (4), (8), and (12), pressure p was optically calculated from the observed temperature and frequencies. The recorded pressure values obtained by the calibrated gauge and optical pressure measuring equipment. The graph's slope coefficient was 0.997757. The cavity material's bulk modulus determines how the pressure variation causes the cavity to deform. The bulk modulus is equal to the nominal value of the glass ceramic employed in the spacer, which is 6.0×10^{-12}/Pa, supposing that the slope error is solely due to deformation (Silander et al. 2018). In reality, the slope value includes the impacts of both the bias and the distortion of the temperature sensor's calibration value. By dividing slope coefficient, the optically recorded pressure was adjusted for. The pressure computed using a calibrated gauge

and the pressure measured optically differ from one another. Several measurements at each pressure point exhibited repeatability of 0.1 Pa, while the range's non-linearity having a standard deviation of 0.5 Pa.

Continuous Pressure Measurements

The laser frequency was fixed to the cavity's resonance frequency while pressure was continually recorded over a wide range utilizing the optical pressure measurement method. The optical pressure measuring system can continually compute the range of ±9 kPa due to the optical system's detectable range of ±12 GHz, by fixing the resonant order m. (100 ± 9) kPa was chosen as the target pressure range. The needle valve was used to admit nitrogen gas at a pressure rise rate of around 0.5 Pa/s. The transition from 91 to 109 kPa in pressure took roughly 10 h. The beat frequency was evaluated by the frequency counter and the pressure as recorded by the calibrated gauge. The frequency range was precisely ±11.4 GHz. However, because the frequency counter employed can evaluate frequencies in the range of 0.25–12 GHz, the beat frequency curve was broken in the vicinity of about ±0.35 GHz. By dividing the slope coefficient, the pressure that was optically measured was taken into account. This experiment's frequency ranged greatly; therefore, the impact of the refractive index's dispersion (Peck and Khanna 1966) was mitigated. The readings from the pressure gauge from 91 to 109 kPa were linearly adjusted using the two calibrated points at 100 kPa and 80 kPa because the pressure gauge was calibrated at distinct pressure values. The discrepancy between the pressure values obtained using the optical pressure measuring device and the pressure gauge (Takei et al. 2020). The standard deviation of the range's non-linearity was 0.15 Pa (Takei et al. 2020).

The calibrated gauge's uncertainty was not exceeded by the slope of about 36 mPa/kPa. Because the frequency counter employed in the experiment is not capable to compute low frequencies, the beat frequency graph is broken in the middle. Beat frequencies in practically all ranges, with the exception of roughly 0 Hz, could be monitored with the addition of a frequency counter for low frequencies. The frequencies of the totally continuous entire range may be evaluated if the reference laser frequency was altered during the trials or if a second reference laser was employed. The graph's line width had an 88 mPa standard deviation. The gauge's pressure measurements exhibited a dispersion with a standard deviation of 64 mPa.

While the optical pressure measuring setup's temperature scattering data had a standard deviation of 0.08 mK, the scattering of its pressure measurements at 100 kPa had a standard deviation of 27 mPa. The optical pressure measuring setup's frequency scattering data in vacuum had a standard deviation of 0.01 MHz, which is equivalent to a scattering in the pressure measurements with a standard deviation of 7.7 mPa. This number would be equal to the dispersion of frequency measurements in gas-filled environments. Because of the temperature data, the line width was wider than the sum of the scatterings. The gas temperature along the light channel should be recorded in the optical pressure measuring system. However, the surface temperature of the cavity was recorded since it is technically challenging to detect the gas's

temperature along the path of the light due to the sensor's self-heating and spatial laser blockage. Continuous measurements may contain errors due to minute variations in temperature data and variations between the gas and cavity surface.

In this investigation, a continuous range of 91–109 kPa was used to compare the proposed optical pressure measuring system with a pressure gauge. Pressure gauges are calibrated at certain pressure values using pressure standards like pressure balances and mercury manometers. The sensitivities of the gauges' whole measurement range are adjusted using the calibration points at the discrete pressure values and the assumption that the sensitivity between the pressure points is roughly linear. Although a pressure range around atmospheric pressure was continually recorded for this investigation, it would be ideal to be able to measure a larger range of pressures, from vacuum to atmospheric pressure.

The measurement of beat frequencies at frequencies greater than 12 GHz presents a problem in extending the measurable range; however, this problem might be overcome by utilizing an optical comb with a variety of reference frequencies. Changing the gas species is a further strategy for extending the measured range. At atmospheric pressure, nitrogen's refractivity is 270×10^{-6} whereas helium's is 32×10^{-6}. The optical pressure measuring system's range might be extended to around ± 72 kPa by using helium gas with a lower refractive index, although measurement scattering would be greater.

Korea Research Institute of Standards and Science (KRISS)

The laser resonance frequency in a vacuum state, which served as a reference pressure, and that in an arbitrary pressure state were compared in a two-channel FP cavity structure also created by the KRISS team (Song et al. 2021). The cavity was constructed out of Zerodur. Taking into account the He-Ne laser's wavelength (633 nm), the pressure range to be employed, and the range of a single mode, the cavity was created as a rectangular parallelepiped with dimensions of 50 mm in width and 150 mm in length. Instead of using a readily accessible commercial laser, they independently created a single-mode (SM) He-Ne laser that allowed them to arbitrarily vary the frequency and obtain a single polarization regardless of the quantum number. With the help of our method, the internal pressure of a cavity served as a gauge for the beat frequency and pressure for about 1 Pa was measured.

Fabrication of a Cavity

They created the FP cavity structure in this work utilizing an optical approach with two canals to compute a random pressure by comparing the laser resonance frequency in a vacuum state, which serves as the reference pressure, and that in an arbitrary pressure state (Song et al. 2021). The FP cavity manufactured by the KRISS team is comparable to that of the NIST (Egan et al. 2015). Zerodur, a Schott-produced material with a thermal expansion coefficient of 1×10^{-8}/K, was chosen as the cavity's material. The FP cavity was a rectangular parallelepiped measuring 50 mm in width and 150 mm in length; it contains a rectangle channel measuring

7 mm in width and 11 mm in height at the upper section, and a circular channel measuring 7 mm in diameter at the bottom. The He-Ne laser was used as the light source, and mirrors were mounted to both extremities of the FP cavity for reflection and resonance. The two mirrors were of different shapes: one was flat, the other concave. In order to reflect more than 99.7% of the He-Ne laser utilized, the mirrors attached to the FP cavity's two ends were coated.

The mirror's curvature radius was determined using a Gaussian beam chart (Kogelnik and Li 1966), which is necessary for a precise resonance in the cavity. The lens, which has a 250 mm focal length and a 370 mm radius concave mirror, was created using a Gaussian chart. Additionally, the reflectance of each mirror was taken into account while calculating the finesse appropriate for the mirror (Eq. 19). The optical performance improves with increasing finesse. However, it is better to design the finesse to have an optimum value taking reflectance into account since it turns out to be more sensitive to the atmosphere as the finesse increases. The finesse in this study was created to have a value of 1500.

$$F = \frac{\pi (R_1 R_2)^{\frac{1}{4}}}{1 - (R_1 R_2)^{\frac{1}{2}}} \tag{19}$$

where R_1 and R_2 are mirrors's reflectivities attached to the two ports of the FP cavity.

The designed cavity length of 150 mm seems to be appropriate for the cavity to work as a stable resonator (Weichel and Perdrotti 1976). FP cavity and mirror were joined using an optical contact technique without epoxy. The vacuum level in the constructed cavity was monitored because one of the two channels of the FP cavity must retain a vacuum condition (a pressure $\leq 10^{-2}$ Pa). Epoxy is commonly employed in a variety of chemical bonding techniques, however in this situation, the outgassing from the epoxy during vacuum extraction might provide a concern. Despite using an epoxy-free optical contact approach, the finished cavity showed a minimum pressure of roughly 3 mPa after being continuously evacuated for 12 h. This demonstrated the usefulness of the optical contact approach for connecting the mirrors to the cavity.

Fabrication of a SM Polarized Laser

Instead of utilizing a commercially available He-Ne laser, they independently created an SM He-Ne laser, since it is difficult to freely modulate the frequency and to produce a single polarization regardless of the quantum number when using a commercial He-Ne laser. The optical length will vary even though the mechanical length of the resonator length L does not change when the polarization is altered in accordance with the quantum number due to the anisotropy of the cavity mirror, which is an issue. They therefore altered the Brewster's angle in a commercial laser tube for an iodine (I_2) stabilized He-Ne laser in order to give it a single polarization independent of the quantum number.

Zerodur was specifically employed to reduce the space between the two mirrors. The plane mirror jig was also equipped with a lead zirconate titanate (PZT) module

for frequency modulation (made by PI Co.), which may alter the length of the cavity. To concentrate the light between the two mirrors, the angle adjustment jig was fitted on the laser tube and the plane mirror. They measured the beating frequency with the reference I_2 stabilized He-Ne laser using a spectrum analyzer in order to assess the properties of the manufactured SM He-Ne laser. The FSR was around 890 MHz, which was close to the design frequency of 903 MHz. In comparison to the I_2 stabilized He-Ne laser, the laser displayed a beating frequency with a $\pm$ 2 MHz stability. This appears to be caused by changes in the ambient temperature.

Setup of the Laser Interferometer

The created SM He-Ne laser was locked into an FP cavity using a laser interferometer (Song et al. 2021). The laser's light beam travels via the isolator, which suppresses light produced by reflection, and the EOM, which generates a side band. It then moves successively via the focus lens, $\lambda/4$ wave plate, and polarization-beam-splitter (PBS) before entering the resonator. In order to alter the polarization of the light produced by the cavity, it is reflected and then sent via the focus lens and $\lambda/4$ wave plate once more. This light is reflected by the PBS and is then fed to the lock-in amplifier through a photodiode. Additionally, a function generator is used to provide the phase-delayed signal to the lock-in amplifier. The proportional-integral (PI) controller then uses a PZT control based on the error signal acquired from the lock-in amplifier to maintain the resonance.

With this setup, the laser frequency was locked to the upper cavity's resonant frequency while the internal pressure of the cavity was monitored using a CDG over a pressure range from 360 to 480 Pa. Without altering the mode number, the system was capable of measuring a range of 120 Pa. (m). The pressure was recorded by the CDG and the beat frequency determined by the spectrum analyzer (Song et al. 2021). It was discovered that 1 MHz beat frequency is about equivalent to 1 Pa of pressure, which is quite comparable to the findings reported by NIST (Egan et al. 2015, 2016) and NMIJ (Takei et al. 2020).

They are aiming to increase temperature stability by employing a double-chamber arrangement with an outer aluminum chamber and evaluating the cavity's arbitrary pressure using a measurement of its resonance frequency.

National Institute of Metrology (NIM)

The National Institute of Metrology (NIM), China has created an OIM on optical refractometry utilizing nitrogen gas (Yang et al. 2021). A dual FP cavity constructed of ULE glass, a copper compartment to house it, a thermal management setup, and an optical setup are further components of the NIM's OIM. By frequency-locking two tunable diode lasers to the reference and measurement cavities at a wavelength of 633 nm, the pressure within the copper compartment was recorded. The FP cavity's performance was examined, along with the impacts of creeping and the coefficient of thermal expansion. Within 1 mK, the copper chamber's temperature homogeneity was measured. All measurements were made with the leakage and

outgassing taken into account, and the so-called heat-island effect was explained and evaded. For the deformation of the reference cavity, non-linear and hysteretic behavior was seen. Direct comparison of the major piston gauges from NIM and OIM for the pressures assessed between 20 and 100 kPa indicated no deviations more than 10 ppm. The OIM's expanded uncertainty was calculated as $[(0.13\ \text{Pa})^2 + (23 \times 10^{-6} p)^2]^{0.5}$ (Yang et al. 2021).

Experimental Setup

The dual FP cavity employed in this study is comparable to the NIST design (Egan et al. 2016), except it is shorter (100 mm), with a 1.5 GHz FSR. While the thermal homogeneity of the shorter cavity length is advantageous, greater tuning ranges for the laser frequencies and a wider measuring range for the frequency counter are required. The cavity was created by optically connecting vacuum port, mirrors, and the spacer made of ULE glass (Corning Inc.) having a coefficient of thermal expansion (CTE) $\approx 3 \times 10^{-8}$/K. One mirror in each cavity is concave, with a radius of curvature of 500 mm, while the other is flat. A cavity finesse of $\approx$ 1000 corresponds to a reflectivity of 99.8% at 633 nm for all mirrors.

A copper vacuum compartment with impacted windows for coupling laser was used to seal the dual FP cavity. Two bellows located at the bottom of the copper chamber allow for gas filling and evacuation. A longitudinal slit having 2 mm width on the spacer's top connects the measuring cavity to the copper compartment's volume. About 63.5 mL of the chamber's total interior capacity may be filled with gas. The reference cavity is kept at vacuum, which is enclosed in a connecting tube made of polytetrafluoroethylene, and is not visible from the copper chamber (PTFE). The heat sharing between the copper compartment and the turbo pump-connected bellows is reduced by the PTFE tube. The bellows are submerged in a substantial sandbox to reduce vibration from the pump. The copper chamber was roasted for a number of weeks at a temperature of around 100 °C after the system had been put together and pumped down to vacuum. An ion gauge mounted in the manifold showed that the offset vacuum in the copper compartment was obtained to be less than 1 mPa.

The pressures determined by the OIM are directly influenced by the gas temperature. A temperature consistency of under millikelvin (mK) in the measuring cavity is necessary for the OIM to exceed cutting-edge pressure standards like a piston gauge and mercury manometer. Consequently, a unique thermal control mechanism was created. The next parts will provide an explanation of the optical setup and temperature control system.

Thermal Control System

Four poles were used to hang the copper chamber from an optical table, and a cylindrical temperature-controlled enclosure encased it. According to Fig. 6, the enclosure is made up of three coatings: outermost layer is filled with water which is maintained at 24.000 (3) °C, two aluminum shells with heating foils which are stable at 28 and 30 °C using thermal controllers (Eurotherm, model 2704). The thermal control setup was planned by considering following points:

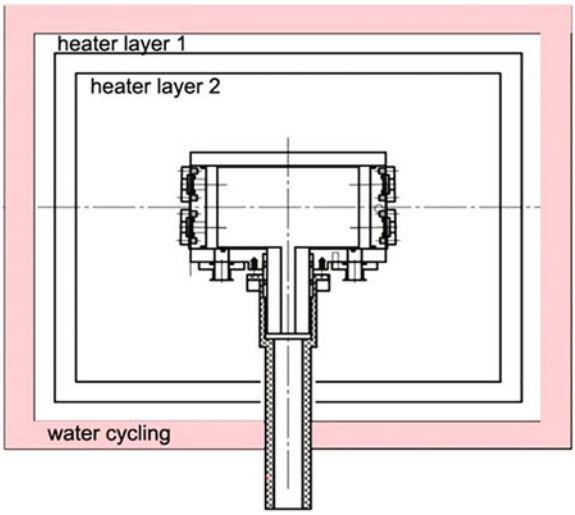

Fig. 6 Thermal controlled setup (Yang et al. 2021)

(a) The copper chamber's placement in the local area was made possible by the water-cycling shell, which also served to form a steady and constant thermal atmosphere. This is essential because the temperature of the lab is only stabilized by an air conditioner, resulting in a $\pm$ 0.5 °C difference.
(b) It was distant from the optical table to minimize vibrations from the water bath. The water tubing is about 8 m long, and the thermal steadiness of the water bath relies on ambient temperature. In order to increase the thermal constancy in the compartment, supplementary thermal-controlled heating layers were added. Dual heating layer setup's advantage over single heating layer setup is to minimize the thermal fluctuations and increase the uniformity in temperature inside the complete enclosure.
(c) The thermal enclosure's center included the location of the copper compartment, which should have a reasonable degree of temperature homogeneity which causes due to its strong thermal conductivity. Despite having many centimeters of gap between them, the copper compartment was thermally linked to inner heater layer through air. The copper chamber's temperature, which was established as stated below, is extremely stable since the aluminum shell's temperature changes are muted.

Four standard platinum resistance thermometers (SPRTs), of the capsule type, were put into the compartment at various locations to measure the temperature and its uniformity. The four SPRTs were able to measure temperatures with a maximum variation of roughly 1 mK, and the mean temperature fluctuated within 1.5 mK throughout the course of 9 h.

The degree to which the gas temperature deviates from the copper chamber's temperature is a different problem with temperature determination. This problem

was addressed by Ricker et al. (2021) in relation to a structure that had a copper compartment and the spacer made of ULE glass of equivalent size. As per the finite element analysis (FEA) simulations, it was assured that the temperature in the spacer was about 1.5 mK higher than that of inside the copper compartment after sufficient duration of applying the N_2 gas.

In seconds at the specified dimensions, the nitrogen attains the temperature of the walls, as will be demonstrated in a subsequent paper by Rubin et al. (2022). It is reasonable to presume that the temperature of the gas is somewhere between that of the copper compartment and that of the ULE glass. It should be noted that in order to prevent any potential heat-island effects, the copper chamber must be kept at low pressure (∼1 Pa) for a long enough period of time (∼15 min) during the evacuation process. Without performing this step, the temperature difference between copper compartment and the spacer is equal and greater than 10 mK which was given in more detail in section "Heat-Island Effect."

Optical Setup

The major component of the optical setup was two tunable diode lasers (Toptica, DL pro), which were frequency-locked to the reference and measurement cavities, respectively (Fig. 7). Both lasers had tuning ranges of around 20 GHz and operated at a 633 nm center wavelength. In free running mode, both the lasers have the linewidth of 200 kHz; by locking the lasers' frequencies to the FP cavities, this linewidth was reduced even further. When the diode current is changed, diode lasers operating at 633 nm frequently enter multimode. It is crucial to maintain the laser operating in single-mode in order to lock the laser to a cavity. The mode state of the diode lasers was observed using an etalon that was a commercial FP interferometer. The laser frequency was locked using dither technology to the FP cavity's resonance peak, which corresponds to the cavity's maximum light transmission. As a result of providing an oscillating signal to the diode current, the diode laser was briefly frequency and amplitude modulated at 10 kHz, causing the light transmission from the FP cavity while approaching resonance at 20 kHz. A lock-in amplifier was used to measure the photodiode's (PD) 10 kHz oscillating signal, which becomes zero when it reaches resonance. To maintain the laser frequency locked to the cavity, a proportional-integral servo was used to regulate the diode laser's piezo voltage. A PD having a 1.5 GHz bandwidth and to evaluate the beat frequency of the two lasers after they had been locked to the measurement and reference cavities, a frequency counter with gate time of 1 s was used.

Principle for Pressure Measurement

The beat frequency varies in accordance with the gas filled in the copper compartment with great N_2 sensitivity of 1.2 kHz/mPa by continually locking the lasers to the FP cavities. On the basis of fundamental physics rules, the relevant mathematical model was developed to count the pressure evaluation and assess the uncertainty.

When the FP cavities are kept at vacuum, then the locked frequencies help to solve the Eqs. (20a, 20b),

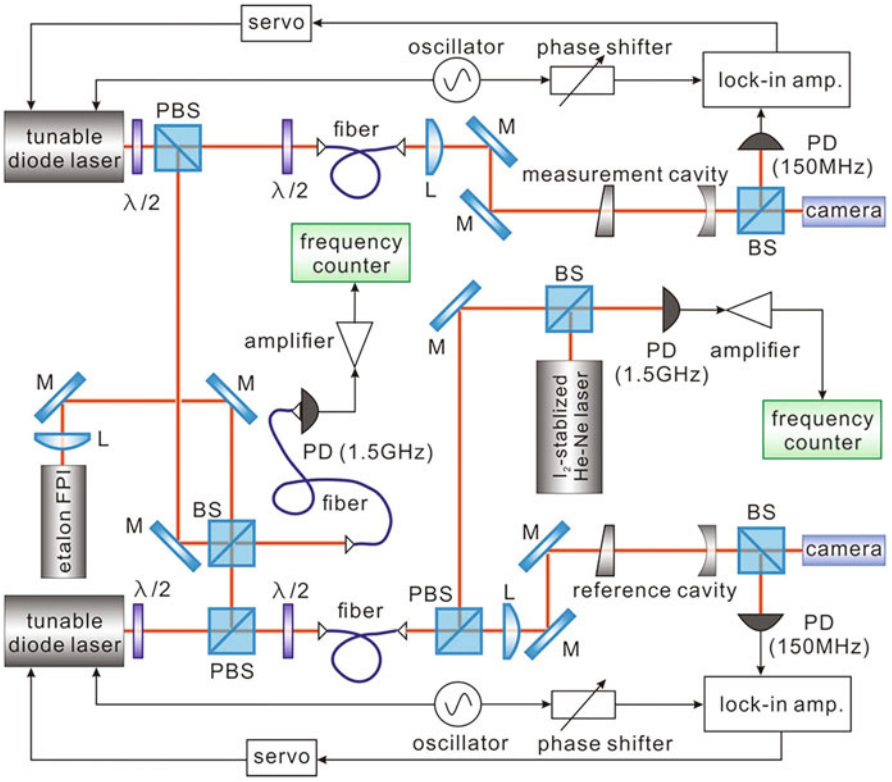

Fig. 7 Schematic drawing of the optical setup. Mirror: M, Lens: L, Half-wave plate: λ/2, Photodiode: PD, Beam splitter: BS, Polarizing beam splitter: PBS (Yang et al. 2021)

$$\nu_0^M = \left(m_0^M - \frac{\phi_0^M}{\pi}\right)\nu_{FSR}^M \tag{20a}$$

$$\nu_0^R = \left(m_0^R - \frac{\phi_0^R}{\pi}\right)\nu_{FSR}^R \tag{20b}$$

where superscripts R and M symbolize the reference and measurement cavity, respectively, ν_0 is the locking frequency, ϕ_0 is the mirror phase shift, m_0 is the mode number, ν_{FSR} is the free spectral range. Their heart rate was immediately determined to be $f_0^{MR} = \nu_0^M - \nu_0^R$. The frequency ν_0^Rf was calculated by measuring the beat frequency $f_0^R = \nu_0^R - \nu_{\mathrm{He-Ne}}$ with respect to an I_2 stabilized He-Ne laser. The locked laser frequencies vary in accordance with η and the cavity length's compression when the reference and measurement cavities are kept at vacuum and pressure p, respectively. Eqs. (20a, 20b) become:

$$\eta(1-d_m p)\nu_p^M = \left(m_0^M + \Delta m - \frac{\phi_p^M}{\pi}\right)\nu_{FSR}^M \tag{21a}$$

$$(1-d_r p)\nu_p^R = \left(m_0^R - \frac{\phi_p^R}{\pi}\right)\nu_{FSR}^R \tag{21b}$$

where ν_p^R and ν_p^M are the locking frequencies for the reference and measurement at pressure p, Δm is the change in the mode number and d_r and d_m are the distortion coefficients for the reference and measurement cavity, respectively. Mode hopping is also required if the beat frequency tends to zero, which cannot be measured with the frequency counter, in order to maintain the beat frequency below 1.5 GHz and permit measurement. Subtracting Eqs. (20a) and (21a) gives:

$$\eta - 1 - nd_m p = \left[\left(\nu_0^M - \nu_p^M\right)\left(1 + \frac{k\nu_{FSR}^M}{\pi}\right) + \Delta m\nu_{FSR}^M\right]/\nu_p^M \tag{22}$$

where k is given by $\left(\phi_p^M - \phi_0^M\right)/\left(\nu_p^M - \nu_0^M\right)$ and called as the mirror dispersion coefficient. With the beat frequency measurements $f_p^{MR} = \nu_p^M - \nu_0^M$, Eq. (22) can be written as follows:

$$\eta - 1 - nd_m p + d_r p = \frac{\left(f_0^{MR} - f_p^{MR}\right)\left(1 + \frac{k\nu_{FSR}^M}{\pi}\right) + \Delta m\nu_{FSR}^M}{\nu_0^M(1 + d_r p) + f_p^{MR}} \equiv \frac{\Delta f}{f} \tag{23}$$

The pressure may be calculated from $\frac{\Delta f}{f}$ using the Lorentz-Lorenz model and the gas state equation, as was previously mentioned (Egan et al. 2016). The beat frequency between reference and measurement (f^{MR}) is used to determine the term $\frac{\Delta f}{f}$ in Eq. (23). If just one cavity is to be used with the OIM, d_r is set to zero. The definition of $\frac{\Delta f}{f}$ switches to the right side of the equation in this situation (22). In this scenario, the difference in frequency obtained from standard (I_2 stabilized He-Ne laser) and measurement cavity is presented by adding their beat frequencies f^R and f^{MR}. In any instance, using equation, the pressure is then calculated from this (9). The high order components in Eq. (9) at a temperature of around 300 K were approximated for N_2 and He based on the published estimates of the virial coefficients (Puchalski et al. 2016; Egan et al. 2016, 2017).

Performance of the NIM's OIM

Measurements of the CTE, FSR, creeping effects, and heat island mechanism of the FP cavity were all done to study the OIM's performance at NIM. Pressure data of OIM was compared with the piston gauge (PG). An extrapolation technique was used to investigate and adjust the outgassing impact on the pressure determined by the OIM. Non-linear and hysteretic pattern for the d_r was observed and described, and the OIM's uncertainty was assessed.

FSR of the Measurement Cavity

A crucial factor for determining pressure is the ν_{FSR}^{M} of the measuring cavity, as illustrated in Eq. (23). The measurement and reference cavities, which were both evacuated to background vacuum and were in thermally stable circumstances, were locked to by the lasers in order to determine ν_{FSR}^{M}. $\Delta m = 1$ modified the locked TEM00 mode for the measuring cavity. Measurements were made of the two beat frequencies, f_0^R and f_0^{MR}. It was determined that the laser's absolute frequency was $\nu_{\mathrm{He-Ne}} + f_0^R + f_0^{MR}$, where $\nu_{\mathrm{He\ -\ Ne}}$ is defined as 473612514.643(11) MHz. Following the instructions in Axner et al. (2021), each of the beat frequency determinations for the two neighboring modes mentioned was finished in few minutes to reduce the drifting effects of the cavity length.

The experiments were performed several times, and it was discovered that the neighboring modes' frequency difference Δf was 1480294.2 ± 0.9 kHz. The FSR should be adjusted by $\frac{k\Delta f}{\pi} = -6.2 \times 10^{-6}$, where k is equal to $-1.3129 \times 10^{-8}\ \mathrm{MHz}^{-1}$ supplied by the mirror manufacturer, to account for the mirror dispersion effect. As a result, it was discovered that the measuring cavity's FSR was 1480285.0 kHz with a standard variation of 0.9 kHz. The He-Ne laser's short-term stability and the adjustment for mirror dispersion are both part of the FSR's type B uncertainty, which is expected to be 1.5 kHz.

Coefficient of Thermal Expansion

According to the manufacturer, the FP cavity's material has a CTE, or fractional change in length per K, of $0 \pm 3 \times 10^{-8}$/K. The FP cavities locking frequencies when it was kept at vacuum were continually tracked while the thermal management setup was operating in order to confirm the declared CTE value. By measuring the beat frequencies f_0^R and f_0^{MR}, respectively, it was possible to determine the cavities's locked frequencies. Even though the heat-island effect caused the FP cavities' temperature to differ from the copper chamber's under vacuum conditions, the temperature change was considered to be the same.

The CTE was derived from the frequency's rate of temperature variation (Yang et al. 2021). The effects of temperature increases and decreases on two thermal equilibrium processes were investigated. The "rapid" heating and cooling cycles that required less than 9 h were used to capture the two temperature ranges. The range of temperature near the thermal equilibrium value, which required several hours to attain.

The temperature relationship was obscured during this time because the frequency drift began to outweigh the temperature-induced drift, hence the data are not displayed. The reference cavity's CTE spans from -1.2×10^{-8}/K to 7.5×10^{-9}/K, whereas the measurement cavity's CTE falls between -2.9×10^{-8}/K and -7.5×10^{-9}/K (Yang et al. 2021). Despite the fact that the ULE spacer in the two cavities is the same, the non-uniformity in the temperature gradient and spacer's material may be to blame for the variance in CTE (or a combination of the two). In any event, these numbers match those that the manufacturer claims.

Equation (23), for example, demonstrates that a key measurand is the beat frequency between the reference and measurement cavities, f_0^{MR} and f_0^R. From its thermal dependency behavior, it is demonstrated that the frequency change was about 7 MHz/K per degree change in temperature. This suggests that the beat frequency will change by 70 kHz for a temperature change of 10 mK.

Creeping Effect of the FP Cavity

The creeping effect was noticed few 100 days by analyzing the baselines of both cavities kept at vacuum. The baselines for both the cavities were rose by 5–7 MHz during a 500-day period, showing a reduction in the spacer's length with the drift rate of about 1×10^{-8} per year. The copper compartment's temperature was maintained within a maximum difference of 0.07 °C during the experiments. The frequency shift brought on by a change in temperature will be below 1 MHz, as per the CTE value stated in section "Coefficient of Thermal Expansion." As a result, an aging procedure having spontaneous relaxation was given credit for the frequency creeping (Kobayashi et al. 2016). The reference cavity originally drifted more quickly when the cavity was repeatedly inflated and released. After pressurization at high pressures, it was discovered that the reference cavity's baseline had greatly risen (e.g., 100 kPa). If the hollow had been drained for a while, this tendency would become more obvious. For instance, the cavity was vacuum-stored from 90 to 500 days. After applying the 100 kPa, reference cavity's baseline rose by 1.3 MHz, whereas measurement cavity's baseline reduced by 0.77 MHz. This might be attributed to the tension created by the optical contact used to link the ULE vacuum port and reference cavity. Since the ULE vacuum port is cylindrical in shape, it shrank more slowly than the cavity. Over time, stress will accumulate and may be released during pressurization by relaxing, which may result in the baseline changes shown. The data before and after applying pressure was plotted for initial phase, whereas for long-term phase, only the data after applying pressure was plotted. Because of this, the initial rapid drift rates outside the linearly fitted curves were not the actual creeping rates of the cavity.

Heat-Island Effect

The gas temperature drops which further reduces the temperature of the cavity surface if the compartment is evacuated rapidly. The temperature gradient between the copper chamber and the cavity will be preserved if the background vacuum (< 1 mPa) is maintained, as a result of the poor thermal contact between them (known as the heat-island effect). The copper compartment is thermalized, but because of the ULE spacer's poor thermal conductivity at background vacuum, the spacer will continue to be colder than the chamber for a considerable period of time. When gas is added to the chamber, the PV work will increase the temperature of the gas while also transferring heat from the hollow walls to the chamber. Such an effect did occur, which shows the temperature of compartment as recorded by the SPRTs. The compartment's temperature decreased by 10 mK in 30 min after being filled with N_2 gas at 100 kPa, despite the gas's increased temperature as a result of its PV action,

showing that there existed previously a thermal gradient between the cavity surfaces and the compartment of at least 10 mK. The measurements collected after 5 h, when the gas was pushed out, also show that the thermal impact of the PV operation was around 2 mK. This PV work's scope is comparable to that of reference (Ricker et al. 2021).

The pressure readings will be impacted by a baseline offset brought on by the temperature gradient. After the gas has been evacuated, the copper chamber shouldn't be immediately fetched at vacuum; instead, it should be occupied with a nominal pressure of ≈100 Pa for a significant length of time to prevent this offset. Therefore, for baseline measurements, the copper compartment was merely evacuated to the ambient vacuum. A subsequent study will demonstrate that the cooling period after pumping out the cavity near vacuum has a time constant of a few hours. As a result, the baseline measurements were finished in 10 min for all the pressure evaluations indicated in the following sections. The temperature gradients between the copper compartment, the cavity, and the gas were calculated to be within 2 mK by applying this rule.

Pressure Measurements

A complete setup was built to link the OIM, resonant silicon gauge (RSG; Manufacturer: Yokogawa) and the PG for pressure comparison measurements. For this investigation, nitrogen 6.0 was employed, which has a purity rating of higher than 99.9999%. No data were recorded between 90 and 500 days and all the findings in this section are based on pressure readings taken after day 500 (Yang et al. 2021). As stated in section "Creeping Effect of the FP Cavity," if the aging cavity is evacuated for a lengthy period of time, the stress effect between the reference cavity and ULE vacuum port will almost certainly always take place. The stress effect theory is supported by first pressure readings from day 500. The nitrogen gas was pumped into the manifold, and during the course of 11 h, the pressures from 100 Pa to 100 kPa were reached. A Python script was used to record the OIM's frequency outputs, copper chamber temperatures, and RSG data all at once.

First, for each pressure level, d_r was determined as:

$$d_r = \frac{1}{p} \frac{f_p^R - f_0^R}{\nu_{\mathrm{He-Ne}} + f_p^R} \left(1 + \frac{k\nu_{FSR}^M}{\pi}\right) \tag{24}$$

where f_0^R is the baseline and f_p^R is the beat frequency for reference cavity with respect to the I_2 stabilized He–Ne laser at a pressure of p. It was anticipated that the cavity would deform linearly with pressure, yielding a uniform d_r value. Unexpectedly, however, showed notable variability, ranging from $1.54 \times 10^{-11}\mathrm{Pa}^{-1}$ to $1.66 \times 10^{-11}\mathrm{Pa}^{-1}$, and was steadily rising over time. The previously mentioned stress effect between ULE vacuum port and cavity is one reason for this phenomenon. As previously mentioned, pressurization caused the associated baseline to change, but the d_r calculated using Eq. (24) employed a constant baseline taken before the compartment was occupied by gas.

The baseline rose by around 1.3 MHz following the initial pressure computations (Yang et al. 2021). If d_r is assumed to be constant for all pressures, it is possible to compute the baseline change during pressurization using the d_r data. The baseline changes are computed under the constant d_r assumption of 1.60×10^{-11} Pa^{-1}. The greatest alteration took place when the highest pressure of 100 kPa was applied, and it recovered when the pressure was steadily reduced to 5 kPa. The assumption that had been formed was validated by the baseline change computed at the final 5 kPa being rather near to the baseline change seen following the initial observations.

The stress effect between the ULE vacuum port and cavity, which influence becomes considerable after creeping for a protracted period of many months, may be responsible for the variations at high pressure in the bonding state. Due to the fact that this bonding is accomplished without glue through an optical contact, it could not be strong enough to endure the load. High pressure pressurization may have relieved the tension in this situation. The baseline change with and without applying pressure was obtained to be less than 0.2 MHz, as evidenced by further observations following the initial measurements, as will be explained below. Therefore, in order to establish a stable baseline when a cavity is held for such a long duration, a pre-pressurization of up to 100 kPa is required. Eq. (9) and the virial coefficients for N_2 taken from Egan et al. (2016) may be used to determine the pressure as recorded by the OIM using the copper compartment's temperature and frequency values. The OIM pressure functioned as a single cavity utilizing $d_r = 0$ as previously described, taking into account the unpredictable d_r value affected by the stress effect. The FEA simulation outcome (Yang and Rubin 2018), which was $9.936 \times 10^{-12}Pa^{-1}$, was used to calculate d_m. The data obtained from RSG which was calibrated with respect to the PG with an expanded uncertainty of 2 Pa were compared to the OIM pressure data. The initial measurements' pressure discrepancies between the RSG and the OIM fall within a wide range of uncertainty of the RSG (Yang et al. 2021).

The difference in pressure rose when the compartment was occupied by gas, going from 100 Pa to 8 kPa, and the PG was not exposed to the components of the calibration setup like tubes, bellows, valves, etc. (Yang et al. 2021). This rise was brought on by the buildup of gas that was mostly water (water's A_R is 17% lower than nitrogen's). By shutting the valves, the leak rate of the calibration setup components, including the RSG and OIM, was evaluated. About 2 Pa/h of pressure rise was occurring. Since the OIM pressure was computed using pure nitrogen, it would have decreased if the leakage gas had simply been water vapor and increased the pressure differential relative to the RSG by roughly 0.34 Pa/h. The pressure differential growth rate is somewhat slower than the calculated rate of 0.34 Pa/h (Yang et al. 2021). This makes sense because air leakage, whose A_R is only 2% lower than that of nitrogen, may also contribute to the 2 Pa/h pressure rise rate in addition to water outgassing.

It was unable to clearly analyze the outgassing impact for the data collected after 5 h (Yang et al. 2021). The PG was left open to the manifold at that period, and once the manifold was evacuated to lower the setting pressure, gas that had collected due to outgassing or leaking was also pushed out. As a result, there was sporadic

reduction in the leakage effect on the pressure differential. The outgassing impact when the OIM and PG were compared is examined in considerably more detail in the next section.

The best PG utilized at NIM (China) was compared to the OIM's performance in the pressure range of 20 to 100 kPa in order to show the OIM's maximum potential metrological performance. The effective area (A_p) of piston-cylinder assembly (PCA) in PG (Fluke, model 7607) was determined at reference temperature (t_0) using dimensions data calibrated at NIM and rarefied gas dynamics (Yang and Yue 2011; Sharipov et al. 2016). The pressure (p(PG)) determined by PG at temperature (t) using effective area is given by,

$$p(\mathrm{PG}) = \frac{mg}{A_p[1 + \alpha(t - t_0)]} + p_{vac} + p_{head} \tag{25}$$

where g is the acceleration due to gravity, m mass of the load applied, α is the CTE of PCA, p_{vac} is the residual vacuum in the bell jar, and p_{head} is the head correction between reference levels between OIM and PG. The expanded uncertainty for absolute pressure when OIM was calibrated to PG evaluated to be ($0.05\ Pa + 1.4 \times 10^{-5}p$) (Yang et al. 2021).

To consider the leakage effects, comparison experiments were carried out in a time-controlled way. Each pressure experiment tracked a procedure known as 0-P-0: in this procedure, the baseline was initially logged for less than 10 min, then the valves are shut, and the time was documented. This procedure is similar to that used in the gas modulation refractometry (GAMOR) procedure (Silander et al. 2018). The measurements then began once the chamber was filled with nitrogen gas to float the PG at the desired pressure p. In order to record the baseline, again for less than 10 min, the manifold was pushed out until background vacuum was reached. Using a Python script, the OIM pressure, PG pressure, temperature of copper's compartment, and time stamp were logged as the measurements were being made. When the valves were shut, the time plotted against the pressure differential between the PG and OIM was 0 (Yang et al. 2021). The pressure differential trend was consistent with expected behavior for air and water leaks, both of which had values lower than nitrogen outgassing. A formula that combines two exponential decay functions was used to predict the consequences of air and water leaks. The two exponential decay functions have temporal constants of 6.35 h and 0.319 h correspond to air leakage and water outgassing, respectively (Yang et al. 2021). The genuine difference between the PG and OIM was found by fitting the data with the model and projecting to time 0. Here, using a linear fit for the initial brief period is an easy, quick, and accurate enough method (Yang et al. 2021). By utilizing the linear fit, the difference between the PG and OIM is calculated to be 0.18 Pa, whereas the exponential fit results in a difference of 0.15 Pa. The fitting method's inherent uncertainty was calculated to be within 0.05 Pa.

The relative differences between the OIM and the PG at pressures ranging from 20 kPa to 100 kPa were evaluated after the outgassing/leakage effect was removed using the fitting approach (Yang et al. 2021). There were four measurement runs

performed. All of the values fell between −5 and 10 parts per million. As a result, despite the PG's hesitation, the OIM and PG were in good agreement. As previously said, the PG should be rather stable at 1 ppm. The OIM was responsible for the scatter of roughly 10 ppm, which might also be attributed to the temperature gradient in the copper compartment, the variability of the baseline, or the unpredictability of the fitting procedure (Yang et al. 2021).

Consider the scatter to be the OIM's type "A" uncertainty. When the average of the differences across all pressures was calculated, the outcome showed a systematic inaccuracy between the OIM and the PG of 3.3 ppm. The systematic mistake is rather tiny, however it can be caused by the OIM's d_m error or the PG's effective area error. Prior to and following each pressure measurement, the baselines acquired for both cavities were noted. The history of the baseline changes illustrates the pressure measurement cycle, which includes upwards and downwards measurement. The variations in the baseline for pressure readings under 80 kPa were within ±50 kHz. The baseline changed more when the pressure was measured at 100 kPa, while the changes remained within ±100 kHz. In comparison to what was seen during the initial measurements, the baseline's stability was far better. Compared to what was seen in the earlier measurements, the variance of d_r was substantially less (Yang et al. 2021). The deformation of the reference cavity, however, was shown in non-linear and hysteretic behavior types in the history of d_r. It is unknown why these behavioral patterns exist, and more research is needed. One theory is that as tension built up on the bonding surface, the reference cavity underwent different deformation than the ULE vacuum port did. In this study, the OIM pressure was computed as a single cavity using just d_m due to the considerable uncertainty of d_r resulting from the non-linear and hysteresis behavior. The findings of the comparison between the OIM and the PG showed no non-linear or hysteretic behavior, proving that the d_m was constant and stable.

Uncertainty Evaluation

Equation (9) was used to determine the uncertainty of the OIM. Each parameter involved in calculating pressure was taken into consideration, and the involvement in the uncertainty in pressure was computed by altering the parameter's value by its uncertainty while maintaining the values of the other parameters constant. The outgassing/leakage impact was also evaluated using the fitting errors and included additional variables that contributed to the uncertainty. In Table 3, each parameter's uncertainty contribution is indicated.

The virial coefficients (A_R, B_R, C_R, B_p, C_p) values and uncertainties were taken from reference (Egan et al. 2016). Due to the small temperature difference of only 0.4 °C between this study and reference (Egan et al. 2016), greater uncertainties were chosen for B_p and C_p. Because their contributions were proportional to or quadratic in relation to the pressure, the pressure uncertainties supplied by B_R, C_R, B_p, and C_p indicated in Table 3 are at 100 kPa and were considerably decreased at lower pressures.

The history of the copper compartment temperature throughout a pressure measurement period was displayed in order to assess the uncertainty brought on by the

Table 3 Uncertainty budget of the OIM for N_2 when calibrated against PG (Yang et al. 2021)

Parameters	Value	Standard uncertainty	Uncertainty
A_R (cm^3/mol)	4.446139	1.5×10^{-5}	$3.4 \times 10^{-6}\, p$
B_R (cm^6/mol^2)	0.81	0.1	$< 0.89 \times 10^{-6}\, p$
C_R (cm^9/mol^3)	−89	5	$< 0.0018 \times 10^{-6}\, p$
B_p (cm^3/mol)	−3.973	0.12	$< 4.8 \times 10^{-6}\, p$
C_p (cm^6/mol^2)	1434	102	$<0.16 \times 10^{-6} p$
T (K)	303.28	0.00195	$6.4 \times 10^{-6} p$
d_m(Pa^{-1})	9.927×10^{-12}	1.9×10^{-14}	$7.1 \times 10^{-6} p$
Baseline (kHz)	Stability	50	40 mPa
ν_{FSR}^{M} (kHz)	1480285.0	1.8	$1.2 \times 10^{-6} p$
Outgasing/leakage	Fitting error	0.05 Pa	50 mPa
Expanded uncertainty of pressure at $k = 2$ ($U_c(p)$)		$[(0.13\ Pa)^2 + (23 \times 10^{-6} p)^2]^{0.5}$	

temperature measurement (Yang et al. 2021). The temperature changed with the fluctuation of 3 mK. It was anticipated that the temperature of the gas would match that of the copper chamber, as was previously mentioned. With the typical temperature 1 h after a pressure shift of 100 kPa, there is a maximum offset of 1.5 mK. The expanded uncertainty in the temperature measured was calculated to be 3.9 mK after accounting for the uncertainty components of SPRT (1 mK), the temperature uniformity (1 mK) and the potential temperature gradient in the copper's compartment (2 mK), and the temperature's fluctuation as computed (3 mK).

Since the OIM was used as a single cavity for the pressure computation, the uncertainty of d_r had no bearing on the OIM pressure. Due to the uncertainty data around Poisson's ratio and Young's modulus, it was challenging to get a reliable estimate for d_m from the FEA simulation. The data compared between the pressure obtained from OIM and the PG, however, may be used to calculate the d_m value and uncertainty. The PG's relative standard uncertainty was 7 ppm, while the mean difference between the OIM and the PG was 3.3 ppm. The OIM's uncertainty budget, which serves as a secondary pressure standard, is displayed in Table 3. By combining all the components of uncertainty, the uncertainty in pressure obtained from OIM was obtained to be $[(0.13\ Pa)^2 + (23 \times 10^{-6})^2]^{0.5}$.

Conclusion

The NMIs have established an OIM based on FP refractometry for vacuum pressure measurements in the maximum range of 100 Pa to 180 kPa (Jousten et al. 2017; Thakur et al. 2020). The main constituents of the OIM are an FP cavity fabricated from ULE which is enclosed by a copper compartment, a thermal management setup with a temperature homogeneity of 1 mK and the optical setup used two tunable diode lasers operating at 633 nm wavelength for the determination of beat frequency and locking frequencies in reference and measurement cavities. In addition to the

NMIs mentioned above, other NMIs and other institutes or universities (Silander et al. 2021; Beica et al. 2019; Booth et al. 2019), have also made attempts for developing OIM but still required further experimental data to be as competent as UIM (Heydemann et al. 1977); such as (1) low pressure (< 100 Pa) measurement unlike that of in UIM, 1 Pa can be measured, (2) uncertainty (8.8 ppm) which significantly higher than that of in UIM (i.e., 5.2 ppm) (Heydemann et al. 1977), and (3) pressure measurement range (i.e., 100 Pa – 180 kPa) which is far lower than UIM (i.e., 1 Pa – 360 kPa) (https://www.nist.gov/laboratories/tools-instruments/low-pressure-gauges). Despite these shortcomings, OIM still has a significant advantage over UIM, i.e., the mechanism behind measuring pressure based on the kinetic theory of gases, including fundamental constants. It can widen the pressure range using more dense inert gas that cannot be dissolved into the FP cavity glass and lower the uncertainty by adapting corrections while experimenting, like minimizing the errors in distortion coefficients.

Abstract

Time plays a central role in metrology and in the definitions of other SI units. Time interval or frequency is the quantity that can be determined with the highest accuracy. Nowadays, using optical frequency standards, it is possible to measure frequency with accuracy better than 1 part in 10^{17}. If such a clock runs continuously, it will not lose or gain 1 second over the age of the universe. Such precise frequency standards have become important resources for pushing the frontiers of science and technology for the benefit of the society. Ever-reducing uncertainties in frequency measurement have been steadily driving the innovations in the field of lasers, low-noise electronics, high-resolution imaging, statistical tools, and many others. Before we start to understand various concepts on time and frequency covered in this section, it is better to have a brief review of commonly used terms in time and frequency domain followed by a concise overview of the forthcoming chapters on timescales, atomic frequency standards, and time transfer techniques.

Basics of Time and Frequency Measurements

Time-of-the-day, time interval, and frequency are the three basic information of interest in time and frequency metrology. Time-of-the-day, defined in terms of hours, minutes, and seconds, sometimes clubbed with date and year, is what is displayed or recorded by a clock. Setting two clocks to display the same time is called synchronization. Time interval is the duration between two events, measured in seconds. Time is one of the seven base units of the SI system and is used to define many other units. Frequency is the rate at which an event repeats. It is reciprocal of time period or time interval. It is measured in events/cycles per second and the standard unit is hertz (Hz). A device that is source of frequency is called an oscillator. The process of setting different oscillators to same frequency is called syntonization. An oscillator's quality is often defined in terms of accuracy, stability, and precision. Accuracy is the extent of closeness of a measurement, or the average of a set of measurements, to the definition of the quantity being measured. Accuracy is related to the offset from an ideal value. Stability indicates how well an oscillator can produce the same frequency offset over a given time interval. It doesn't indicate the correctness of a quantity being measured but only if it stays the same. It is basically a statistical estimate of time or frequency fluctuations of a signal over a given time interval. Fluctuations over intervals less than 100 s usually define short-term stability, while those over longer intervals (usually a day or longer) define long-term stability of an oscillator. Stability can be measured in either the frequency domain or time domain. Due to the non-static or dynamic data, the stability of an oscillator in time domain is defined with Allan deviation rather than standard deviation.

The stability of an oscillator improves as the averaging period gets longer, as some noise types can be removed by averaging, until it hits the noise floor. Noise floor is the point beyond which longer averaging does not improve the performance. The slope of the Allan deviation vs. averaging time graph (frequency instability graph) helps in the identification of the noise type prevalent in the measurement. Five noise types (with different slopes on the frequency instability graph) are white phase, flicker phase, white frequency, flicker frequency, and random walk frequency.

In the frequency domain, the standard measure for characterizing phase and frequency instabilities is one half of the double-sideband spectral density of phase fluctuations. The amplitude instability in the frequency domain is one half of the double-sideband spectral density of the fractional amplitude fluctuations. The unit of such measurements is decibels or dBc/Hz.

Precision is related to reproducible consistent measurements. It refers to the extent with which a set of measurements of a quantity stays close to the mean value of the set. For more details on various terminologies and basics on time and frequency metrology, the reader is referred to (Jespersen and Fitz-Randolph 1999; Riehle 2004; Lavine 1999; Arias et al. 2018).

The signal for time measurements is usually a pulse that occurs once per second (1 pps), while the signal for frequency measurements is usually a frequency of 5, 10,

and 100 MHz. Any clock or oscillator can be characterized and calibrated with its frequency or 1 pps signals.

Timekeeping and Timescales

Since the redefinition of SI second in terms of cesium transition frequency, the timekeeping is being done with atomic clocks worldwide (Panfilo and Arias 2019; Petit et al. 2015). For critical applications, an ensemble of clocks is used instead of relying on a single clock in order to avoid any single-point failure. In an ensemble of clocks, the time outputs of individual clocks in a group are combined, using a statistical averaging or timescale algorithm, to form a timescale. National Metrology Institutes (NMI) of several countries operate national timescales (based on ensemble of atomic clocks) and contribute the data to BIPM on regular basis for generating the international reference timescale known as Coordinated Universal Time (UTC). The International Bureau of Weights and Measures (BIPM), an international organization, established by the Metre Convention, is responsible for global timekeeping as it calculates "the time" for the world by processing the data collected from atomic clocks kept in national institutes around the globe. Since January 1, 1988, the maintenance of International Atomic Time (TAI) and Coordinated Universal Time (UTC) has been the responsibility of BIPM. TAI is a uniform and stable scale which is not related to the slightly irregular rotation of the Earth. The timescale with astronomical definition based on rotation and orbital motion of the Earth is known as UT1. UTC is derived from TAI by the adding or removing an integral number of seconds so that UTC tracks the irregular rotation of the Earth. UTC is identical with TAI except that from time to time "one second" (known as "leap second") is added or removed to ensure that the difference between UTC and UT1 remains within 0.9 s. The dates of application of the leap second are decided and announced by the International Earth Rotation and Reference Systems Service (IERS). The local realization of UTC at laboratory "k" is named UTC(k). On a monthly basis, BIPM issues "Circular T," a scientific bulletin, with deviation and uncertainties of UTC – UTC(k). More details on timescales are given in the chapter on "Atomic Timescales" in this section.

Standards of Time and Frequency

The quest for better timekeeping has been about finding better and stable oscillators. In the preatomic era, timekeeping and standard frequency measurements were mostly based on mechanical and electrical oscillators (Bize 2019). There were mechanical clocks (based on balanced wheel, pendulum, etc. as oscillators) and later on quartz clocks (based on periodically vibrating crystal as oscillator). With the advent of atomic frequency standards, there has been a rapid improvement of

timekeeping accuracies, which improved by nine orders of magnitude in the last 100 years alone. There can be several standards, but the primary standard is the one which realizes the SI unit of a quantity with highest accuracy. Primary frequency standard as present is cesium fountain clock, where Cs atoms are laser-cooled before they are tossed through the microwave cavity and interrogated for change in state. However, there is a possibility of redefinition of SI second in terms of an optical transition in the near future. Each type of atomic frequency standard is discussed and described in the chapter on "Atomic Frequency Standards" in this section.

Time and Frequency Transfer Techniques

Various modern applications require clocks or oscillators at different locations to be synchronized or syntonized. Different kinds of time and frequency transfer techniques are used to compare and adjust clocks and oscillators at different locations. It can be done through signals broadcast via many different media, including coaxial cables, optical fiber, radio signals, telephone lines, and the Internet (Bauch 2015; Matsakis et al. 2014; Lavine 2008). For synchronization, one requires an on-time pulse as well as a time code broadcasted or obtained from the reference or transmitting station. For syntonization, one requires extracting a stable frequency from the broadcasted or transmitted information. The frequency can be extracted from the carrier or time code or other information modulated onto the carrier.

Precision techniques for time and frequency transfer are based on satellites. The most common satellite time and frequency transfer technique in based on global navigation satellite system (GNSS), GPS being the most widely used satellite system for precise navigation and timing (PNT) services. Chapter on "Time Transfer via GNSS" in this section elaborates more on GNSS-related technical details.

The most precise satellite time and frequency transfer technique at present is two-way satellite time and frequency transfer (TWSTFT) which allows time transfer with ± 1 ns accuracy. TWSTFT is mostly used by NMIs and mission-critical strategic sectors for maintaining the traceability with respect to a better known reference. Basics, present, and future of TWSTFT technique is presented in chapter on "Time and Frequency Transfer via TWSTFT" in this section.

To complete the section, chapter on "Time and Frequency Transfer via Telephone, Radio Waves, and the Internet," has been included. These are lower accuracy transfer methods and used as common methods of time and frequency dissemination to the masses.

Summary

This section covers all important aspects of time and frequency metrology starting from the realization of the SI unit of time to the time and frequency transfer techniques while discussing the applications of precision time and frequency metrology.

After this brief introduction chapter, chapter 2 is on "Atomic Timescales," chapter 3 is on "Atomic Frequency Standards," chapter 4 is on "Precise Time Transfer via Telephone, LWR, and Network," chapter 5 is on "Precise Time and Frequency Transfer via TWSTFT," and finally, chapter 6 is on "Precise Time and Frequency Transfer via GNSS."

After going through the section, readers will realize that time interval and frequency are the most precisely measured physical quantities. Several critical applications, which have become integral part of modern lifestyle such as navigation and high-speed optical communication, rely completely on atomic clocks and allied technologies. There has been phenomenal improvement in the field of timekeeping in the last several hundred years especially in the last 100 years which saw nine orders of magnitude in performance. The realization and rapid development of optical frequency standard since the beginning of twenty-first century is enabling newer applications and opening new frontiers in the understanding of the universe. Ever-reducing uncertainties in frequency measurement are still steadily driving the innovations in the field of lasers, low-noise electronics, high-resolution imaging, statistical tools, and many others. Not alone the atomic frequency standards, there has been an equivalent amount of emphasis on developing better and more accurate time and frequency transfer techniques. However, there is still a lag in the intercontinental comparison of optical clocks. Redefinition of SI second on the basis of optical clocks will not be done until remote comparison of optical clocks over different continents becomes feasible. It is not possible to predict how this dynamically growing field will shape up, but there will surely be more accurate oscillators with further reduced uncertainties and newer unexplored applications will continue to emerge in time and frequency metrology.

Abstract

In this chapter general aspects of atomic timescales (AT) are discussed. As an introduction, the history and importance of AT and their applications is presented. Then, the construction of AT from an ensemble of atomic clocks is exposed. Different types of AT exist depending on their applications. There are AT defined by a physical signal, typically an electrical signal, usually distributed in real time by different means. An example of this type of AT is the UTC(k) timescale. For most developed countries, the UTC(k) atomic timescale is the reference for the

national official time. Meanwhile, there exist also AT that are not defined by a physical signal, alternatively defined by a mathematical algorithm. An example of this type of AT is the Coordinated Universal Time, UTC, timescale which is produced by the *International Bureau of Weights and Measures* (BIPM). The UTC has a remarkable role worldwide because, mainly, it is the international reference for the local UTC(k) timescales. This chapter discusses how the UTC atomic timescale is produced by the BIPM and how it and UTC(k) timescales provide traceability to the time unit of the International System of Units (SI), the second. Finally, the most important technical requirements in setting up an AT laboratory are listed.

Introduction: A Brief History of Time Scales

When the history of timescales began? With the aim to give an answer to this interesting question, we certainly can say that timekeeping is as old as the civilization itself. The current sexagesimal structure to measure time (minutes of 60 s, hours of 60 min) is a reminiscence of the ancient cultures civilizations and their methods in measuring time. It is well known that these ancient cultures used mathematics in base 60. The reader can remember here that our nowadays common mathematics are built in base 10 and computers work in mathematics in base 2. As a curious fact, we would like to draw the reader's attention on the fact that the "average" human heartbeat rate is about one beat per second. Here we can ask ourselves if this is just a casual coincidence or, by the contrary, the Sumerians used the human heartbeat as unit of time to build timescales (minutes, hours, days, and so on)? A positive answer to this question about Sumerians will certainly explain many facts about time measurement through the different epochs. Any way, we will not go further over this question here. Soon in the history appears a practical way to measure time using the position of the Sun. It was known that the most prominent celestial body, the Sun, lasts 24 h to repeat its position in the sky so that measuring the position of the Sun provides a practical way to measure the time of the day. Sundials were artifacts broadly used through ancient times to measure the time of the day. With minor importance, other astronomical objects were also used to measure time, and so build calendars. One of those astronomical objects was the Moon. An example of a very old civilization that used the Moon to measure time, and build calendars, was the Hebrew civilization.

Astronomical methods to measure time remained until 1967 as the best way (due to the redefinition of the second in the SI) to determine the time of the day and build calendars as well. That situation changed around the Renaissance when mechanical artifacts started to be used as clocks. Galileo Galilei (1564–1642) in Florence, now Italy, first noticed that the period of a pendulum remained nearly constant for small amplitude oscillations. That fact was used to develop the first clocks based on pendulums. Slowly, mechanical clocks got more importance as good artifacts to measure time. In the sixteenth century already existed very accurate pendulum clocks. In some point astronomical methods and mechanical clocks were in a kind of competition to be the most precise method to keep and measure time. Mechanical

clocks were an excellent alternative for timekeeping in quiet environmental conditions (no mechanical vibrations, no big changes in humidity and temperature). However, mechanical clocks showed significant limitations in harsh environments (considerable humidity and temperature variations, and important mechanical oscillations and vibrations like those in a ship on sea). One of the facts that marks the beginning of the Renaissance was the discovery of the American continent. The secure navigation of ships on their transatlantic voyages was a very important issue that involved precise time measurements. The competition between astronomical methods and mechanical ones as the best way to measure time was evident, when the British Government offered, through the longitude act in 1714 (by the parliament), a prize of 20,000 £ (an immense fortune in those days) for a solution which could provide a method to measure the longitude to within half a degree (2 min of time) (Burton 2017; Seidelmann and Hohenkerk 2021). The methods would be tested on a ship sailing from Great Britain to any such port in the West Indies as those commissioners choose without losing their longitude beyond the limits before mentioned and should prove to be tried and found practicable and useful at the sea. Many of the most brilliant and educated people worked on an astronomical method to solve the longitude problem. However, it was solved by John Harrison, a working-class joiner with little formal education. Harrison concentrated on the rigorous scientific establishment of his time and won the longitude prize through extraordinary mechanical insight, talent, and determination. The era of secure navigation on seas by using accurate mechanical clocks was born. One of the most precious elements on a ship was precisely its clock.

The discovery of piezoelectric effect (Uchino 2017), and its application to develop quartz oscillators, was an important milestone in timekeeping. The first crystal-controlled oscillator was built in 1917 by Alexander M. Nicholson at Bell Telephone Laboratories in the United States (Nicolson 1940; Barrett-Gonzalez and Wolf 2022). Quartz crystal oscillators and their application to build clocks were a remarkable technological revolution for timekeeping.

Once quantum physics was developed with the contribution of a few dozens of brilliant scientists during the first half of the twentieth century, the astronomic era was ending and the atomic era began. Quantum physics predicted different energy states for the hydrogen, and hydrogen-like, atom (Davies 1992; Jaeger 2022). By the 1930s the scientific community was curious if predictions of quantum mechanics for hydrogen-like atoms were true or not. Around that date, Isidor Isaac Rabi, at the University of Columbia, conducted an extraordinary experiment, among other objectives, to test if magnetic resonance produces results compatible with predictions of quantum physics (Chodos et al. 2009). Time after, in 1945, Norman Ramsey, at Harvard University, developed the separated oscillatory magnetic fields method used to test the hyperfine structure of hydrogen-like atoms (Ramsey 2000). Both, Isaac Rabi and Norman Ramsey, received by their contributions the Nobel Prize in physics in 1944 and 1989, respectively (Ramsey 1990; Rigden 2000). By 1955 Louis Essen, at the National Physical Laboratory (NPL) in England, using the separated oscillatory magnetic fields method developed by Norman Ramsey, built the first atomic clock (Essen and Parry 1957). Microwaves at 9.192 GHz from a

quartz oscillator were used to produce the transition between the two hyperfine levels of the ground state of a hydrogen-like atom, the ^{133}Cs atom. Time measurement using this atomic clock was found to be more accurate than the astronomical time based on the Earth rotation. In 1967, during the 13th General Conference on Weights and Measures (CGPM), the unit of time of the SI was defined in terms of the frequency of the electromagnetic radiation associated with the hyperfine transition of the ^{133}Cs ground state, as the duration of 9,192,631,770 periods of such radiation (Barrell 1969; Newell et al. 2019). The atomic timekeeping era was born. Nowadays precision on timekeeping is such that the best atomic clock will accumulate an error of a second after nearly a million years of operation.

As a continuous accumulation of seconds produces a timescale, the continuous accumulation of atomic seconds produces an atomic timescale. The current UTC timescale was implemented in 1972 (Smith 1972; Nelson et al. 2001), and it is produced through the participation of timekeeping laboratories which operate atomic clocks and share data with the BIPM. In section "Atomic Timescale," several atomic timescales that the BIPM produces as a preliminary step before getting the UTC are introduced.

The importance of timekeeping in a uniform, consistent, and broadly recognized fashion has long been recognized. Since centuries ago, it was well known that accurate timekeeping is needed for navigation because longitude (Sobel 2004), the geographical coordinate, can be determined by time measurements along with astronomical observations (Tavella and Petit 2020). Local timescales and timekeeping conventions originated centuries ago to support commerce, navigation, and later transportation systems (Dohrn-van Rossum 1996). More recently, timescales that were used internationally date back to Greenwich Mean Time (GMT), an astronomical timescale based on the prime meridian at the Royal Observatory Greenwich in London, England. In 1880, GMT was legally adopted as the official time of Great Britain, and numerous other nations legally recognized GMT as official time during the next few decades. At the twentieth century, in 1928, based on a recommendation of the International Astronomical Union (IAU), the GMT became known as Universal Time (UT). Several improved versions of UT, including UT1 and UT2, were in use before the advent of atomic timekeeping (Howse 1997; Bartky 2007) in 1967.

The development of quantum physics at the beginning of the twentieth century set the bases for the invention of atomic clocks, which first appeared in the late 1940s (Essen and Parry 1955). The accumulation of seconds produced by atomic clocks led to atomic timescales that were far more accurate and stable than the astronomical timescales. Coordinated Universal Time (UTC) was a name first used in the early 1960s to refer to an international timescale based on the use of atomic clocks. However, neither atomic time nor UTC was internationally accepted at that time. In 1967, at the 13 CGPM (*Conférence Générale des Poids et Mesures*), the International System of Unit (SI) second was redefined not in terms of astronomical observations but in terms of quantum properties of the cesium atom. The SI second was established as the duration of 9,192,631,770 periods of the electromagnetic radiation associated with the transition between the two hyperfine levels of the ground state of the ^{133}Cs atom. In 1972 was when the world's current system for

keeping official time went into practice; the use of UTC was corrected periodically with integer leap seconds to keep it in phase with the Earth's rotation angle and so with astronomical timescales (Nelson et al. 2001). The *Bureau International des Poids et Mesures* (BIPM) is the international organization responsible for maintaining and disseminating the UTC timescale (Quinn 2011). The definition of the SI second based on the ^{133}Cs atom formally marked the beginning of the atomic timekeeping era, after many centuries of referencing time interval measurements to astronomical observations.

Currently, the measurement of time is of the utmost importance for many applications, including global satellite navigation systems (Riehle 2006; Giorgi et al. 2019; Tavella and Petit 2020), communication networks (Li et al. 2017; Mahmood et al. 2019), electric power transportation (Lombardi et al. 2016), astronomy (Bhonsle et al. 1981), electronic transactions (Lombardi et al. 2016), and national defense and security.

Atomic Timescale

The continuous accumulation of atomic seconds produces an atomic timescale. There are different types of atomic timescales. Among the most important timescales, it can be mentioned the following (Gérard et al. 2015): the free atomic timescale (EAL), the International Atomic Timescale (TAI), the Coordinated Universal Time (UTC), the physical realizations of the UTC (the UTC(k) atomic timescales), and the Terrestrial Time (TT). EAL, TAI, and UTC timescales are produced by the Time Section of the BIPM with data contribution from about 80 timing laboratories geographically distributed worldwide. The UTC(k) timescales are produced by different timing laboratories, most of them national metrology institutes (NMIs), equipped with atomic clocks that are maintained within a continuous local and/or international comparison.

Clock Ensemble

Timekeeping for critical applications requires demanding characteristics on reliability, stability, and accuracy. Because of the susceptibility to failure of any single clock, critical applications that need time measurement, like national official timescale, or timescales for navigation purposes, among other applications, require the simultaneous operation of more than one atomic clock. A group of N ($N \geq 2$) atomic clocks, which are maintained under a continuous comparison among them, can be used to produce a timescale with superior metrological characteristics to those obtainable from any single member of the clock set. The set of such atomic clocks is referred to as a clock ensemble. The most efficient use of a clock ensemble implies the generation of a timescale which is produced in terms of time difference measurements among the participant clocks. Such timescale is called an averaged timescale.

Averaged Timescale

If a set of N atomic clocks are under comparison among each other, then an averaged atomic timescale TA can be defined in the simplest way as an average of the readings of the clock ensemble:

$$TA(t) = \frac{1}{\sum_{j=1}^{N} \omega_j(t)} \sum_{i=1}^{N} \omega_i(t) h_i(t), \tag{1}$$

where $h_i(t)$ and $\omega_i(t)$ are the reading and weight of the clock i at time t, respectively. Weights must satisfy the normalization condition $\sum_{i=1}^{N} \omega_i(t) = 1$. As a first approach, it is possible to define weights $\omega_i(t)$ as constant in time. However, the best scenario is given when a dynamic weighting approach is implemented, which increases or decreases the weight given to a clock according to its frequency stability characteristics, which, in turns, can change over time for different reasons. Unfortunately, the eq. (1) cannot be implemented experimentally as it is written, because the readings from clocks $h_i(t)$ are not physically observable. Experimentally it is possible to measure time differences between two clocks. The equation can be written in terms of time differences between pairs of participating clocks by subtracting from each side of equation the reading $h_k(t)$ of clock k at time t:

$$TA(t) - h_k(t) = \frac{\sum_{i=1}^{N} \omega_i(t) |h_i(t) - h_k(t)|}{\sum_{j=1}^{N} \omega_j(t)}. \tag{2}$$

If we define $x_k(t)$ as the time difference between clock k and the TA at time t, and define $x_{ki}(t)$ as the difference between clock k and clock i at time t, it is $x_{ki}(t) = h_i(t) - h_k(t)$, then

$$x_k(t) = \sum_{i=1}^{N} \omega_i(t) x_{ki}(t). \tag{3}$$

This equation provides a way to access TA values at the time t through the reading of clock k of the ensemble and the time differences x_{ki} between clock k and the rest of clocks at time t. Notice that, by using the previous equation, once the set of time differences $x_{ki}(t)$ are measured, it is then possible to compute the TA. However, this way of computing the TA corresponds to a post-processing scheme. In cases where a computation of the timescale values are needed not in a post-processed regime but in real time, it is necessary to introduce a method of prediction for the time differences of clocks with respect to the TA. For some applications, like the formation of UTC and UTC(k) timescales, it is important to predict future values of time differences between clocks of the ensemble.

One of the simplest models to predict the time difference $x_{ki}(t+\tau)$ of a clock k with respect to the *TA* once the values $x_{ki}(t)$ are known is (Weiss and Weissert 1991)

$$\widehat{x}_k(t+\tau) = x_k(t) + \left[y_k(t) + \frac{D_k\tau}{2}\right]\tau + \ldots, \tag{4}$$

where $\widehat{x}_k(t+\tau)$ is the prediction of the time difference of clock k respect with *TA* for the future time $t+\tau$; $x_k(t)$ is the time difference between clock k and the *TA* at time t; $y_k(t)$ is the fractional frequency difference of clock k respect to the *TA* frequency at time t; and, finally, D_k is a constant accounting for linear changes in $y_k(t)$.

Once the future time $t+\tau$ is reached, it is possible to measure the time differences among participating clocks, and then, it is also possible to compute the value of the *TA* for that time $t+\tau$. Of course, the predicted value of the *TA* computed at time t for the time $t+\tau$ will not be equal to the computation of *TA* at time $t+\tau$. Once the time difference measurements $x_{ki}(t+\tau)$ at time $t+\tau$ are known, the prediction $\widehat{x}_k(t+\tau)$ for $t+\tau$ can be corrected according to the following equation:

$$x_k(t+\tau) = \sum_{i=1}^{N} \omega_i[\widehat{x}_k(t+\tau) - x_{ki}(t+\tau)]. \tag{5}$$

On the other hand, the prediction $\widehat{y}_k(t+\tau)$ of the fractional frequency deviation of clock k with respect to the *TA* can be made according to

$$\widehat{y}_k(t+\tau) = \frac{\widehat{x}_k(t+\tau) - x_k(t+\tau)}{\tau}. \tag{6}$$

Finally, when the future time $t+\tau$ is reached, the fractional frequency deviation prediction $\widehat{y}_k(t+\tau)$ can be corrected by

$$y_k(t+\tau) = \frac{1}{1+m_k}[\widehat{y}_k(t+\tau) + m_k(\tau)y_k(t)], \tag{7}$$

where m_k is given by

$$m_k(\tau) = \frac{1}{2}\left[\sqrt{\frac{1}{3} + \frac{4}{3}\frac{\tau_{min,k}^2}{\tau^2}} - 1\right], \tag{8}$$

and $\tau_{(min,k)}$ is the integration time at which the noise floor (Tavella and Thomas 1991; López-Romero and Díaz-Muñoz 2008) of clock k is reached.

Paper Clock (Virtual Clock)

The iteration of the equations presented in the previous section allows the formation of an *TA*. It is important to notice that, because such a *TA* is a result of a mathematical

process, there is not a physical signal associated with *TA*. In that sense, *TA* behaves as a "paper clock" or "virtual clock." It is also important to mention that very important atomic timescales, like EAL, TAI, UTC, and TT(BIPM), are all paper clocks.

In many applications, not only accurate and stable paper clock but also accurate and stable physical signal that can be distributed by different means is needed. Once a paper clock *TA* is produced, it is then possible to implement an experimental setup to "convert" *TA* in a physical signal TA_0. A way to achieve that goal is selecting one clock of the ensemble, typically the most stable and reliable, to correct its output frequency signal in order to "copy" the frequency of the paper clock *TA*. Let us refer to a such selected clock as Master Clock (MC). The corrected frequency of the MC is added as a "new clock" into the ensemble. Now, let us refer to the corrected frequency of the MS as y_0. In order to avoid any undesirable perturbation on *TA* due to the manipulation of the frequency $y_0(t)$, its corresponding weight $\omega_0(t)$ must be set to zero; it is $\omega_0(t) = 0$ for all time t. The frequency $y_0(t)$ is then adjusted to produce time differences with respect to *TA* as small as possible; it is $x_0(t) \approx 0$ for all t. In other words, in the conversion process of the paper clock *TA* into a real clock TA_0, it is necessary to correct the frequency of the MC in order to copy the frequency of the *TA*. Eventually time adjustments could be also needed (Fig. 1).

Coordinated Universal Time (UTC)

The BIPM, located in Sevres, France, is responsible to produce the international reference timescale, the Coordinated Universal Time (UTC). The UTC is the

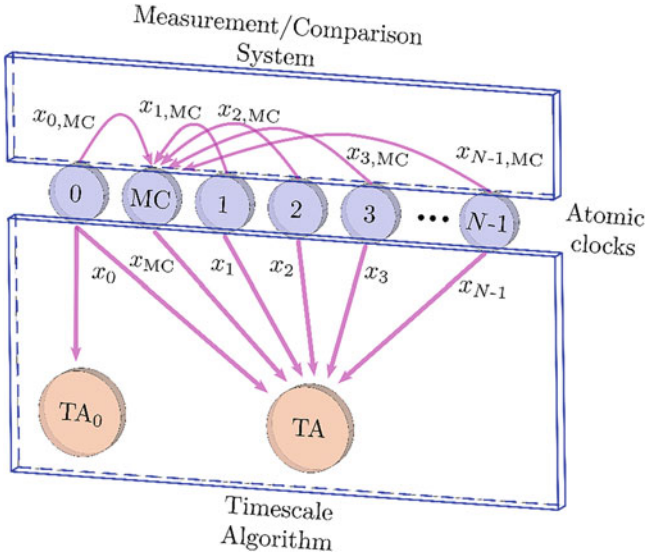

Fig. 1 Clock ensemble and timescale algorithm producing a paper clock *TA* and its physical realization TA_0

international reference timescale that forms the basis for the coordinated dissemination of standard frequencies and time signals; UTC is obtained from International Atomic Timescale (TAI) by the insertion of leap seconds according to the advice of the International Earth Rotation and Reference Systems Service (IERS) to ensure approximate agreement with the time derived from the rotation of the Earth, the UT1 timescale. The UTC timescale is defined by the next equations (Beard and The role of the ITU-R in time scale definition 2011; McCarthy 2011):

$$UTC = TAI + n, \tag{9}$$

where n is an integer number of seconds that made

$$|UTC - UTC1| \leq 1\ s. \tag{10}$$

UT1 in turns is an astronomical timescale which is proportional to the rotation angle of the Earth (Arias and Petit 2019; Wang et al. 2020). The IERS is the international organization in charge of *UT1*.

The TAI timescale is produced through a comparison of the fundamental time interval of the free atomic timescale (EAL) with respect to primary realizations of the SI second maintained in about a dozen NMIs. The EAL timescale is produced by clock data contribution of about 80 laboratories that operate atomic clocks. The main characteristic of the EAL is to keep a robust and continuous timescale with very high frequency stability. The UTC is an averaged timescale which is produced by a similar algorithm to that described in the previous section. Figure 2 shows the process at the BIPM to produce the UTC timescale.

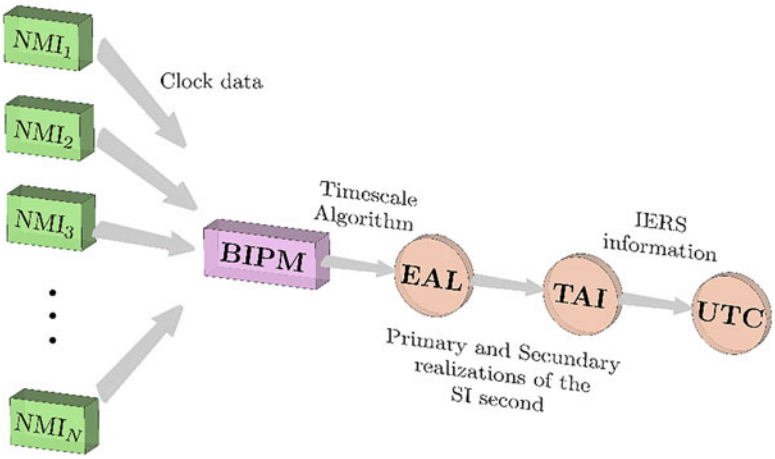

Fig. 2 Production of UTC timescale at BIPM through data clock contribution from NMIs. There are about 80 NMIs contributing with clock data to the BIPM ($N \geq 80$), around 420 atomic clocks contributing to the formation process of the UTC and 17 primary and secondary realizations of the SI second

The UTC(*k*) Timescales

With the aim to achieve enough level of reliability, stability, and accuracy, national measurement institutes (NMIs) usually keep in operation, and under a permanent comparison among them, more than one atomic clock to produce its local physical realization of the UTC timescale. The physical realization of the UTC, made by a laboratory k, where k is an identifier of such laboratory, is referred to as UTC(k). Physical realizations of UTC, named UTC(k), are maintained mainly in NMIs and astronomical observatories, which contribute to UTC computation by sending periodically their clock measurements to the BIPM. The UTC(k) atomic timescales can be seen as predictions of UTC. Values of [*UTC-UTC*(k)] at 5-day intervals are published in the monthly BIPM Circular T document (BIPM 2022a). For those institutes participating in the CIPM MRA (Di Giuseppe et al. 2013; MRA-D, CIPM 2016), their results are also published in the form of a key comparison, CCTF-K001. UTC (BIPM 2022b), resulting in a monthly publication of the degrees of equivalence with respect to the worldwide reference timescale UTC. Currently, there are about 80 laboratories (Panfilo and Arias 2019; Bauch et al. 2020), distributed worldwide, which maintain their own physical realization, UTC(k), of the UTC. The BIPM publishes the complete list of those laboratories on the Circular T. Some physical realizations of the UTC with high frequency stability and excellent approximation to UTC are UTC(USNO), UTC(NIST), UTC(PTB), UTC(OP), UTC(ROA), and UTC(NPL), among others. The identifiers of laboratories are USNO for US Naval Observatory, NIST for National Institute of Standards and Technology of the United States of America, PTB for *Physikalish Technische Bundesanstalt* of Germany, OP for Observatory of Paris of France, ROA for *Real Observatorio de la Armada* of Spain, and NPL for National Physical Laboratory of England.

In Fig. 3(a) and (b), it is shown the time differences between UTC and UTC (USNO) and UTC(PTB), respectively, from 50,800 MJD (December 18, 1997) to 59,699 MJD (April 30, 2022), as an example of performance of UTC(k) atomic timescales.

Physical realizations of the UTC are very important for economy and demanding real-time applications that need accurate time. Such is the case of telecommunications industry, navigation systems, defense, and electrical power distribution systems, among others. Signals of UTC(k) are distributed by different techniques: GNSS common-view and all-in-view methods (Weiss et al. 2005), two-way time and frequency transfer methods (Kirchner 1991), radio signals (Lichtenecker 1997), time transfer protocols by the Internet like precise time transfer protocol (PTP) (Marc et al. 2016), network time transfer protocol (NTP), (Mills and others 1985) and telephone.

The Circular T of the BIPM

The BIPM Circular T document is a monthly publication of the BIPM Time Department. Circular T is the source of traceability to UTC for the physical

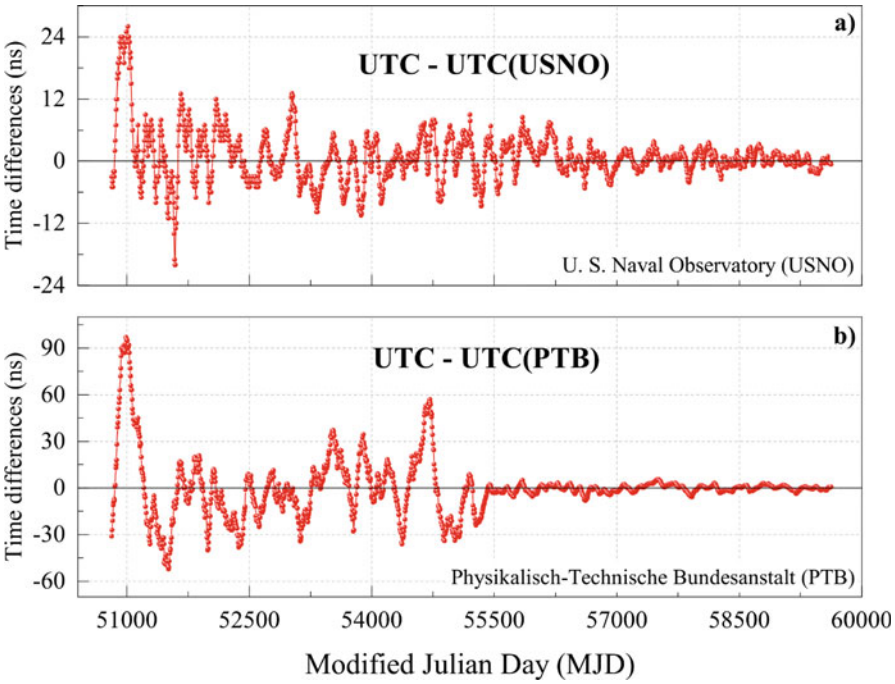

Fig. 3 Time differences between (**a**) UTC and UTC(USNO), (**b**) UTC and UTC(PTB) atomic timescales from 50,800 MJD (December 18, 1997) to 59,699 MJD (April 30, 2022)

realizations UTC(k). Circular T provides one numerical value of the time difference [*UTC-UTC*(k)] for every 5 days and corresponding uncertainties, for about 80 institutes that contribute regularly to the BIPM with their clock comparison data. It includes also other relevant information like time links used for the computation of TAI, calibration information of the time transfer equipment, and the corresponding uncertainties. Figure 4 shows a portion of the first page of the BIPM Circular T 412 (May 2022).

Other Atomic Timescales

The Rapid UTC, UTCr

Because UTC values are published monthly providing one value for every 5 days, UTC is not well adapted for real and almost-real-time applications. With the aim to serve the international community that needs high accuracy time measurements in real and almost-real-time regime, the BIPM produces the rapid UTC, denoted as UTCr (Petit et al. 2013; López-Romero et al. 2019). The UTCr is a preliminary computation of the UTC, with the purpose to know, with several weeks in advance, an estimation of UTC values that will be published in the next Circular T. Values of UTCr published by the BIPM weekly provide daily values of *UTCr-UTC*(k) time differences.

Fig. 4 BIPM Circular T 412 (May 2022) with time difference UTC-UTC(*k*) data from March 31 to April 30, 2022

Terrestrial Time, TT

The Terrestrial Time, denoted as TT, is defined by the International Astronomical Union (IAU) as $\mathrm{TT} = \mathrm{TAI}^{*} + 32.184$ s, where TAI^{*} is a recalculation of the TAI (United States Naval Observatory 1992; Panfilo 2022). TT is defined to be exactly 32.184 seconds offset from TAI at 00:00 of January 1, 1977. Before 1955, TT must be extrapolated backward using ephemeris time (ET), a timescale defined by the motions of solar system bodies (Petit 2003). ET was originally based upon the length of the tropical year 1900. Different realizations of TT are denoted by $\mathrm{TT}_{(xxx)}$, where *xxx* is an identifier of the laboratory/organization in charge of such realization (Matsakis 2007). One of the most important realizations of the TT is that of the BIPM, denoted as TT(BIPM), computed in deferred time, each January. TT(BIPM) is based on a weighted average of evaluations of the frequency of TAI by the primary and secondary frequency standards. It is mostly used in scientific applications requiring long-term frequency stability and high-frequency accuracy. Values of the TT(BIPM) can be found at the BIPM website (BIPM 2021).

Hybrid Atomic Timescales and the Redefinition of the SI Second

Since around 2000 year, secondary representations of the SI units based on optical transitions became with equivalent or better uncertainty that the primary realizations based on the ^{133}Cs atom. Figure 5 shows progress on the fractional frequency uncertainty of optical clocks. Since then, optical clocks have improved their uncertainty by about two orders of magnitude with respect to cesium clocks. Due to this fact, the international time and frequency metrology community, the BIPM, the

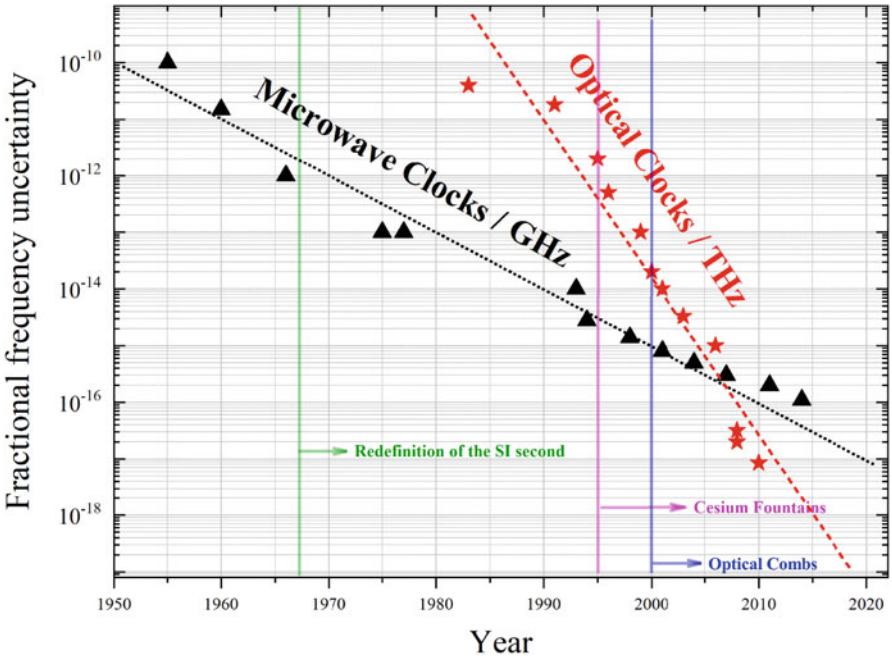

Fig. 5 Progress of microwave and optical clock uncertainties (Margolis 2010; Ludlow et al. 2015; McCarthy and Seidelmann 2018)

CCTCF, and CIPM are preparing the road to adopt a new definition of the SI second based on one, or even several, optical transitions.

One technical requirement to be in place to adopt such a new definition is the one related with capabilities to produce atomic timescales based on an optical transition, or in other words, the capability to produce atomic timescales based on the operation of optical clocks. Currently some research groups are developing the knowledge and technology to produce timescales based on the operation of both types of atomic clocks, radiofrequency (RF) atomic clocks (Cs, Rb, H), and optical atomic clocks (Yb, Sr, Al, Hg, etc.) (Margolis 2010; Ludlow et al. 2015; McCarthy and Seidelmann 2018). A timescale produced by the contribution of RF and optical clocks is called a hybrid atomic timescale, or, simply, hybrid timescale. Methods based on machine learning (ML) algorithms, particularly neural networks, are among the investigations in progress to produce hybrid atomic timescales (Jian et al. 2019).

Technical Requirements for Setting up a UTC(*k*) Laboratory

Figure 6 shows the basic infrastructure for a UTC(*k*) laboratory. Of course, the atomic clocks are the main equipment of the whole laboratory system. It is recommended to operate, at least, three atomic clocks to be redundant producing

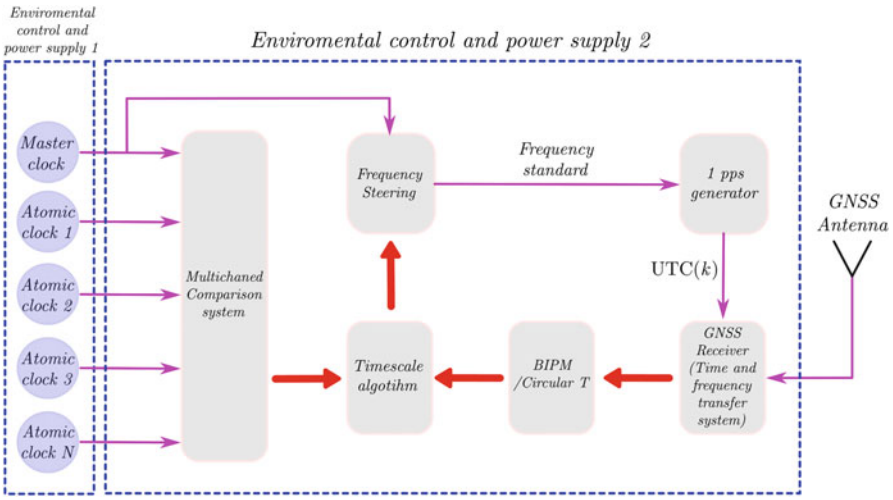

Fig. 6 Basic infrastructure for a timekeeping laboratory/UTC(k)

atomic seconds but also to be capable to determine, at any time, if a particular clock has or not an adequate metrological behavior. If a unique clock is in operation, then it is not possible to know if that clock is working properly. If two clocks are in operation, and time differences or frequency differences exhibit an anomaly, there is no way to determine which clock is not working properly. With at least three clocks in operation, it is possible to determine which clock is misbehaving (if there is any anomalous condition). Also, an ensemble with a least three atomic clocks allows a better clock performance characterization, among other reasons, because it is possible to use the three-cornered hat method to estimate the absolute, not relative, frequency stability of any clock of the ensemble (Gioia et al. 2019; Parker et al. 2022).

Additionally, it is necessary to have a comparison system to measure continuously time or frequency differences between atomic clocks. Ideally, it is necessary to compare any clock with the rest of the ensemble; however, this technique requires a robust and powerful comparison system. For instance, if N atomic clocks are in operation, then, the number of channels needed to support these comparisons is $N^2(N-1)$. This number increases rapidly as N^3 when N increases. However, an affordable way to compare the N atomic clocks is comparing a "master clock" with the rest of clocks of the ensemble. Let say that $x_{0,i}(t) = T_i(t) - T_0(t)$ is the time difference between the master clock 0 and the i^{th}-clock at time t. Here, $T_i(t)$ and $T_0(t)$ represent the reading of clock i^{th} and master clock at time t, respectively. Now, suppose you are interested to find $x_{(k,j)}(t)$, the time difference between an arbitrary pair of clocks j^{th} and $k^{\text{th}}x_{(k,j)}(t)$ at any time t, then you can find it by using the relation $x_{(k,j)}(t) = x_{(0,j)}(t) - x_{(0,k)}(t)$. Using this strategy to compare N atomic clocks, a comparison system with *N-1* channels and a well-selected "pivot clock" (here named also as a master clock) is enough. Actually, this comparison philosophy is

used by the BIPM to produce the UTC with the participation of around a hundred timekeeping laboratories. In the case of the BIPM, the PTB (*Physiskalish-Technische Bundesanstalt*) is selected as the "pivot laboratory."

The most efficient use of an ensemble of N atomic clocks is through a timescale algorithm, so that a system containing such algorithm feed by the measurements data is required to steer the frequency output of the master clock. The frequency steered will be the frequency standard of the laboratory. This timescale algorithm must also consider the information on the Circular T of the BIPM to maintain the frequency standard of the laboratory as close as possible to the definition of the SI second. Now, the UTC(k) is defined by a pulse per second (PPS) electrical signal, which is typically a square pulse with a rise time of around 1 ns a duration of around 1 μ s and an amplitude of about 5 V (Fig. 7). Therefore, a 1 PPS generator is also needed as part of the fundamental infrastructure of a timekeeping laboratory.

Finally, the 1 PPS signal that defines the UTC(k) must be compared to the UTC. To do that, a time and frequency transfer system is required. Typically, a global navigation satellite system (GNSS) receiver is used. The GNSS receiver measures the phase difference between the local 1 PPS signal and the 1 PPS signal of a GNSS constellation (GPS or GLONASS). That information is used along with a technique named common view (Allan and Weiss 1980; DangLi et al. 2011) to determine the time difference between the UTC(k) timescale and the UTC(k') produced by another timekeeping laboratory k'. The UTC(k)-UTC(k') time differences are used by the BIPM to produce, first, the free atomic timescale (EAL) and then with the participation of primary frequency standards produce the International Atomic Timescale (TAI), and, finally, with information from the International Earth Rotation and Reference Systems Service (IERSS), the BIPM produces the UTC. Information published by the BIPM about the time differences UTC-UTC(k), available in a monthly fashion on the Circular T document (BIPM Circular T 2022), must be used by a k laboratory to keep the UTC(k) as close as possible to the UTC. In other

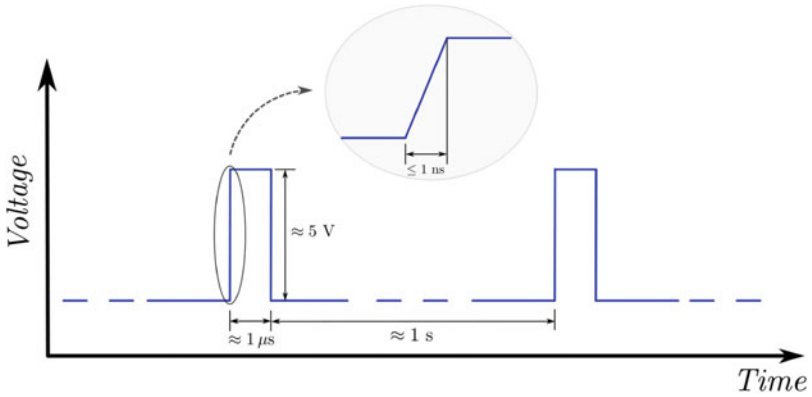

Fig. 7 A typical 1 PPS signal used to define the UTC(k) timescale.

words, the UTC(k) timescales are the prediction a month ahead, and physical realization as well, of the UTC.

The Most Used Atomic Clocks in UTC(k) Laboratories

There are several types of commercial atomic clocks which are used by UTC(k) laboratories, designated institutes (DIs), or NMIs worldwide to generate an AT and create an official and/or reference time with superior metrological performance for different purposes.

Every atomic clock, independent of the atomic specie, has, in general, a quartz oscillator which is the flywheel that can be adjusted using information of atomic transitions like rubidium (Rb), cesium (Cs), or hydrogen (H) atoms. Also, an option of a rubidium or quartz oscillator adjusted using GNSS is commercially available. The type of oscillator used depends on the metrological requirements of a particular application. Specifically for UTC(k) labs, the BIPM reports the number of clocks participating in the UTC calculation since 2004. There are two kinds of clocks reported, hydrogen masers and cesium clocks (data are presented in Fig. 8), which general aspects are presented below.

Cesium Beam Atomic Clock

It is the most used atomic clock worldwide by UTC(k) laboratories, telecommunications companies, and different sectors which require a very precise and reliable

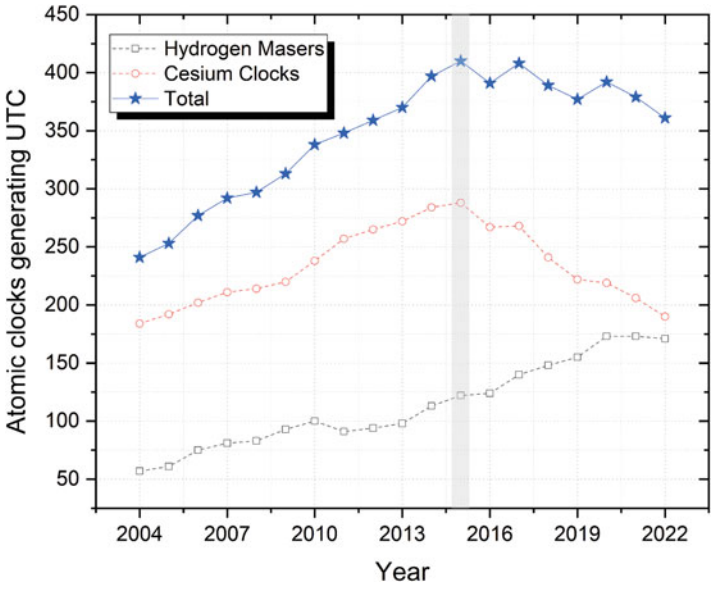

Fig. 8 Number of atomic clocks (hydrogen masers and cesium) generating UTC, reported by BIPM since 2004

source of time. The market prices are round some tens of thousands of US dollars. Cesium atomic clock uses the intrinsic properties of the cesium atom to operate, particularly, the alignment of the nuclear and electron spins. The minimum energy state of this system corresponds to both spins pointing in opposite directions. The required energy to align the spins is 38 μeV which according to Planck's equation corresponds to a frequency of 9,192,631,770 Hz.

In this kind of clock (Fig. 9), cesium is evaporated at the atomic source to create a thermal beam of atoms which travel at less than 300 ms^{-1}, through a low-pressure chamber. First, atoms in the minimum energy state are selected using a magnetic selector. Then, selected atoms pass twice through a very precisely controlled microwave field in a very uniform magnetic field, tuned to the resonance frequency which produces that cesium atoms evolve to a higher energy level. The cavity is isolated from external magnetic fields using a magnetic shield to avoid perturbations from external magnetic fields. Then, a second magnetic selector deviates the atoms which did not complete the transition to be absorbed by a carbon getter and deflects toward a detector those which evolves to the excited state. Using this information, the quartz oscillator is adjusted automatically by a servo control to maximize the number of cesium atoms detected, keeping the microwaves tuned to the correct frequency. After the small remaining biases are determined and eliminated, the short-term stability (observation time of 1 second) is less than 1×10^{-11} and reach the noise base at 1×10^{-14}.

Hydrogen Maser

It is the most precise, elaborate, and expensive frequency standard commercially available. The market prices are round some hundreds of thousands of US dollars.

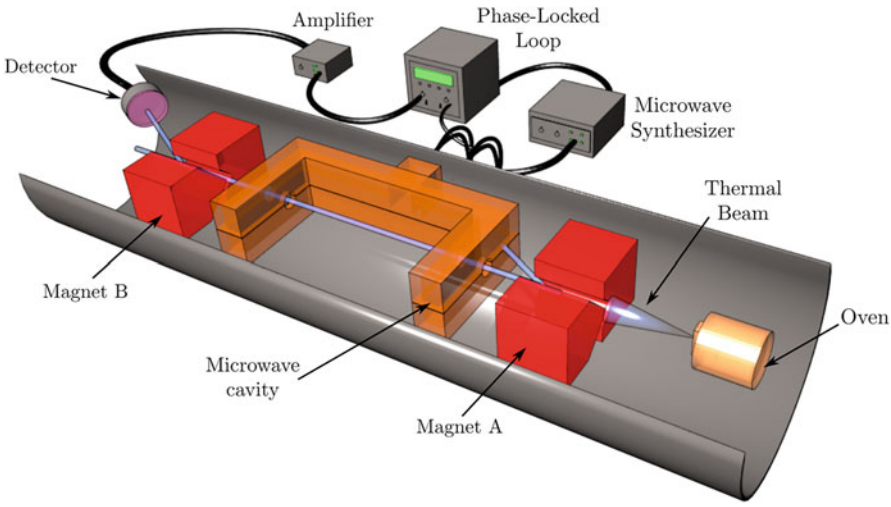

Fig. 9 Schematical diagram of a cesium-beam frequency standard using magnetic state selection and detection

The word maser means microwave amplification by stimulated emission of radiation (Townes 1965; Kekez 2018). The maser effect was the antecessor of the laser effect (Schawlow and Townes 1958; Kronenberg and Traxer 2019) in which the photon frequency is higher. In a maser, microwave photons are "copied" using a seed photon as reference to obtain an adequate signal for practical applications.

A hydrogen maser uses the intrinsic properties of the hydrogen atom to operate. Particularly, the alignment of the proton and electron spins. The minimum energy state of this system corresponds to both particle spins pointing in opposite directions. The required energy to align the spins is 5.87 μeV which according to Planck's equation corresponds to a frequency of 1,420,405,751.786 Hz.

In this artifact (Fig. 10), a controlled amount of molecular hydrogen gas, H_2, is fed into a discharge lamp to dissociate the molecules using an electric arc. Then, hydrogen atoms pass through a collimator and state selection magnets to be stored in a quartz cavity covered with polytetrafluoroethylene (PTFE) to reduce perturbations, chemical interactions, and absorption. This cavity is inside another microwave cylindrical resonant cavity made of precisely machined copper or ceramic covered with silver, tuned to the atom's resonant frequency to align the spins of the electron and the proton (1.420 GHz). Eventually some atoms decay emitting microwave photons which stimulate other photons to drop to a lower energy

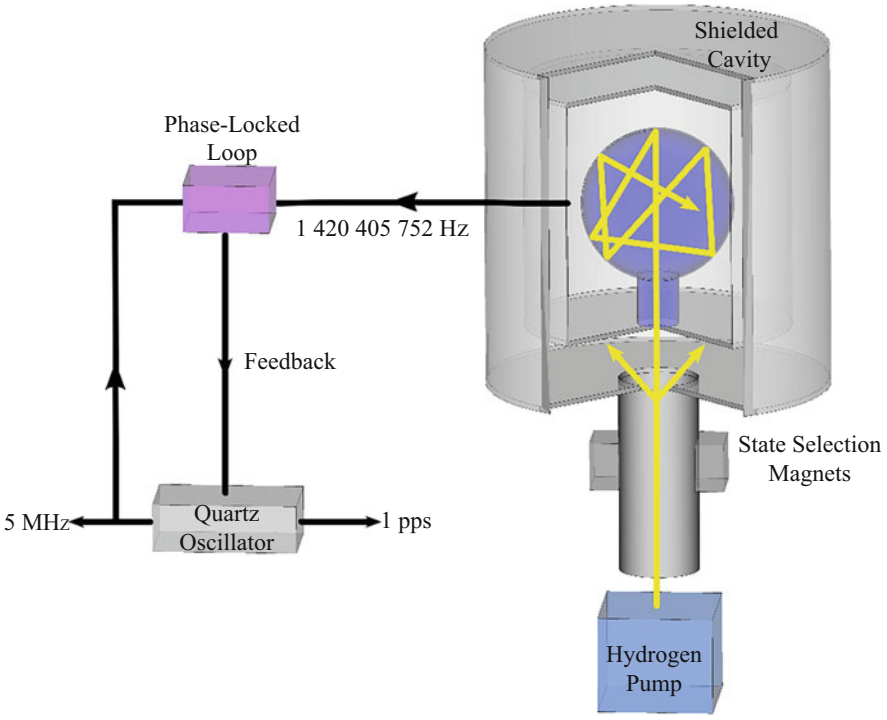

Fig. 10 Schematical diagram of a hydrogen maser frequency standard

level and, therefore, emit additional photons, and it creates a self-sustained microwave field. The cylindrical cavity redirects photons back to the system to maintain oscillations. Also, an axial low-intensity magnetic field is applied to break the degeneracy of the magnetic sublevels (Zeeman sublevels). Additionally, the cavity is surrounded by magnetic shields to minimize perturbations produced by external magnetic fields. Finally, a high-spectral purity signal tuned to the hydrogen resonance is produced, and it is continuously emitted as new atoms are fed into the system. This signal is used as reference to adjust the frequency of a quartz oscillator.

The hydrogen resonance frequency is lower than that of cesium (9,192,631,770 Hz); however, the width of the hydrogen resonance is around some Hz. Therefore, the quality factor, Q, is about 10^9, or at least an order of magnitude better than a commercial high-performance cesium clock. The short-term stability (observation time of 1 second) is less than 1×10^{-12} and reaches the noise base at 1×10^{-15}. Due to the quadratic variation of the resonance frequency as time function, the long-term stability is worse in comparison with cesium atomic clocks. However, the most recent models include the cavity tuning feature to compensate the frequency drift and achieve better long-term instabilities than cesium beam clocks.

There are two kinds of hydrogen masers: actives and passives. In the former case, the microwave cavity is the oscillator itself which requires a high atomic density and a high Q (Bai et al. 2018; Tiezhong et al. 2020). Meanwhile, in a passive hydrogen maser, the cavity is fed by an external frequency reference, and it is tuned to maximize the cavity response. The active hydrogen masers are typically four times more stable than the passive ones and one hundred times more stable than high-performance cesium beam clocks.

Traceability to the SI Second

Participation of primary frequency standards on the process to steer the free atomic timescale (EAL) implies that the fundamental time interval of the UTC timescale is a realization of the definition of the SI second (Panfilo and Arias 2019), so that the UTC provides traceability to the unit of time. It is important to noticed that, because UTC is a virtual timescale (no physical signal exists to define UTC), practical access to UTC is through the UTC(k) timescales. UTC(k) is the physical realization of the UTC established by laboratory k. Time dependence of the UTC-UTC(k) differences gives information about the frequency difference between those two timescales. In other words, Circular T contains information about traceability of UTC(k) to UTC, so that a calibration process of an oscillator with respect to the UTC(k) timescale can be taken as part of a chain of comparisons with respect to the international realization of the SI second. An adequate estimation of uncertainties on the calibration process of a local oscillator with respect to the UTC(k), along with the information published on the Circular T, establishes the traceability to the SI second.

Conclusions

Time measurements are strategic in contemporary economy. Different systems for critical applications, like telecommunications, power distribution, global navigation, deep-space vehicle navigation, defense, precise astronomical observations, and stock markets, among others, strongly depend on atomic clocks and AT. The AT results from a coherent accumulation of seconds. Therefore, it is important to understand well this topic and ensure that time requirements are attended. UTC and UTC(k) AT can provide traceability to the SI second. The next generation of AT will provide traceability to the upcoming definition of the SI second, which will be in terms of an optical atomic transition (Gill 2016; Bize 2019). The SI second, the AT, and time measurements are the SI core and the basis of ultra-high accurate measurements.

Abstract

From tracking the movement of celestial bodies to mechanical clocks and now prevalent atomic clocks, timekeeping has been one of the greatest quests for finding stable and better oscillators. Measurement of transition frequency between two designated levels of an atom forms the basis of atomic clocks. Time is derived from the measurement of frequency and that is the reason that atomic clocks are more appropriately called atomic frequency standards. Since the realization of first atomic frequency standard based on cesium in 1955, the field of precision time and frequency metrology has been revolutionized. Along with the evolution of timekeeping, a detailed description of various types of atomic frequency standards, applications, and the roadmap toward redefinition of SI second is presented in this chapter.

Introduction

Four coordinates that are required to precisely define when and where something takes place consist of three spatial ones and one temporal one, i.e., time. Time may or may not be fundamental and often is illusive for researchers. Even Einstein said that time is relative for each and every observer and there is nothing like "absolute time." But time is real and it does exist as we are able to observe measure and quantify its passage. Measuring time has been a fundamental quest for humans and various ways have been developed over centuries for tracking it. The quest for precision in timekeeping has made it possible to measure time with nanosecond accuracy routinely. The modern technology of atomic clocks has been a game changer in pushing the frontiers of precision timekeeping. This chapter begins with section "Brief History and Evolution of Clocks" on brief history of timekeeping and evolution of clocks. The classification of atomic frequency standards is described in section "Classes of Atomic Frequency Standards" along with description, principle of operation, and other significant details on each type of atomic frequency standards. Some of the major applications which critically depend on atomic clocks are discussed in section "Applications."

Brief History and Evolution of Clocks

Evolution of time tracking technologies is related to the human evolution. In the early ages, people needed to measure just years and months. This led to track the time based on a calendar to define interval of time. Tracking the position of sun in the sky was good enough to have a perception of time, and further precise measurement of time was simply not needed then. Egyptians invented sundials in 1500 BC which divide day into smaller parts based on duodecimal system. The time was decided on the basis of lunar cycles (12 or 13 lunar months) in a year and numbers of stars were used to count the passage of night. However, the Babylonians created sexagesimal system for their mathematics and astronomy which was based on Sumerians counting (counting in 60s). In the year 46, Julian calendar was formed by Julius Caesar during Roman Empire and was further modified by Pope Gregory XIII in 1582 which was adopted worldwide.

For tracking the passage of time, various other methods were adopted as sundials had limited use depending on the presence of sun. Water clocks, candle clocks, hour glass, etc. were used before the mechanical clocks were invented as reliable means of timekeeping. With the rise in industrialization, the need was felt to have timekeeping device which could measure passage of time in seconds, based on physical mechanism. In the year 1656, a Dutch scientist, Christiaan Huygens, developed first

pendulum clock-based period of oscillation. The clock developed had shown error less than 1 minute in 1 day. Further Huygens in 1675 developed clock having balance wheel and spring assembly, which was able to achieve time with even better accuracy. In 1761, John Harrison from England developed clock based on chronometer which could be used to calculate longitude while at sea and was able to measure time with one fifth of a second a day accuracy. By then, it was realized that every clock works on some version of pendulum (or oscillator). The progress of evolutions of clocks has been presented in Table 1. Mechanical clocks worked well but the gears and springs wore down with time, thus limiting the time accuracy gradually. For details of timekeeping, evolution of clocks and basics of time and frequency standards, readers are referred to books (Vanier and Audoin 1989; Riehle 2004; Major 1998; Jespersen and Fitz-Randolph 1999; Sullivan et al. 1990).

Another breakthrough in timekeeping was the discovery of quartz crystal. It was now possible to develop a clock based on oscillations produced in crystalline quartz on applying electric field (due to piezoelectric effect). However, quartz crystal exhibits disadvantages as resonance frequency depends on thickness of the resonator and also quartz oscillation frequency alters with temperature and humidity variations.

Advances in science, technology, and many industrial processes and machines required to have further precise measurements of time. Most of the modern digital

Table 1 Progress of clocks

Standard	Oscillator	Counter	Date of origin	Time uncertainty (24 hrs)	Frequency uncertainty (24 hrs)
Obelisk	Rotating earth	Sundial	3500 BC	N.A.	N.A.
Verge escapement	Verge and crown wheel	Foliot	Fourteenth century	15 min	1×10^{-2}
Pendulum	Pendulum swing	Gears and hands	1656	10 s	7×10^{-4}

technologies require clocks that run faster than the processes and machines in order to control and manipulate them for their proper usage. These technologies require time to be measures in milliseconds, microseconds, and even nanoseconds with astounding accuracy. Quartz-based oscillators continued to serve as laboratory frequency standards, but at the same time, quest began for a universal time standard whose pendulum (or oscillator) will never wear down.

As predicted by James Clerk Maxwell (Maxwell 1870), each atom was found to be a perfect oscillator for measuring the time. The transition frequency between the designated states of atoms formed the basis of atomic clocks. Since frequency is inverse of time, an accurate measurement of frequency in atoms transcribes into precise measurement of time. Due to this reason, atomic clocks are better known as atomic frequency standards. First experiments in this direction led to the measurement of microwave transition frequencies in ammonia molecules. Cesium atom was later on found to be better and preferred for measuring time. The first working cesium clock was built in 1955 by Essen and Perry at NPL UK (Essen and Parry 1955). Finally, at the 13th General Conference on Weights and Measures (CGPM) held in 1967, second of atomic time in SI unit was defined as "the duration of 9,192,631,770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom." Since then, research in this area has led to astonishing improvements in timekeeping accuracies. Today, atomic clocks operate at different frequencies including optical frequencies. Cesium fountain clocks remain the most accurate primary standards, but the optical clocks have been demonstrating increasingly competitive performance than their microwave counterparts. Based on the consistent measurement of fractional uncertainties lower than their microwave counterparts, one can expect that optical clocks will replace the cesium hyperfine transition in the definition of the second in the International System of Units. Gearing up for a possible redefinition of the SI second on the basis of one of the many candidates being investigated, the International Committee of Weights and Measures (CIPM) has approved a few candidates as "secondary representations" of the second.

Classes of Atomic Frequency Standards

Standards are often classified as primary and secondary. A primary standard is a device that is used to directly realize the SI unit with highest precision. In the case of atomic frequency standards, a primary frequency standard is the one that realizes the definition of the SI second based on the ground-state hyperfine transition in the cesium 133 atom. Moreover, all the sources of frequency shift in a primary frequency standard can be identified and determined quantitatively as well as reproducibly. As the cesium fountain clocks provide the best realizations of SI second with respect to accuracy and frequency instability, they are the primary frequency standards. A

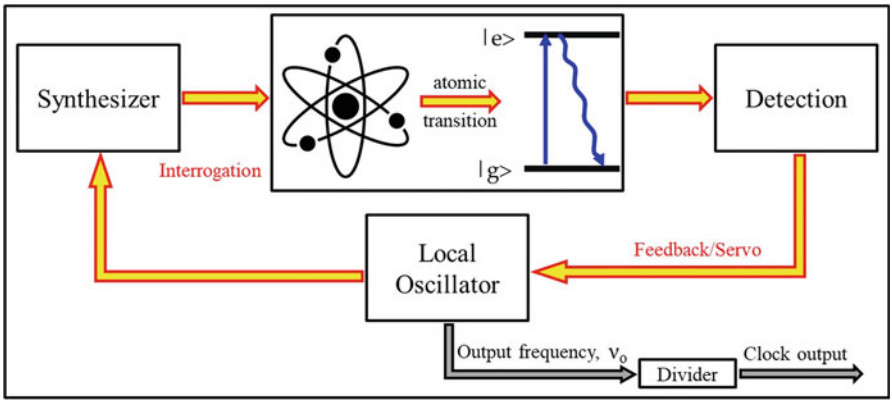

Fig. 1 Block diagram of an atomic frequency standard

secondary frequency standard realizes secondary representation of SI second based on an approved list of secondary representations. In standards, such as Rb clock or H maser, there are sources of frequency shifts that cannot be quantified. Thus, these categories of atomic standards are known as secondary frequency standards.

In any atomic frequency standard, one needs a mechanism to probe the transition frequency between the designated levels of the atomic species. In most of the cases, a local oscillator (LO) is used as reference to lock its frequency onto the atomic transition as shown in Fig. 1.

At present, there are two broad classes of AFSs: microwave frequency standards and optical frequency standards. In a microwave frequency standard, the atomic transition frequency to be probed lies in the microwave region of the electromagnetic spectrum and therefore, the LO is generally a quartz crystal oscillator. In an optical frequency standard, the atomic transition frequency lies in the optical region and therefore, the LO is a laser system.

The quartz oscillator typically has a 5 MHz frequency output. A microwave synthesizer takes this 5 MHz as reference and produces the appropriate microwave frequency for interrogating the atomic transition. An error signal is generated based on the difference between the synthesized microwave frequency and the atomic transition frequency. Based on this error signal, a feedback servo loop generates a control voltage to tweak the LO until the microwaves are tuned to the atomic transition frequency. The same concept is used in the optical frequency standards with a difference that the LO is generally a laser and an optical frequency comb is used as the counting mechanism which converts the output signal from the optical domain into the RF domain. Atomic frequency standards have been reviewed in several articles (Lewis 1991; Hellwig 1975; Beehler 1967; Ramsey and Res 1983; Bauch and Telle 2002; Audoin et al. 1976; McCoubrey 1967; Levine 1999; Schmittberger and Scherer 2021).

Microwave Frequency Standards

Microwave frequency standards are mostly based on alkali atoms (in particular H, Rb, and Cs). These atoms have a single valence electron, relatively simple energy spectrum, and long-lived ground states, thus resulting in slow relaxation. Hyperfine levels of these ground states, differing in relative orientation of the nuclear and electron magnetic moments, have narrow transition linewidths centered at frequencies in the range of 1–10 GHz.

Four types of microwave frequency standards are being widely used. Cesium fountain clocks, the most accurate atomic clocks at present (based on present definition of SI second), are the laboratory standards. There are about 15 of such primary frequency standards which have been indigenously built in only ten countries so far. Cs beam clocks are the workhorses, contributing to more than two-thirds of atomic clocks being used for timekeeping the world over. Hydrogen masers, with excellent short-term stability (active masers), are widely used in timekeeping laboratories worldwide. Low-performance, lightweight vapor cell atomic clocks based on rubidium atoms confined in a cell with a buffer gas are used for satellites, low-accuracy timekeeping in telecommunications, military, etc. and as a time base for many test and measurement devices. Apart from these four variants, chip-scale atomic clocks have also been developed, and a lot of work is going on to improve the performance and to reduce the power requirements of portable microwave frequency standards.

Microwave frequency standards are further classified into active and passive devices based on the interrogation method of the atomic transition. In an active device, the atoms are confined to a storage volume which is enclosed by a very high Q microwave cavity, tuned exactly to the transition frequency. Initially, a small thermal noise at the resonance frequency present in the cavity is able to amplify itself by inducing transitions in the confined atoms. Low loss cavity allows high-intensity atomic vapor to interact with microwaves in a way to generate self-sustained oscillations. A small amount of this energy is tapped out as a usable signal, which is then used to phase lock a quartz oscillator at 5 MHz. Active hydrogen masers fall in this category.

In a passive device, on the other hand, the atoms are allowed to interact with a microwave signal, externally synthesized from a quartz oscillator at 5 MHz. If the synthesized signal frequency matches the atomic transition frequency, many atoms make transition to the other state. The number of atoms detected after state-change is recorded, and a frequency control servo adjusts the quartz oscillator frequency so as to maximize the detected signal. Under this condition, the accuracy and stability of the atomic standard are transferred to the quartz oscillator. Cs clocks, Rb clocks, and passive hydrogen masers fall in this category.

Cesium Beam Frequency Standards

From the first cesium atomic clock to almost all commercially available Cs clocks are beam frequency standards (Bauch 2005). In these, hot Cs atoms leave the oven in

the form of an atomic beam that travels through a vacuum tube toward a pair of state-selection magnets which produces a strong magnetic field gradient resulting into two physically separated beams of the Cs atoms (one with atoms in the F = 4 and another in F = 3 state; F is the quantum number corresponding to the hyperfine levels). One of the state-selected beams of Cs atoms interacts with microwaves in a microwave cavity that is excited with a 9.192 GHz synthesized from a quartz oscillator. When the microwave frequency matches that of the Cs hyperfine transition frequency, many atoms are excited to the other hyperfine level. After passing through the interaction region, the Cs beam passes through another pair of magnets (similar to state-selection magnets) which physically separates the atoms in two different states. The magnets are followed by a hot wire ionizer detector in such a position as to detect the atoms that have made transitions during interaction (Fig. 2). Those atoms which did not change their state during microwave interaction are deflected away from the detector. The detector drives a servo feedback loop that continually tunes the frequency of the quartz oscillator till the detector output is maximized. This way, the quartz oscillator is kept locked to the Cs hyperfine line and produces the usable output frequency of the standard, usually at 5 MHz. This frequency is further divided to generate standard 1 PPS (pulse per second) signal to drive the clock output. As a matter of detail, the geometry of the microwave cavity used is U-shaped, also known as the "Ramsey cavity," named after Sir Norman Ramsey who discovered the novel interaction method of separated oscillatory fields (Ramsey 1949; Markowitz et al.

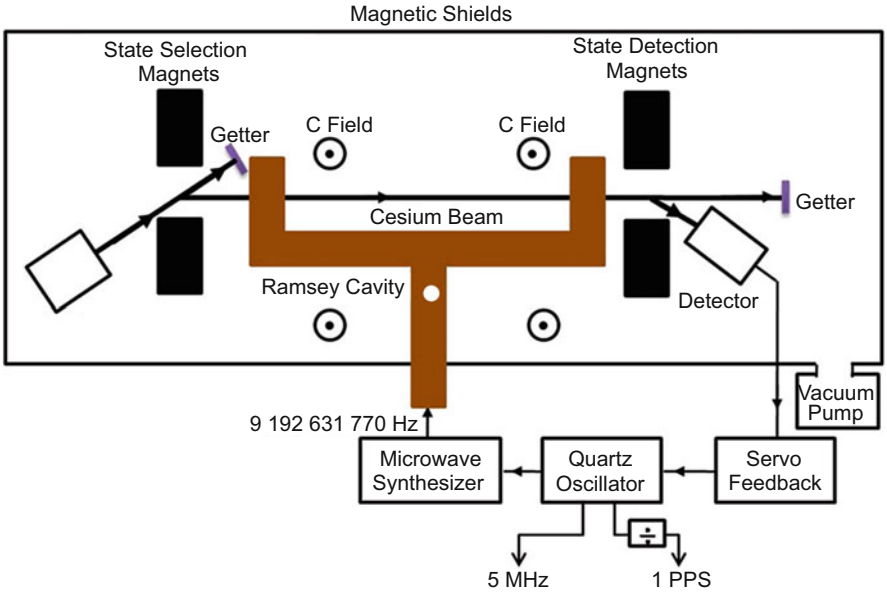

Fig. 2 Diagram of a cesium beam frequency standard using magnetic state selection and detection. The form of Ramsey interrogation involves a U-shaped microwave cavity, called a Ramsey cavity, where the oscillatory fields are spatially separated

1958). Cs beam interacts with the same phase of the microwave excitation in the two spatially separated regions. This results in an interference effect (in temporal domain) that produces a narrower atomic resonance linewidth than would occur if the atoms had interacted with the microwaves for the entire time. A uniform small magnetic field, known as the "C-Field," is produced over the whole interaction zone by a solenoid to define the quantization direction and to lift the degeneracy of the hyperfine levels. In order to avoid any perturbation from external magnetic fields, the whole interaction region is covered with layers of magnetic shields. There are few systematic effects which cause the frequency shifts in the Cs standard, but these can be evaluated quantitatively (within small measurement uncertainties). Typical values for stability of commercial Cs clocks are about few parts in 10^{12} for 1 s averaging time. The length of the Ramsey cavity is typically less than half a meter, thus limiting the interaction time of hot Cs atoms with microwaves to a few milliseconds, and the transition linewidth to a few hundred hertz. Since the instability of an atomic clock is directly proportional to the linewidth of atomic transition, laboratory models of Cs beam clocks have been developed with Ramsey cavity lengths of 1 m or more (to increase the interaction time). Recently, in some models of Cs clocks, optical pumping technique (using a carefully tuned and stabilized laser) has been used for state selection of atoms rather than magnetic field gradient. Optically pumped Cs clocks are more accurate with larger number of state-selected atoms leading to better signal-to-noise ratio and significant reduction in the frequency shifts caused by inhomogeneous magnetic fields due to the absence of strong state-selection magnets (Makdissi and de Clercq 2001; Shirley et al. 2001; Hasegawa et al. 2004).

Cesium Fountain Frequency Standards

As discussed in the previous section, the primary limitation of the frequency stability of a Cs beam clocks arises due to the transition linewidth caused by the short interrogation time. This time is essentially the interaction time of the Cs atoms as they pass through the Ramsey cavity. Laboratory models with longer cavities were built to increase the interaction time but these could not be translated into sustainable commercialization. Another way to increase the interrogation time by choosing slower atoms at room temperature did not work as the slow atomic beam is relatively weak and slowly sags down along its horizontal movement due to gravity. These limitations were practically overcome in two ways. Firstly, with implementation of laser cooling (Chu 1992; Cohen-Tannoudji 1998; Phillips 1998), the atoms are cooled down to a few micro Kelvin temperatures, thereby reducing the atomic velocities to few cm/s. Secondly, the problem of sagging of a horizontal atomic beam due to gravity is taken care of by using a vertically moving atomic beam. The basic idea of Cs fountain was proposed for the first time in the 1950s by J. Zacharias (Zacharias 1954); however, the first successful practical realization of the fountain principle with laser-cooled Cs atoms was done at BNM-SYRTE (presently LNE-SYRTE) at Observatoire de Paris in the year 1991 (Clairon et al. 1991). For laser cooling of Cs atoms, the system typically comprises a set of six mutually orthogonal counter-propagating beams of a laser whose frequency is tuned slightly to the red of a strong transition of the Cs atoms at 852 nm. The atoms, moving in the

direction opposite to a laser beam, see the laser frequency upshifted and closer to the resonance due to the Doppler effect. Hence, the absorption and reradiation rate of photons is higher than for the case atoms that are moving along the direction of the laser beam. At the intersection of the six orthogonal counter-propagating laser beams, no matter which way an atom moves, it encounters a laser beam opposing it. Due to the momentum exchange with photons, the atoms keep losing their energy and thus slow down rapidly. This mechanism is known as Doppler cooling and system is often termed an optical molasses.

A Cs fountain works on the same basic principle as a Cs beam frequency standard discussed in the previous section. Schematic of a typical Cs fountain is illustrated in Fig. 3. The difference primarily is that here the Cs beam consists of a bunch of laser-cooled atoms, which are launched vertically upward with a velocity of few m/sby slightly offsetting the frequencies of the two vertical lasers and then turning all six lasers off and which, after attaining a height of a few tens of cm, fall back downward due to gravity. Just after launching, the atoms in the bunch are subjected to a process of state selection, so that the upgoing atoms are mainly in one of the two ground-level hyperfine states. During flight, the atoms pass through a microwave cavity twice – on their way up and down. The microwave cavity is excited with the hyperfine frequency of 9.192 GHz, synthesized from a quartz oscillator. On their way down, atoms are detected using laser-induced fluorescence. The fluorescence intensity is directly proportional to the number of atoms and thus transition probability is estimated. As the microwave interrogation frequency is slowly tuned about the nominal value, the transition probability goes through successive maxima and minima exhibiting the typical Ramsey pattern. The top of the central fringe in the Ramsey pattern signifies the maximum transition probability and corresponds to the microwave frequency that alters the states of most of the cesium atoms and maximizes their fluorescence. This frequency is the natural resonance frequency of the cesium atom (9,192,631,770 Hz), or the frequency used to define the second. Due to the vertically moving slow atomic beam, the total interaction time (from upward till downward transit of atoms through the Ramsey cavity) is fairly long. Typically, it is possible to have a very narrow central Ramsey linewidth of the order of 1 Hz or even smaller – almost two orders of magnitude smaller than in the conventional Cs beam device. This implies frequency instability of a typical fountain approaches 10^{-15}(may approach 10^{-16} for few best ones) at 1-day averaging time. Since the development of first fountain at BNM-SYRTE (France), similar clocks have been developed in national metrology institutes (NMIs) in only 11 countries around the world. The countries which developed Cs fountain clocks which were approved as primary frequency standards (PFSs) and contribute/contributed data for the calibration of International Atomic Time (TAI) are France, Germany, the USA, the UK, Japan, Italy, India, Russia, China, Switzerland, and Canada (Clairon et al. 1995; Gerginov et al. 2010; Guéna et al. 2012; Jefferts et al. 2002; Szymaniec et al. 2005; Kurosu et al. 2004; Kumagai et al. 2008; Domnin et al. 2013; Heavner et al. 2014; Levi et al. 2014; Acharya et al. 2017; Fang et al. 2015; Jallageas et al. 2018; Weyers et al. 2018; Beattie et al. 2020). Some of the fountains are running almost continuously, and typically reports from about six to eight fountains are being generated

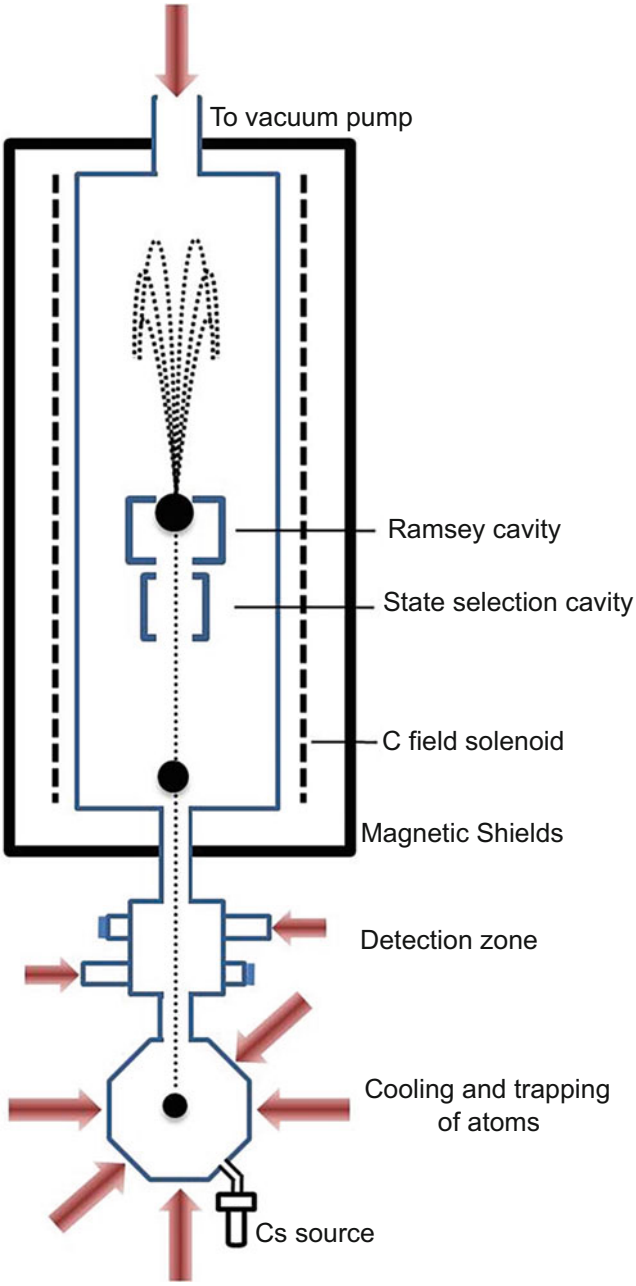

Fig. 3 Schematic of a Cs fountain

monthly data to calibrate TAI. Laboratories like PTB (Germany), LNE-SYRTE (France), USNO (USA), and INRIM (Italy) are steering their timescales with fountain data, thus greatly improving stability and performance of their timescales (Bauch et al. 2012; Peil et al. 2014; Rovera et al. 2016). Even with a possible redefinition of SI second on the basis of an optical clock, Cs fountains will continue to play a significant role in T&F metrology just the way Cs beam clocks still continue to be the field workhorses for precision timekeeping. Even today, some of the laboratories like NPL (India), KRISS (Korea), and NMIJ (Japan) are developing new Cs fountain frequency standards (Bharath et al. 2019; Heo et al. 2017; Takamizawa et al. 2022).

Rubidium Frequency Standards

Just like cesium, rubidium atoms also have a ground-state hyperfine transition in the microwave domain which is widely used for making atomic clocks for field deployment (Happer 1972; Camparo et al. 2005; Vanier and Mandache 2007; Kitching et al. 2001). The clock transition $F = 1$, $m_F = 0$ to $F = 2$, $m_F = 0$ in the $^2S_{1/2}$ ground state of ^{87}Rb with corresponding frequency of 6,834,682,608 Hz is also recommended as a secondary representation of second (SRS). LNE-SYRTE (France) and USNO (USA) have developed and regularly operate Rb fountains with the former contributing the Rb fountain data regularly for the calibration of TAI as a SRS. However, most commercial versions of Rb frequency standards are based on vapor cell or glass cell filled with low-pressure ^{87}Rb vapor with a buffer gas (neon, helium, argon, etc.). Optical pumping is used for state selection of atoms which then interact with microwaves and are detected optically using a photodiode. Initially, the two states of the clock transition are equally populated in thermal equilibrium. Atoms are then optically pumped into the $F = 2$ state typically by using a discharge lamp containing ^{87}Rb after passing its light through an absorption/filter cell containing ^{85}Rb. The lamp light can induce optical frequency transitions from both the $F = 1$ and $F = 2$ states to higher excited levels. Natural rubidium consists of a mixture of two isotopes, ^{85}Rb and ^{87}Rb, with an overlap in their atomic energy levels. Due to this reason, the lamp light component which could induce transitions from the $F = 2$ state is absorbed by the^{85}Rb filter cell, thus letting the transmitted lamp light with the component which can excite only the $F = 1$ state of the clock transition. Atoms in $F = 1$ state get optically excited and then decay into either one of the ground states, while those in $F = 2$ state cannot be excited by the filtered lamp light anymore. $F = 2$ state becomes a "dark state" and after a few absorption-emission cycles, almost all ^{87}Rb atoms are optically pumped into the $F = 2$ state, and the absorption cell becomes transparent to the filtered light, whose power is monitored with a photodetector. A resonant microwave signal at 6.834 GHz, derived from a quartz oscillator, is then applied to induce transitions from $F = 2$ to $F = 1$. This restores some population to the light-absorbing state with more atoms in the absorption cell to absorb the filtered light, thus resulting in less light arriving at the photodetector. A servo loop adjusts the microwave frequency such that the detector signal is minimized. The quartz oscillator is thus kept on atomic resonance frequency and provides a usable output of the Rb frequency standard (Fig. 4).

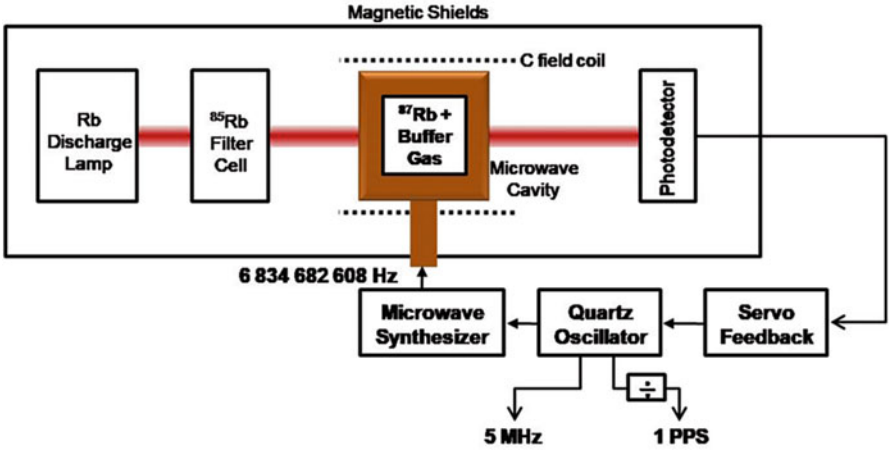

Fig. 4 Block diagram of Rb vapor cell clock

Typical Q-value of Rb oscillators is several 10^7 and typical stability is in the range of 1×10^{-11} at 1 s. Atomic collisions as well as the simultaneous action of the light and the microwave signals on the same atom cause frequency shifts which depend strongly on the composition, temperature, and pressure of the buffer gas and on the intensity of the light. Just like quartz oscillators, Rb frequency standards need frequent calibration to compensate for the frequency drift and aging.

In attempt toward miniaturization and reduction in power consumption, microwave excitation was replaced with all-optical excitation using lasers. Chip-scale atomic clocks are based on MEMS micro fabrication, laser pumping, and the phenomenon of coherent population trapping (CPT) (Arimondo 1996; Knappe et al. 2004; Wynands and Nagel 1999; Vanier 2005). CPT can be understood with a three-level quantum system. When the two hyperfine ground states are simultaneously resonantly excited by two coherent lasers, atoms are pumped into a so-called dark state, and there is an increase in optical transmission through the vapor cell. The interaction of the two fields creates coherence in the ground states by CPT. Practically, instead of using two phase-locked lasers, a single laser source is used with its current modulated at exactly half the hyperfine frequency, thus generating two phase-coherent side bands. Fast modulation of the laser current provides microwaves, thus completely eliminating the need for a tuned microwave cavity. Rb or Cs compact cell standards based on this interrogation scheme have been developed. The typical stability of a CPT-based rubidium standard has been reported in the range of 1×10^{-12} at 1 s.

Hydrogen Masers

The acronym maser stands for microwave amplification by stimulated emission of radiation. Masers have been built with various atomic and molecular species for the purpose of microwave spectroscopic investigations. A hydrogen maser, also known

as hydrogen frequency standard, is a specific type of maser that uses the intrinsic properties of the hydrogen atom to serve as a precision frequency reference (Goldenberg et al. 1960; Vessot 2005). Hydrogen masers are extensively used for building stable timescales. There are two variants of hydrogen masers: active and passive. Active H-masers are relatively bulky and have excellent short-term stability, while the passive hydrogen masers are smaller and lower-performance variants. The ground-state hyperfine transition $F = 0$, $m_F = 0$ to $F = 1$, $m_F = 1$ of atomic hydrogen, with a transition frequency near 1420 MHz, is the clock transition. A beam of atomic hydrogen is generated from H_2 gas in a radio frequency discharge. The atoms in the upper ground states are focused by a pair of state selecting magnet into a storage bulb inside a microwave cavity resonant with the 1.4 GHz frequency of the hyperfine transition, while the atoms in the other ground states are defocused and do not reach the storage bulb (Fig. 5). Hence, the storage cell, which is placed in a microwave resonator, contains more atoms in the upper state which can emit radiation by stimulated emission. When the number of incoming atoms and their storage time in the bulb is large enough, self-sustained maser oscillations are generated. These oscillations are detected by an antenna and used to tune the

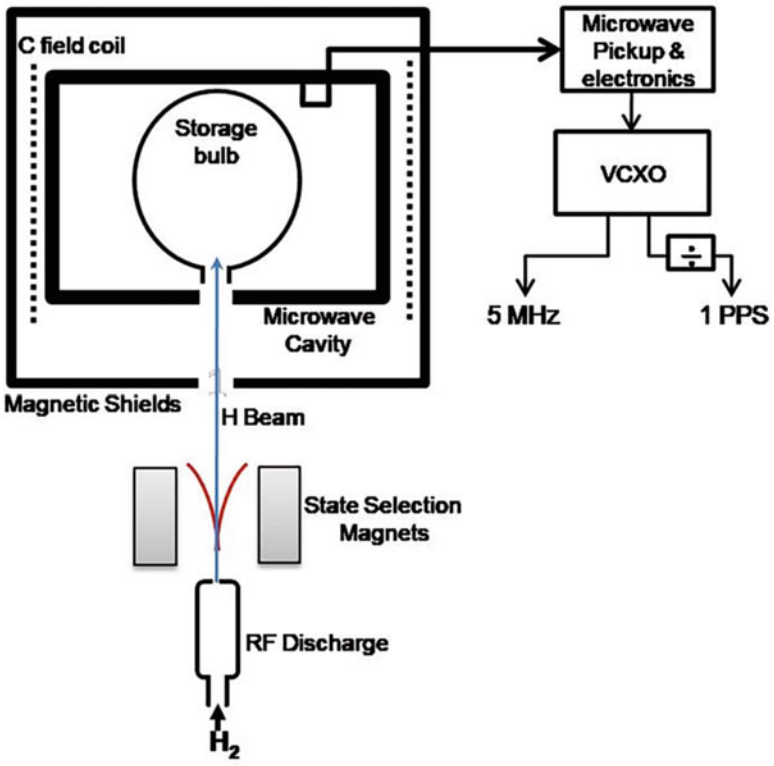

Fig. 5 Block diagram of an active hydrogen maser

frequency of a voltage-controlled crystal oscillator (VCXO) from which the output signal of the frequency standard is derived. The atoms typically spend about 1 second in the storage bulb, and due to this long interaction time, a narrow linewidth atomic transition is detected in a maser.

In an active maser, the losses of the cavity are small enough so that the device oscillates at the hyperfine transition frequency. The frequency of oscillation of an active maser is a function of both the cavity resonance frequency and the atomic transition frequency, so that some means of stabilizing the cavity is usually required. Collisions with the walls of the bulb also affect the frequency of the device. Various strategies are used to minimize these effects, including applying special "nonstick" coatings to the inside of the bulb and actively tuning the resonance frequency of the cavity so that it is exactly on atomic line center. In spite of these techniques, hydrogen masers usually have frequency offsets that are large compared to the stability of the device. The fractional frequency offset of a hydrogen maser is typically of order 5×10^{-11}, while the fractional frequency fluctuations at 1 day can reach 2×10^{-16}. In any case, the short-term stability of an active hydrogen maser is much better than the best commercial cesium beam clock. Active hydrogen masers are therefore selected as flywheel for generating stable timescales.

The construction of a passive hydrogen maser is similar, except that a microwave signal at 1.4 GHz is fed into the cavity and is amplified by the hydrogen atoms inside the cavity. The maser acts as an amplifier with narrow linewidth limited by linewidth of atomic transition. The atomic transition is probed by measuring the amplified signal and the external oscillator frequency is tuned until output signal is maximized. The passive maser is made with a smaller and compactor microwave cavity and therefore is generally smaller in size as compared to active maser. However, smaller size comes at the expense of larger short-term instability.

One of the key components of a hydrogen maser is the storage bulb, which is coated with Teflon or similar materials so that a hydrogen atom survives thousands of wall collisions before it gets spin depolarized. Storage times of several seconds are thus possible for the hydrogen atoms. The main advantage of a hydrogen maser is its low relative short-term instability. However, its long-term stability suffers from drifts mainly due to chemical changes and aging of its wall coating, which in turn changes the frequency shift due to the wall collisions.

Optical Frequency Standards

Any clock is characterized in terms of stability and accuracy. Accuracy is a measure of closeness to the true value (duration of SI second in case of clocks), and stability is the measure of ability to produce the same value over extended time (clock ticks produced at regular intervals in case of clocks). Stability as well as accuracy of atomic clocks is limited due to several factors. Stability of atomic frequency standards is assessed through Allan deviation. Fractional frequency instability (σ) of AFS, as a function of averaging time (τ), is expressed as

$$\sigma(\tau) = \frac{1}{\pi}\frac{\Delta\nu}{\nu_0}\frac{1}{S/N}\sqrt{\frac{T_{cycle}}{\tau}} \quad (1)$$

Here $\Delta\nu$ is the width of the atomic transition with center frequency ν_0, S/N is the signal-to-noise ratio of the detection process, and T_{cycle} is the time required for a single measurement cycle.

From this equation, it can be immediately understood that the instability is reduced for narrower lines ($\Delta\nu$), shorter measurement cycles, and higher signal-to-noise ratio.

Optical atomic clocks operate at frequencies around five orders of magnitude higher than the frequency of the cesium primary frequency standard, while linewidth-limiting processes in the two spectral regions are almost similar (Gill 2005). For a given linewidth $\Delta\nu$ of the absorption feature, the line quality factor $Q = \nu_0/\Delta\nu$ increases on operating at optical frequencies instead of microwave frequencies. An enormous reduction in instability can thus in principle be gained by basing a frequency standard on a transition in the optical region of the spectrum. This gain is, however, not as large as the 10^5 increase in frequency, because of various other fundamental and technical factors. The exact improvement factor depends on the signal-to-noise with which the atomic absorption signal is observed. It can also be seen from Eq. (1) that atomic frequency standards follow the $\tau^{-1/2}$ white noise behavior until hitting a noise floor at a certain time which differs for different standards. Cs fountains typically reach $\sim 10^{-15}$–10^{-16} stability levels at averaging times approaching a day. Optical frequency standards reach the similar stability levels at few seconds averaging times with many optical clocks reaching the noise floor of 10^{-17}–10^{-18} within a day.

While considering frequency uncertainty, optical frequency standards also suffer from a number of systematic shifts due to various physical effects, e.g., Doppler, Zeeman, Stark, collisional, gravitational, etc. In most of the vases, the magnitude of these shifts is inversely proportional to the frequency, thus making optical frequency standards less susceptible to environmental, electromagnetic perturbations. In addition, evaluation and suppression of systematic frequency shifts can be accelerated and measured with higher precision with optical standards possessing much smaller instabilities.

Thus, optical frequency standards offer potential advantage, over their microwave counterparts, both in terms of stability and accuracy.

Optical frequency standards are based on weak forbidden optical transition in a certain species of laser-cooled ions or neutral atoms. There are three key elements, which are necessary for the realization of an optical frequency standard (OFS) as shown in Fig. 6. These are stable local oscillator, optical transition in laser-cooled atomic species (atoms/ions), and a frequency counting mechanism. For optical clocks, the local oscillator is a highly stable laser, generally servo-locked onto a narrow resonance of a high-finesse, environmentally isolated, ultralow expansion (ULE) cavity. The atomic reference or clock transition is a weak, forbidden optical transition in a single cold ion or cold atomic cloud. Using laser-cooled atomic

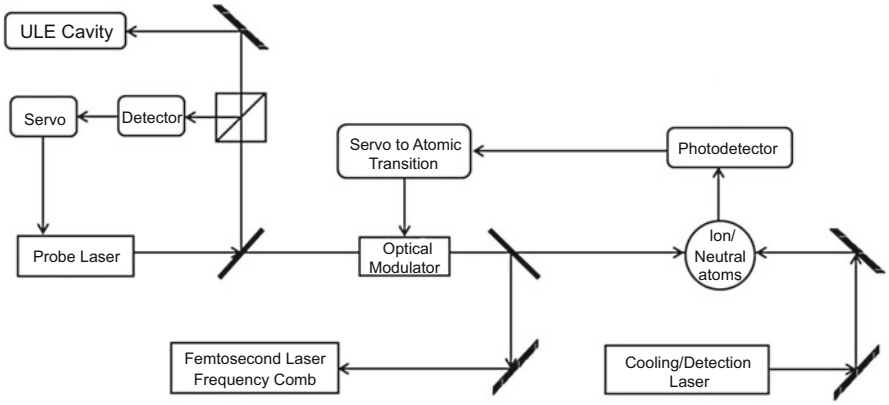

Fig. 6 Schematic of a generic optical frequency standard

samples enables the extended interaction times required to observe a narrow transition linewidth in the sub-1 Hz to a few hertz range, depending on the precise element. The frequency counting mechanism or clockwork, which is capable of relating the frequency of the standard to other standards, is a femtosecond laser frequency comb, which generates a large number of modes across the optical near-infrared region. In the year 2000, with the development of optical frequency combs (OFC) (Hansch 2006; Hollberg et al. 2005), realization of optical frequency standards became feasible.

Initially, atoms or ions are laser-cooled using a cooling laser, tuned slightly below the center frequency of a strong (allowed) transition. A second (repumping) laser is used to pump the atoms/ions back to the cooling cycle. To avoid broadening of the transition via the ac Stark shift, another (probe) laser is used to interact with the cold atomic species after switching off the cooling laser using an optical modulator. After a brief interaction time, the probe laser is turned off and the cooling laser is switched back on to interrogate the atoms/ions and the corresponding transition probability is measured. The probe laser is detuned in steps to measure the transition probability at different clock frequencies and generate a line profile of the clock transition. A servo loop is closed by locking the probe laser on the center of the clock transition. The frequency of the stabilized probe laser is measured using a frequency comb, which down converts the frequency from the optical to the microwave domain and serves to produce the RF/microwave output of the frequency standard.

For developing state-of-the-art OFS, the choice of the atomic reference transition is one of the most critical aspects. The required narrow linewidth transitions (clock transitions), almost insensitive to external perturbations such as frequency shifts caused by magnetic and electric fields, exist in both ions and neutral atoms. Therefore, there are two choices for realizing an OFS based on working with few ions or a large number of neutral atoms. Depending on the priority for low instability or low uncertainty, one can choose a single ion or a cloud of cold atoms. With many atoms, one obtains a much higher signal and thus higher stability, but on the other hand,

those atoms could potentially interact with each other to produce larger shifts. Single trapped ion-based clocks are more accurate due to long observation time with no dependence on inhomogeneity of external magnetic or laser light fields.

Optical clocks have made significant progress in recent years (Chou et al. 2010; Huntemann et al. 2016; Katori et al. 2003; Rosenband et al. 2007; Ludlow et al. 2015; Lemke et al. 2014; Peik et al. 2006; Falke et al. 2011; Margolis et al. 2004; King et al. 2012; Le Targat et al. 2013; Yi et al. 2011; Takamoto et al. 2011; Lin et al. 2015; Huang et al. 2012; Oskay et al. 2006). Out of the 11 atomic transition frequencies recommended by the consultant committee of time and frequency (CCTF) as the secondary representations of the second (SRS), ten transitions are in the optical frequency region besides Rb transition (https://www.bipm.org/en/publications/mises-en-pratique/standard-frequencies-second n.d.).

Neutral Atom Optical Frequency Standards

In neutral atom-based optical atomic clocks, large numbers of neutral atoms are cooled, trapped, and probed simultaneously, thus enabling an extremely high S/N ratio and potentially very high stability. As the fractional instability depends inversely on the square root of the number of atoms in the system, neutral atom optical frequency standards are expected to have unprecedented stability. However, absolute frequency uncertainty estimation is complicated and varies from one atomic system to another.

Methods of confining neutral atoms, as done in Cs fountain frequency standards, are efficient but, during the probe cycle using a laser beam, lead to shifts in the transition frequency due to Doppler and scattering effects. As a solution to the confinement problem, optical/laser lattice is used to trap the neutral atoms. In this method, counter-propagating laser beams interfere to create spatially localized potential wells which attract sufficiently cool neutral atoms to its minima. Such a periodic potential well structure is called optical lattice which spatially confines laser-cooled neutral atoms in so-called Lamb-Dicke regime where a carefully chosen wavelength of the lattice laser beams leads to minimized shifts of the clock transition (Dicke 1953). Such a confinement arrangement results in long interaction times and small Doppler shifts, along with the good S/N ratio due to large numbers of neutral atoms.

With prudent choice of atomic transition and lattice wavelength, perturbations to the clock frequency induced by the lattice beams are easily suppressed better than sub-10^{-17} level. Even with the additional experimental efforts required, optical lattice clocks are now dominating the field of high-precision neutral atom clocks. Such optical lattice clocks are being developed at several NMIs around the world. Most common choice of neutral atom systems currently under development for optical clocks includes Sr, Yb, and Hg atoms (Lodewyck et al. 2010; McFerran et al. 2012a; Falke et al. 2014; Wang et al. 2009; Blatt et al. 2008; Akatsuka et al. 2015; Yamaguchi et al. 2012; Sherman et al. 2012; Levi et al. 2016; Yasuda et al. 2012; Park et al. 2013; McFerran et al. 2012b). Many of these optical lattice clocks are being continuously operated and contribute to TAI as a secondary representation of second (SRS). Work is under progress in developing miniaturized and

transportable versions of optical lattice clocks. With rapid advancements in this area, the best laboratory optical lattice frequency standards have reached record levels of instability (ADEV of 4.7×10^{-17} at 1 s) and fractional uncertainty (5.8×10^{-19} after 1 h of averaging).

Trapped Ion Optical Frequency Standards

The idea of using single trapped ion as optical frequency reference was first proposed by H. G. Dehmelt in 1973 (Dehmelt 1973; Dehmelt and Walther 1975). A single ion confined in an electromagnetic trap, such as the Paul trap, is the simplest way of investigating weak optical transitions in the trapped ion. The environmental perturbations can be effectively controlled with relatively simpler experimental arrangements. In effectively cooled and trapped ion, the thermal motion-induced Doppler effects which shift the resonance frequency are minimized. With sufficiently deep trapping potentials, cold ions-based systems can be operated in the Lamb-Dicke regime. Moreover, an ion can be probed while being confined in the trap; thus, long interaction times can be achieved. The only limiting factor for trapped ion systems is the poor S/N ratio and thus increased instability. Despite having lower S/N, high-performance optical frequency standards have been developed by observing a weak optical (clock) transition in an ion virtually at rest in near-unperturbed conditions over extended periods (days). A number of laboratories worldwide are investigating the stability and accuracy of different trapped ion optical frequency standards. Till date, several kinds of ion optical clocks have been realized, which are $^{40}Ca^{+}$ion clock, $^{88}Sr^{+}$ ion clock, $^{199}Hg^{+}$ ion clock, $^{171}Yb^{+}$ ion clock, and Al^{+} ion clock (Matsubara et al. 2012; Harlander et al. 2012; Barwood et al. 2001; Dube et al. 2009; Tamm et al. 2009; Godun et al. 2014; Hannig and Pelzer 2019; Che et al. 2017). State-of-the-art ion optical frequency standards have achieved short-term fractional frequency instabilities nearing $10^{-15}/\sqrt{\tau}$ and fractional uncertainties of 9.4×10^{-19}.

Applications

Measurement of time is part of our daily lives with time-bound human activities which require timing accuracies of minutes and seconds, at best. However, accurate and precise time and frequency measurements done with atomic frequency standards (AFSs) have enabled many modern applications which have revolutionized our daily lives. SI unit of time, i.e., second, is the most accurately measured quantity which is used for measurement of other SI units as well. Apart from atomic timekeeping and metrology, there are applications such as navigation, telecommunication, power grids, banking and finance, cybersecurity, etc. which rely on accurate and precise atomic frequency standards.

Navigation is all about locating and tracking the position of an object/person. Global satellite navigation systems (GNSS) like GPS are based on precise measurement of time taken by signal radiated by satellites to reach a particular location. Each satellite has an atomic clock onboard, and atomic clocks on all the satellite systems

should be synchronized to about one billionth of second per day. A difference of just one microsecond between clocks can lead to a positioning error of 300 meters. Nowadays, miniaturized GNSS receivers integrated in mobile phones have enabled easy access to accurate navigation within few meters, thus making navigation an application of atomic clocks touching daily lives.

Another everyday application of AFSs is telecommunications. High-speed mobile networks need time synchronization (better than few microseconds) between base stations of different operators; otherwise, the information may be lost or corrupted in these packet-switched networks. Modern high-speed telecommunication systems require atomic clocks for reliable, uninterrupted services.

Electricity distribution networks, based on smart power grids, need to link sources with identical frequency and synchronized phase. Precise timing synchronization of the order of one microsecond to hundreds of nanoseconds between the power substations is required for the seamless operation of smart grids.

Banking systems and financial markets also need very accurate clocks to guarantee the time and date stamps of high-frequency transactions with microsecond accuracy. Cybersecurity also relies on accurate time stamps and synchronized systems; otherwise, cyber frauds can never be chronologically correlated and solved.

Among the high-end scientific exploration applications of atomic clocks are astronomy, geodesy, test of fundamental constants, etc. (Will 2014; Safronova et al. 2018; Hees et al. 2016; Takano et al. 2016; Mehlstaeubler et al. 2018). With the use of atomic clocks, arrays of distant radio telescopes can be synthesized together in very-long-baseline interferometry (VLBI) to give angular resolutions of 250 micro arc sec which is 250 times better than the best optical telescopes including the improved Hubble telescope. VLBI also provides the most accurate measurements of distances along the surface of the Earth and thereby aids in the study of the Earth's crustal dynamics. Atomic clocks are needed to measure the stability of pulsars, of the Earth's rotation, and of other periodic phenomena. The constancy of the fundamental constants can be tested by comparing different kinds of clocks at different times. With the advancement in atomic clocks technology in terms of accuracy, size, and affordability, many newer applications of atomic clocks will emerge in evolving quantum systems.

Future and Beyond: Towards Redefinition of SI Second

From tracking the movement of celestial bodies to mechanical clocks and now prevalent atomic clocks, timekeeping has been one of the greatest quests for finding stable and better oscillators, having least effect of changing surroundings. A quartz crystal is better than a pendulum, and an atomic transition is much better than a man-made crystal. Continuing with the similar objective, transitions of neutrons and protons in a nucleus are better isolated than electronic transitions in atoms (Peik and Tamm 2003; Beck et al. 2007). Nuclear transition is not affected by stray electric and magnetic fields like electronic transitions and thus could make ideal candidate for realizing more accurate and stable clocks. Typical nuclear transitions require

much higher energy than the normal lasers can provide with the exception of ^{229}Th, where a nuclear transition between a pair of closely spaced energy levels can be excited using ultraviolet lasers. However, a lot of work needs to be done before a single ^{229}Th ion trapped in a Paul trap can provide a new standard of time.

Since 2000, several clocks based on optical transitions in ions and neutral atoms have been developed and have been consistently showing superior performance with around two orders of magnitude lower relative uncertainty (at 10^{-18} level). A 10^{-18} level uncertainty means an error of less than a second in a billion years, the age of our universe. Based on better and consistent performance, optical clocks have been pushing the case for a possible redefinition of SI second in terms of an optical transition (McGrew et al. 2018). However, there is no consensus on the candidate/element and the confinement method for the eventual redefinition. An optical clock can be realized either with single trapped ion or neutral atoms trapped in a lattice. Earlier realization has the advantage of long coherence time and thus lower uncertainty, while the latter one offers large S/N ratio, thus providing better stability. At the same time, there are various species of ions (Yb+, Sr+, Al+, Ca+, Hg+, etc.) and atoms (Sr, Yb, Ca, Hg, etc.) which are being investigated but no candidate has a clear and obvious advantage for redefining the time. Moreover, high-accuracy time transfer/comparison links are required for intercomparing the optical clocks being operated at different countries and continents around the world. It is clear that a significant amount of work still needs to be done before the redefinition of SI second. An envisioned possible timeframe for the redefinition is as early as 2026. However, in order to ensure a smooth transition to an optical second, the International Committee of Weights and Measures (CIPM), in 2018, published a detailed framework with fixed milestones which have to be achieved in the domain of optical clocks before implementation of the new definition (Riehle et al. 2018; Lodewyck 2019). The set of criteria include demonstration of better accuracy and stability, reproducibility of results, continuity with the current SI definition, and even by intercomparison of results from different laboratories with suitable time transfer methods. A number of optical transitions, however, have been accepted as secondary representation of second (SRS) and are already contributing to the maintenance of International Atomic Time (TAI).

In 1967, SI second was redefined from astronomical definition to the atomic transition in cesium atoms, and few years ahead in time, it may be replaced by a transition in the optical frequency region. Another redefinition might happen once nuclear clocks are realized and tested for better stability and accuracy over optical clocks. Until the next redefinition, cesium fountain clocks will remain the primary standards of time and frequency.

Conclusion

Most of the modern world applications including navigation, telecommunications and the Internet, electrical power grids, banking, smart transport, finance, defense, cyber physical systems and upcoming technologies of 5G, artificial intelligence and

Internet of things, etc. rely heavily on precision time measurement and time synchronization. Additionally, precise time with ns accuracy is also required for high-end research in science, namely, measurement of fundamental physical constants, detection of the gravitational waves, geodesy, deep space navigation, radio telescopes, etc.

To meet the growing demand, there has been a remarkable progress in the field of timekeeping with atomic clocks, especially after the developments of the laser cooling and trapping atom techniques. Clock instability, reproducibility, and accuracy have been improved significantly in last half-century. Primary Cs fountain frequency standards, more accurate than Cs beam clocks, achieved a total uncertainty of a few parts in 10^{16}. Since 2000, trapped ion and neutral atom optical frequency standards have reached an uncertainty in a range of 10^{-18}–10^{-19}, thus exceeding the performance of best Cs fountain clocks. Due to the consistent performance of optical clocks, ten optical transitions have been recommended as secondary representations of the second. However, high-accuracy comparison between optical clocks located in different countries or continents is still a challenging issue.

From the present definition of SI second, best realized with laser-cooled cesium fountain clocks, scientific endeavor in the field of optical clocks is pushing for a future redefinition of SI second on the basis of an optical transition. With a number of viable candidates and confinement techniques, a framework has been set up by CIPM to ensure smooth transition to a new definition of SI second in future.

Abstract

Time dissemination from authentic common reference is a key for synchronized operations. This chapter discusses various techniques available for precise time transfer. Depending on the dissemination techniques used, the time synchronization accuracy varies. This chapter provides a brief overview of various dissemination services. Telephone time dissemination technique was establishes owing to its widespread availability in early days. With the development of Internet services and its reachability to masses, time dissemination via NTP is currently the most common methodology with millisecond/microsecond accuracy. Satellite time dissemination is for very precise users whose accuracy demands are of the order of nanoseconds. This chapter elaborates details about all such time transfer techniques with protocols and methodologies adapted and discusses their corresponding results.

Introduction

Precise time synchronization and timestamping are critical for the country's overall growth and security. Time is an extremely important factor, but it is frequently overlooked. Time is only seen as a broader aspect of everyday life, matching time with some events. However, time is incredibly critical and demanding for many

applications and sectors. This chapter discusses some key aspects of the strategic sectors, such as navigation, electronic transactions and cybercrime, digital archiving, international trade, national security, weather prediction, and disaster management, transportation, application in the power grid, identifying underground resources, and so on.

Strategic sectors such as air, naval, and army, defense research laboratories, space sectors, and astronomical observatories, among others, necessitate extremely precise time measurement and synchronization. Surveillance, precise targeting, satellite launch and placement, space applications, and astronomical research all rely on time synchronization. Navigation is used for precise positioning. Time synchronization with nanosecond precision is required. Satellite navigation relies heavily on synchronization. With increasing demands for positioning accuracy, synchronizing the onboard satellite clocks with the base receivers and transmitters is critical. While progressing toward digitalization, digitization of economic involvements plays a crucial role. But unless these e-business dealings are synchronized to a common reference of time, they can turn down the economy instead of elevating it. Avoiding the chances of cybercrime by having traceable time is the key here. Digital archiving is linked to the orderly storage of electronic data. This is critical as otherwise, it may affect the smooth functioning of a multibrach business/sector, as well as their lawful accountability, which can also be in danger.

To avoid any disaster in international trading, accurate time synchronization requires international trade involving all other countries. Then, for national security monitoring of any violence or national calamity, as well as an immediate action against it, time synchronization among security agencies and alarming systems is required. Transfer techniques, weather prediction, and disaster management are all essential for any precise time. The dynamic mapping and evolution of any natural disaster, such as a cyclone, flood, or tsunami, is dependent on precise time synchronization among the devices involved. Furthermore, time synchronization of network devices and associated systems is required for public awareness of natural disasters, civil alerts, traffic information, and early warning on health or weather. Transportation is another critical factor in the efficiency of an automatic signaling system, air traffic control, and navigation of all transport systems, including road traffic, railways, and aviation, relying on the associated devices' accurate time synchronization.

The power grid application demonstrates that significant amounts of electric power can be saved if grids are time-synchronized, as power can be rerouted and grid failures can be detected without wasting time. Finally, identifying underground resources, and tomography of the ocean floor, and determining underground resources are accomplished by sending a sound wave and receiving the reflected signal, followed by geologists post-processing the data. This technique relies on the precise time synchronization of the associated transmitters and receivers. In many fields of technology and science, precise time and frequency are required. Directly or indirectly, the networked synchronization in time or frequency plays a critical role in these industries. A time or frequency signal is broadcast from a standard source to synchronize remote locations. The received time and frequency information is used to synchronize local time scales at the users' locations. However, the accuracy of

synchronization will be determined by the method or technique used to distribute the reference time and frequency signal, the network topology used, and the precision of the users' system. Different time synchronization techniques provide varying degrees of synchronization accuracy. However, depending on whether time information or frequency is transmitted, the transfer techniques must meet different requirements. As the delay is comprised due to many factors (cable delay, path delay), it must be properly considered or corrected for time transfer. As a result, the accuracy with which synchronization of transmitter and receiver is achieved influences source or transmitter capability, linking connecting source and transmitter and receiver capability. The uncertainty of the time transfer is summed up by all of these contributions. However, if frequencies are to be compared as a result of the signal's periodicity, the delay must be constant.

There are three types of time dissemination methods: unidirectional, bidirectional, and common view. These methods are commonly used to send time and frequency data. In the unidirectional method, path delays are modeled and adjusted using auxiliary data. However, path symmetry is critical in this model because the bidirectional method relies on cancelling the online path delay experienced during dissemination. Furthermore, several stations receive data from a common source via paths with roughly equal delays.

Unidirectional Methods

When data flows from transmitter to receiver in only one direction, the communication is referred to as unidirectional communication. This technique is primarily used in functional reactive programming. In this method, only the transmitter can send signals to the receivers, and the receivers have no way of communicating back to the transmitter. This set is useful in many control system applications where better data flow control is required. However, this is not appropriate for many applications where improved data flow control is not the goal.

Using supplementary data, the transmitter-receiver delay is computed in numerous systems. GNSS signal transmission in which path delays are estimated using various parameters that are also sent in the routing information, radio broadcast of time and frequency signals, and some telephone time dissemination services all fall under the unidirectional time dissemination method (refer to Fig. 1). In terms of precision, these methods have limitations. Nonetheless, these services are widely used because they provide adequate accuracy while remaining simple to use.

Bidirectional Methods

The majority of the time dissemination methods are bidirectional. The transmitter and receiving stations are online in this method, and they actively transmit and receive time data (refer to Fig. 2). Because the transmission and reception are bidirectional, the delay can be measured and compensated for. The best example

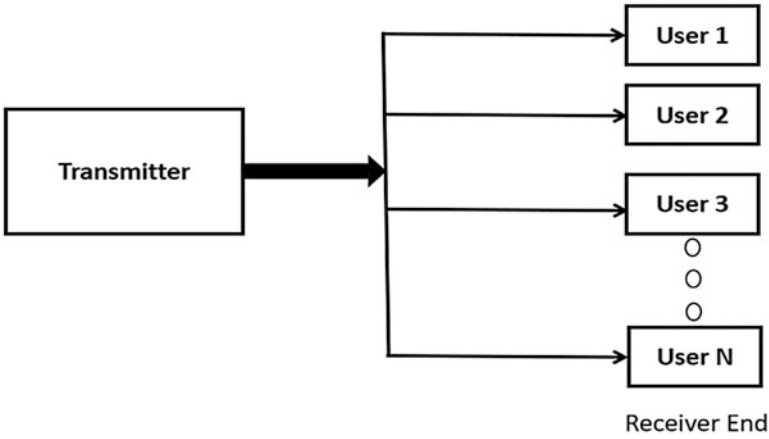

Fig. 1 Unidirectional time transfer

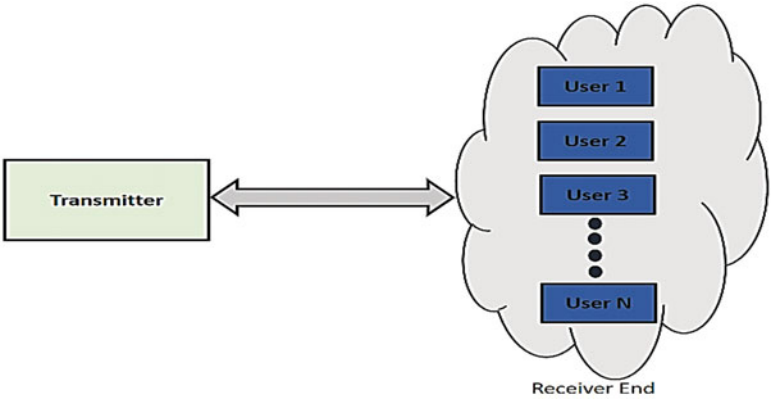

Fig. 2 Bidirectional time transfer method

of bidirectional communication is the two-way satellite time and frequency transfer system (TWSTFTS). This technique compares clocks located in different locations using geostationary satellites.

A modem used in the TWSTFT system generates a code that is synced with local clocks' 1 Hz signal. An uplink carrier frequency (14 GHz) is then modulated by pseudorandom code generated by TWSTFT modem. This signal is uplinked to a geostationary satellite. Downlink is done at 12 GHz frequency for modulated signal retransmitted by satellite. The receiver receives the signal, demodulates it, extracts the code, converts it into a synchronization signal, and verifies it with the available local replica of the same signal. It's a real-time bidirectional, full-duplex communication system with accuracy greater than 1 nanosecond.

Similarly, a commonly used and popular method of time dissemination is Network Time Protocol (NTP) method. In this client-server model, a request to the server is originated by a client which is fulfilled by the server with appropriate information within a standard format. The client extracts information from this data format while adjusting the network delay to half of the total path delay and synchronizing its clock. PTB Germany's telephone time dissemination service, Telefon, is another example of a bidirectional time dissemination method. This service is available via the public telephone network at +49 (0)531 512038. This service operates at a baud rate of 1200 and in full-duplex mode.

Common-View Methods

GPS/GNSS time transmission is a very good example of bidirectional network time transfer. The information generated by one source (onboard clock) is received by the devices in a network comprising several locations which could be termed as the easiest demonstration of the common-view method. Each station keeps track of the time it takes for a specific signal to arrive at its station. After that, the measurements are verified at their end. If there is symmetrical delay observed in the paths followed, then two stations in the same network can be compared using the network source with counting for it. Also, the effects of jitter involved in these paths get cancelled. This category includes CV- GNSS and AIV-GNSS methods.

Typically, the CVGNSS (Levine 2002) method employs atmospheric paths with microwave signals (Fig. 3). Short-wavelength signals are well suited to the requirement that the transmission path is well defined and easy to characterize because they travel in nearly straight lines and can be modeled using geometrical optics approximations. It is impossible to achieve global coverage with a single transmitter at short wavelengths. This can be addressed by the all-in-view method.

One method of achieving global coverage is to use multiple physical transmitters with synchronized signals to a common reference, which is the origin of the AIV and melting pot method. Because there is no actual transmitter whose signal dissipates to such long-distance locations at the same time, this method proves to be very useful. Long distances like India and Canada can use the AIV method.

Measurements in global navigation satellite system (GNSS) are dependent on two main factors:

- The time interval between the satellite
- Reception of pseudo-range noise (PRN) codes

The pseudo-range can be computed using the following equation:

$$P = c(t_r(\text{rec}) - t_e(\text{sat}))$$

where c represents the velocity of light. In applications, where sub-millisecond accuracy is needed, GNSS can be the best method for time synchronization.

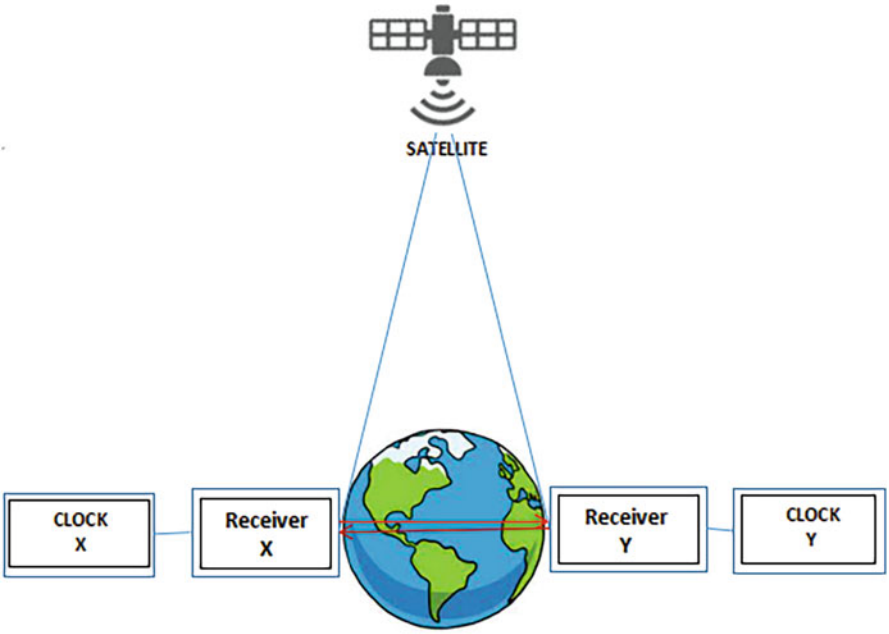

Fig. 3 Time transfer using common-view GNSS

Banking, telecommunication networks, energy transport and distribution network, etc. are some areas of applications where GNSS is utilized for time synchronization.

Telephone Time Dissemination Technique

A telephone is a device that allows for the simultaneous transmission and reception of voice. Telephones are inexpensive and simple to use. Telephone lines can also be used to transmit audible data. Some techniques have also been developed to transmit accurate time over telephone lines. Time transfer over a telephone line can serve a wide range of users who require millisecond precision. This service only requires the existing telephone exchange architecture to transmit the timestamp. Telephone time dissemination has been regarded as a valuable supplement to radio time dissemination services. It avoids the real and perceived problems of antenna placement and signal availability.

The synchronization of digital system clocks using a public switched telephone network (PSTN) is a simple way by which a remote clock can be set accurately. Additionally, it is the least expensive way to synchronize a remote clock. A total of 20 NMIs around the world have implemented telephone time dissemination. As shown in Fig. 4, the basic architecture of this technology includes a time server at the NMI laboratory end and receiver modules at the user end. The time reference for these servers is the time scale of the corresponding NMI. The following section

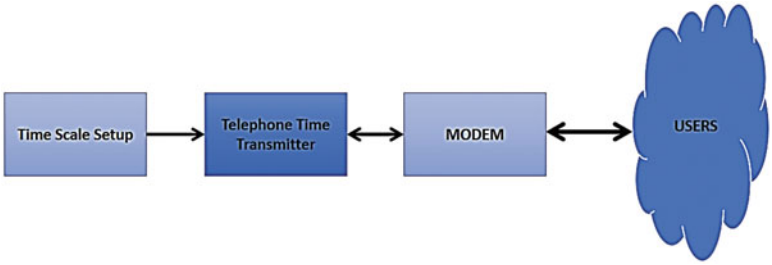

Fig. 4 Generalized block diagram of telephone time transfer

explains various key features of such telephone time synchronization services which are operated by NIST, USA; NPL, UK; NICT, Japan; PTB, Germany; NRC, Canada; and INRIM, Italy. NPL, PTB, and INRIM all use the same data format and transmission scheme. At CSIR-NPL, India is operating a service named Teleclock since 1998.

The NIST in the USA offers a time synchronization service known as Automated Computer Time Service (ACTS). It has been in operation since 1988 (Set Your Computer's Clock via the Telephone: NIST Automated Computer Time Service (ACTS)). ACTS uses analogue modems that connect to telephone lines. The time server can be reached by dialing 303 494-4774 or 808 335-4721. ACTS (Lombardi 2002) can operate at a maximum speed of 9600 baud. This technology uses 8 data bits, 1 stop bit, and no parity bit. For accurate and effective reception of full-time code, the receiver must connect at a speed of 1200 baud. At every second, ACTS transmits full-time code and the code carries more information than the 300 baud time code, which is sent every 2 s. Using this service (ACTS), any clock can synchronized itself with an accuracy of a few milliseconds. This technology has a millisecond delay. This delay is determined by the oath's physical length and the signal's group velocity. The ACTS Transmission Formats are explained and illustrated in Fig. 5:

- The modified Julian day number is represented by the MJD column; the MJD advances by one at 0000 Coordinated Universal Time (UTC) every day. On January 1, 1989, the MJD was 47,527.
- The next six digits represent UTC in years since 1900. This displays the month, day, hour, minute, and second.
- DST is a column that specifies whether a daylight saving time correction is required now or will be required soon. This flag is legal in most of the USA. DST of 00 indicates that standard time is in effect. The value 50 in the DST column indicates that daylight saving time is under effect. If the DST column has a value ranging between 99 and 51, it indicates that a transition to daylight saving time may occur. If the value of DST is between 01 and 49, it means that the transition from daylight saving time to standard time may occur in the near future.
- The leap second flag, LS, is generally not set, i.e., it is zero. If it is set to 1, the leap second will be added on the last day of the current month. The leap second will be

labeled 23:59:60 UTC, and the second after 23:59:60 will be labeled 00:00:00 the following day. If the leap second flag is set to 2, it indicates that a second will be dropped at the end of the current month's last day.

- The column DUT1 represents the difference between a time scale and UTC. It measures the difference using the rotation of earth. Mathematically,

$$\text{DUT1} = \text{UT1} - \text{ms ADC}$$

- The on-time marker's advance in milliseconds is represented by msADV. To arrive at the user on time, the center of the on-time marker's stop bit leaves the transmitter by this amount of time earlier. The method used to estimate this parameter, as well as its uncertainty, is discussed below.
- The on-time marker is denoted by the symbol OTM. It is either "*" or "#," as discussed further below. The center of this character's stop bit is intended to arrive at the user at the time specified by the previous characters on the same line (Levine et al. 1989).

PTB offered a telephone time service named Telefon via the public telephone network under the phone number +49 (0)531 512038. The methodology follows the protocol CCITT V.22 and the connection is established using telephone modems. It can prove an accuracy ranging from 1 s to a few milliseconds. The time code transmitted by Telefon follows the rules defined by the European telephone time code.

TEL-JJY, which is used by NICT to distribute time over the PSTN, can be reached by dialing +81 45 411 7223. With a standard v22 analogue modem, the connection offers baud rates of 300, 1200, or 2400. During the synchronization

process, the path delay between the user and the transmitter is computed. It provides synchronization accuracy of a few milliseconds between the transmitter and the special type of receiver.

NPL, UK, also offers a time synchronization methodology over a telephone network named Phoneclock. This service can be accessed by dialing 020 8943 6333. The synchronization accuracy of the Phoneclock system is around 30 ms (Laverty 1996).

A clock system is developed by NRC, Canada, and a company named Leitch Video Limited which can set the digital clocks automatically. This system uses telephone lines to communicate with the time server. The protocol sends the date, time, and telephone loop delay, and the information is sent in the form of ASCII code formats. The service can be availed by dialing (613) 745-3900. Synchronization accuracy is in the order of a few milliseconds. This system uses a simple protocol to disseminate time information. The protocol utilizes ASCII characters transmitted by frequency shift keying techniques. The UTC is transferred from master to slave clock in this protocol. In this methodology, the slave clock makes a call to the master clock. The call puts the master into a prompt echo mode. The receiver then measures the delay time and applies half of the delay time as a correction to the time it receives from the master clock. This technique of time transfer provides an accuracy of a millisecond. This accuracy is possible over even a relatively low-grade telephone link (Jackson and Douglas 1986).

The CSIR NPL's Teleclock service (Banerjee et al. 2012a, b) provides synchronization accuracy of the order of 1 s. The current service makes use of a CCITT V.22 analogue modem with a baud rate of 1200. The Teleclock transmitters are connected to two accessible telephone lines from different service providers. Users can get the time by dialing 01145608687 and 01145608688. During time broadcast, information is transmitted in hours, minutes, and seconds. This service broadcasts time data in the form of hours, minutes, and seconds. It is a television broadcasting service. When a receiver communicates with the Teleclock transmitter and a successful connection is established, the transmitter begins broadcasting time information five times per second. There is no need for any special hardware to synchronize the computer clock with the Teleclock. The only requirement is to connect the PSTN line to the computer's built-in modem. Like India, few other countries, such as Nepal and Saudi Arabia, used the Teleclock service for disseminating time information. This service is serving many customers in India including Parliament House, CSIR headquarters, airports, railway stations, police control rooms, CSIR laboratories, etc.

Figure 6 depicts the basic unit for gaining access to the Teleclock. It is composed of three major components: a modem, a data identifier, and a clock system (Banerjee et al. n.d.-c, 2009; Thorat and Banerjee 2010, 2011). The modem is important because it allows you to access data from the PSTN line. Data deciphering unit is derived using the output of the modem, which retrieves the data, verifies its accuracy, and stores it for delivery to the clock. The clock system receives data from the modem and corrects the time displayed by the computer or client system's local clock. Digital time information is transmitted over the PSTN as an audio frequency range signal (300–3300 Hz). To send digital data over a telephone network, the digital data must be modulated so that it can be sent as an encoded audio frequency

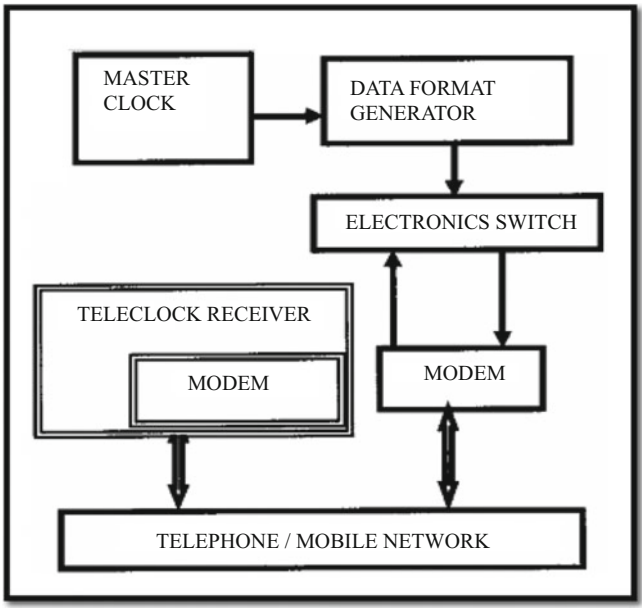

Fig. 6 Scheme of Teleclock service

over PSTN. A demodulator is also required at the receiver end to extract digital information from the modulated signal. To achieve greater accuracy, full-duplex communication is required. As a result, both ends of the system should have a transmitter and receiver, as well as a modem (modulator-demodulator). In the present work, the Conexant standard v.92 56 k USB modem was used.

Improved Teleclock Receiver/Mobile Teleclock

With the advent of telecommunication technology, telephone time dissemination via landline receivers was becoming a limitation. Hence, improved version of Teleclock receivers in the name of mobile Teleclock was developed at NPLI. These receivers were using a SIM card to access Teleclock transmitters. Mobile Teleclock receivers used GPRS modems. The limitation of availability of landline connecting at remote locations was overcome by mobile Teleclock service. The accuracy of this service was less than 1 s. However, this service was shut down in 2016 (Fig. 7).

FonOclock is the upgraded version of Mobile Teleclock (Arora et al. 2017) which is expected to give accuracy of the order of 10 ms. The system includes a transmitter server, a receiver, and a transmission channel. The connectivity over PSTN is used as the transmission channel. The receiver communicates with the time server by dialing the transmitter number on the ver PSTN network. After receiving the data from the transmitter, the receiver corrects its time for path delay as well as the actual date and time. There is a provision to correct the incurred path delay which makes the system better than that of earlier ones with better accuracy (Agarwal et al. 2019). FonOclock

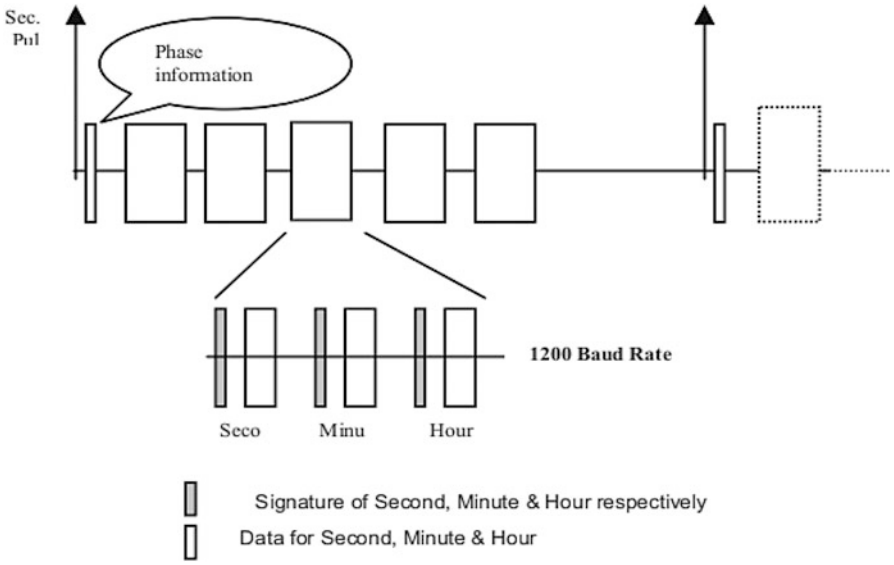

Fig. 7 Teleclock service data Format

transmitter, like Telethelclock, is connected to the public switched telephone network (PSTN) via a dedicated telephone line (Poudel et al. 2019). The receiver contacts the transmitter and requests timing information during the synchronization process. The link delay between the transmitter and receiver is calibrated after the authentication and link establishment processes are completed successfully. The delay compensated digital time information is then transmitted over the PSTN as an audio frequency signal. When a time code is successfully received, the receiver sets its clock and acknowledges the time server (Fig. 8).

The primary difference between transmitter and receiver is that no external 1 PPS is required to run the clock in the receiver. Using a software counter, the duration of a second is directly extracted from the oscillator used in it. The system employs a standard 10–20 ppm crystal oscillator. However, if greater stability or performance is required, better oscillators such as temperature-compensated oscillators, oven-controlled oscillators, and so on can be used. However, the system's cost will inevitably rise.

Network Time Dissemination

Daytime Protocol

This protocol is commonly used by small computer systems running MS-DOS, Windows, and other similar operating systems. The server listens on port 13 and responds to the client in either tcp/ip or udp/ip format in this protocol. Daytime Protocol is mentioned as a service in RFC 867 (1983), which defines Internet

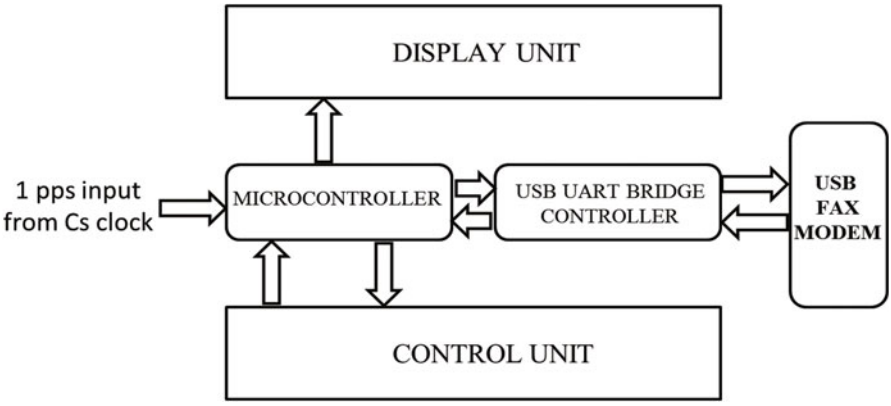

Fig. 8 Block diagram of transmitter/receiver hardware of FonOclock at CSIR_NPL

protocol suite (IPS) (Postel 1983). It is possible to form and measure computer networks. On TCP or UDP port 13, a host can communicate with a Daytime Protocol server. In an unspecified format, the server returns an ASCII character string containing the current date and time.

Time Protocol

The Time Protocol is a network protocol that was defined in 1983 in RFC 868 (Postel and Harrenstien 1983) by Jon Postel and K. Harrenstein as part of the IPS. It is aimed at providing a date and time which could be understood by machine and also is not position reliant. The Time Protocol can be implemented using either the TCP or the UDP protocols on port 37. The time is transmitted as 32-bit unsigned integer corresponding to the number of seconds elapsed since 00:00 (midnight) January 1, 1900, GMT. The connection of the server is terminated after this. Because there is no UDP connection setup, operation over UDP necessitates sending any datagram to the server port. Because of the fixed 32-bit data format, the timestamp resets every 136 years, with the first occurrence on February 7, 2036. Programs that use the Time Protocol must be carefully designed to distinguish these dates from those in 1900 by utilizing context-dependent information. The Time Protocol was used by many Unix-like operating systems for clock timestamping using the date utility. But NTP provides a more advanced solution with accuracy in milliseconds.

This straightforward protocol yields a 32-bit unformatted binary number representing UTC time in seconds since January 1, 1900. It's no longer commonly heard. The server accepts Time Protocol requests on port 37 and responds in tcp/ip or udp/ip format. The time is converted to local time by the client program (if necessary). The 32-bit binary format, with a resolution of 1 s, can represent times ranging from 136 years to 136 years. There are no provisions for extending the resolution or the time limit. The strength of the Time Protocol lies in its simplicity. Because many computers internally store time as the number of seconds since January 1, 1970 (or another date), converting received time to the required format

is often as simple as binary arithmetic. However, no additional information, such as advanced notification of leap seconds or daylight saving time, or information about the server's health, can be sent using this format.

Time Dissemination Using the Internet: NTP

Network Time Protocol

Network Time Protocol is abbreviated as NTP. It's a protocol for synchronizing the time on the Internet. It uses the Internet to synchronize computer clocks to a time reference. Prof. David L. Mills of the University of Delaware devised this protocol. NTP can sync all connected computers within a few milliseconds of Coordinated Universal Time (UTC) (Riehle 2004). It uses a modified version of Marzullo's algorithm to select the correct time server. It is intended to reduce the impact of network latency on time synchronization. Asymmetric routes and network congestion can result in errors of 100 ms or more (Lavineavine 2008; Blair 1974).

NTP provides a mechanism for synchronizing the local machine time with the Coordinated Universal Time. It employs a returnable-time design in which a distributed subnet of time servers self-organizes. NTP accuracy is determined by the precision of local-clock hardware as well as transaction latency. Even if the primary reference source is lost, the mechanism can maintain millisecond accuracy. NTP timestamps are represented as an unsigned fixed-point number of 64 bits (Mills 1989).

NTP is commonly referred to as a client-server architecture, but peer-to-peer architecture is also associated with NTP. Figure 9 depicts (Riehle 2004):20. Implementations use the User Datagram Protocol (UDP) on port 123 to send and receive timestamps (Mills 1981; Su 1981). Other modes for configuring NTP server are broadcasting or multicasting (Eliezer et al. 2007). The current version of the NTP, according to RFC 590,5, is NTPv4. It was, as documented in RFC 5905, the proposed standard.

Development of NTP

The application of network time synchronization finds its root in 1979. However, satellite-based Internet time synchronization technology was exhibited in New York's Conference on National Computer, which was mentioned in the 1981 published Internet Engineering Note (IEN) 173. This is how a public protocol got evolved as RFC 778 (Mills 1981). Realized using the Fuzzball router, this technology was used in LAN with preexisting "Hello" protocol.

The Daytime and Time protocols are two network tools for time synchronization. They are used to record the time of events and the timestamp of ICMP messages. They are also used to timestamp Internet protocol (IP) (RFC781) (Su 1981). The

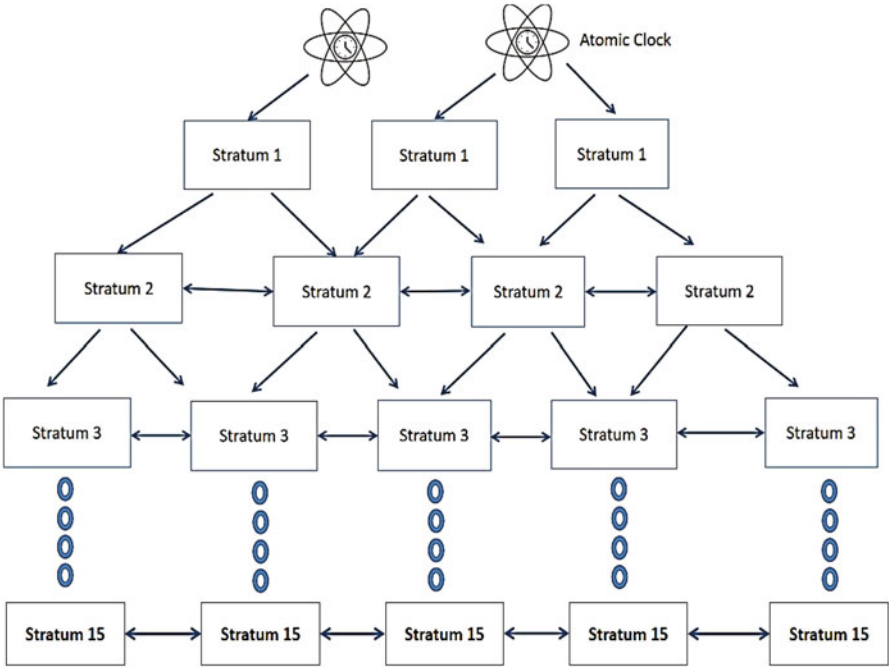

Fig. 9 Stratum structure of NTP architecture

Unix timed daemon provided better synchronization than the Daytime and Time protocols. An election algorithm was used in this protocol to identify the master server for client synchronization. However, this protocol did not perform any data analysis and did not use a clock disciplined algorithm like NTP. The Digital Time Synchronization Service (DTSS), like the NTP architecture, had a hierarchical structure of synchronization servers.

In 1985, Fuzzball- and Unix-based implementation of the initial version of NTP was achieved in the name of NTPv0. The RFC 958 elaborates on the important computations involved in the latest NTP form NTPv4 like offset and network delay (Mills 1985a). It is the specialty of this protocol that the best performance (surpassing 100 ms) was achieved even with contained devices available then.

RFC 1059 (Mills 1988) published an NTPv1 protocol with more specifications and associated algorithms in 1988. NTPv1 pioneered and explained client-server and peer-peer architecture which is existing to date and is considered as the best methodology for network time synchronization. RFC 956 (Mills 1985b) details the algorithm for clock filter with results as was published in 1991 IEEE Transactions on Communications by David L. Mills.

NTPv2 was published in 1989, using a state machine and pseudo-code to describe its operation, which was documented in RFC 1113. Management protocol with cryptographic authentication scheme was first time implemented in this version of

NTP. The DTSS penalized NTPv2 for a lack of formal correctness. As a result, from NTPv3 onward, Marzullo's algorithm was adapted for clock selection (Eliezer et al. 2007). NTPv3 was implemented in 1992 and documented in RFC 1305 (Mills 1992). The RFC contained an analysis of all potential sources of error, allowing calculation of a method for best server election. The broadcast mode was added to this version. NTPv3 was in use for quite a long time till 2010 when RFC 5905 proposed NTPv4 provisions (Mills et al. 2010).

Basic Features of NTP

NTP makes use of a reference clock, like a GPS, calibrated cesium clock, calibrated rubidium clock, NIST telephone time service, PTB telephone time service, or radio navigation service like LORAN-C. These clocks determine the correct time of the system. The NTP architecture's stratum-0 is the reference clock. For greater accuracy, NTP servers synchronize with the reference clock. UTC is typically used as the reference time for NTP time services. NTP is a fault-tolerant protocol. NTP is both accurate and scalable. NTP provides up to tens of milliseconds of accuracy over a wide area network (WAN) and less than 1-millisecond accuracy over a local area network (LAN). NTP provides good accuracy even in the absence of a network (temporarily). In the absence of network connectivity, NTP uses measurements from previous values to synchronize the local clock.

Architecture of NTP

NTP employs a hierarchical, semi-layered time source system. It's a top-down synchronization approach, where each step/layer is termed as stratum. The stratum starts with a reference clock itself and is identified the d as 0th stratum. The next layer, i.e., stratum-1, is directly connected to the previous stratum and gives synchronization to the following stratums in the architecture. It should be noted that the stratum numbers only specify the distance of the NTP server from the reference atomic clock (i.e., stratum-0) and do not necessarily depict the performance of the NTP server. It shows that the server is in synchronization in the hierarchy. It must be noted that clock strata are defined differently in telecommunications systems. The basics of various strata are explained in brief below:

Level: Stratum-O

Reference source races themselves are termed as 0th stratum Reference time source can be anything as calibrated cesium source, calibrated rubidium clock, NIST,

USNO telephone time service, or radio navigation services like LORAN-C or satellite constellations like GPS, GLONASS, or NAVIC. Precise time and frequency signal generated by this source is used to synchronize the connected NTP server, which is then termed stratum-1.

Level: Stratum-1

The servers which are first in layer and are directly connected with reference sources, i.e., 0th stratum, are termed as stratum-1. Due to this, microsecond-level synchronization to that of reference clocks is possible in this level. For sanity checks and backup, stratum-1 NTP servers may peer with other stratum-1 NTP servers (Mills et al. 2010). They are primary time servers (Lavineavine 2008; Blair 1974).

Level: Stratum-2

These are the systems that are network-synchronized with stratum-1 systems and provide synchronization to the next level in stratum (i.e., stratum-3). Besides being an interface layer between stratum-1 and stratum-3, it works on peer synchronization within this layer as well. Hence, NTP becomes an extremely robust architecture with consistent timing.

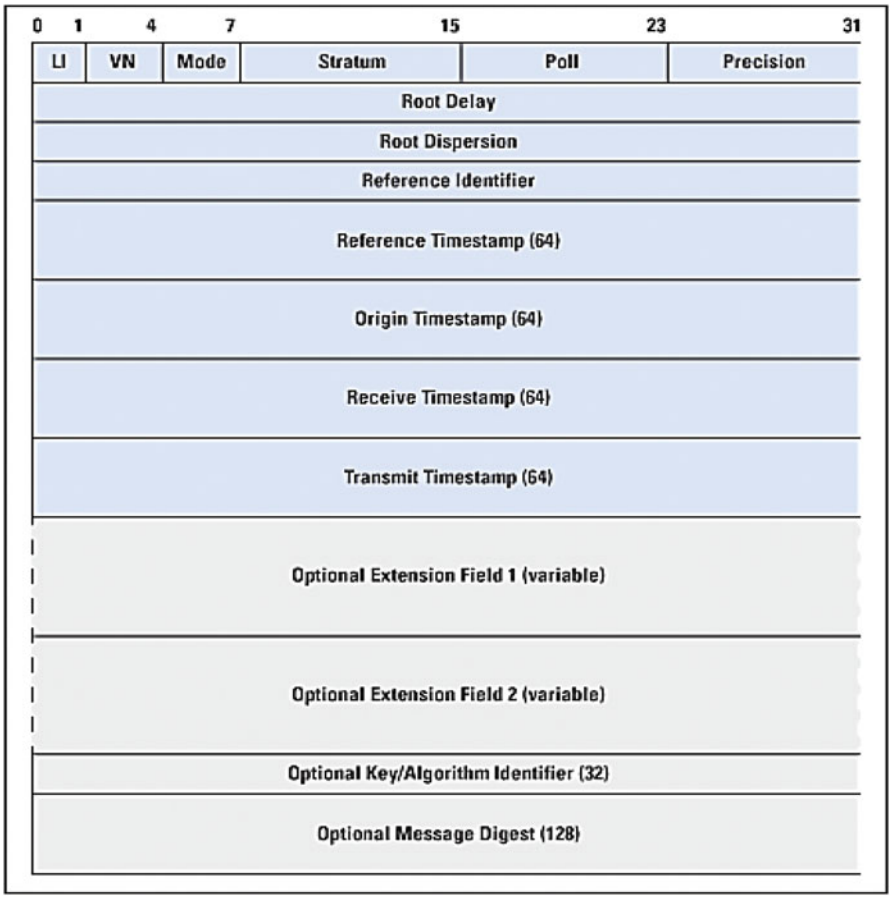
Level: Stratum-3

As mentioned in stratum-2, this is an intermediate stratum between stratum-2 and stratum-4. The functionality of this stratum is almost similar to that of earlier stratum-2 by taking synchronization from stratum-2 and providing synchronization to stratum-4 with peering capabilities. This continues till stratum-15.

The last stratum in the architecture is stratum-15; the next level, stratum-16, indicates that a device's clock is out of sync. Each computer's NTP algorithm collaborates to construct a Bellman-Ford shortest-path spanning tree in order to reduce the total round-trip delay to stratum-1 servers for all clients (Riehle 2004).

NTP employs a 64-bit timestamp. Seconds are represented by 32 bits, and 32 bits are used for displaying the fractional value of the second. NTP employs the January 1, 1900, epoch. The protocol is expected to be extended to 128 bits in future NTP versions. But Dr. Mills believes that the 64-bit value is more than sufficient as it can signify the second's value to the utmost resolution and any ambiguous depiction of time can be avoided using these timestamps (Banerjee et al. 2012b).

NTP Message Format



Algorithm

For details of each field of the message format, refer to RFC 4330 (Fig. 10).

A typical NTP client will poll three or more servers on different networks on a regular basis. To synchronize its clock, the client must compute its time offset and round-trip delay using Eqs. (1) and (2). The time offset and the round-trip time are denoted by Eqs. 1 and 2, respectively. T_1 is the client's request packet transmission timestamp, T_2 is the server's request packet reception timestamp, T_3 is the server's response packet transmission timestamp, and T_4 is the client's response packet reception timestamp.

Figure 2: Reference Identifier Codes (from RFC 4330)

Code	External Reference Source
LOCL	uncalibrated local clock
CESM	calibrated Cesium clock
RBDM	calibrated Rubidium clock
PPS	calibrated quartz clock or other pulse-per-second source
IRIG	Inter-Range Instrumentation Group
ACTS	NIST telephone modem service
USNO	USNO telephone modem service
PTB	PTB (Germany) telephone modem service
TDF	Allouis (France) Radio 164 kHz
DCF	Mainflingen (Germany) Radio 77.5 kHz
MSF	Rugby (UK) Radio 60 kHz
WWV	Ft. Collins (US) Radio 2.5, 5, 10, 15, 20 MHz
WWVB	Boulder (US) Radio 60 kHz
WWVH	Kauai Hawaii (US) Radio 2.5, 5, 10, 15 MHz
CHU	Ottawa (Canada) Radio 3330, 7335, 14670 kHz
LORC	LORAN-C radionavigation system
OMEG	OMEGA radionavigation system
GPS	Global Positioning Service

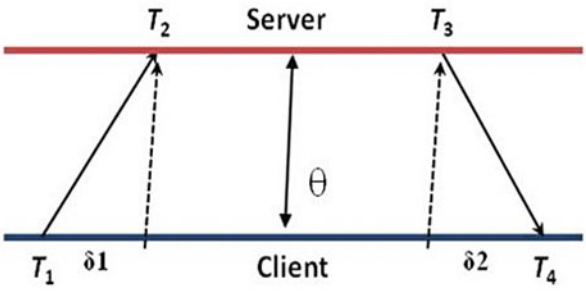
Fig. 10 Reference Identifier Codes (from RFC 4330)

The synchronization is correct when both the paths (i.e., from client to server and vice versa) followed between client and server are the same or encounter a delay of a similar value (Fig. 11).

But this is not the case in practical networking conditions. Hence, a systematic bias of half the difference between the forward travel time and backward travel times always exists (Matsakis et al. 2014).

NTP Security

NTP is linked to a slew of security issues. NTP servers are prone to man-in-the-middle attacks. As a result, cryptographic signing of NTP packets is required for authentication. Security of transport layer T-L-S, security extension of DNS, caching methods like DNS, gateway protocol like B-G-P, and other permanent login systems are some of the concerns with the NTP service. A Network Time Protocol (NTP) server can be damaged or degraded by a variety of NTP server misuse and abuse behaviors. NTP has been utilized in DDoS assaults. In this NTP server receives a small request spoofing the return address. This makes the NTP server send heavier data packets in response, which allows the hacker to significantly upsurge the number of packets transmitted to the destination. This issue is being targeted and it is expected that in upcoming versions, i.e., NTPv4, it will be taken care of.



$$\theta = \frac{1}{2}[(T_2 - T_1) + (T_3 - T_4)] \quad (1)$$

$$\delta = (T_4 - T_1) - (T_3 - T_2) \quad (2)$$

Fig. 11 Methodology of NTP

Modes of Operation

Based on the peers involved in the network, there are three classes in which the NTP time servers may operate: multicast, procedure-call, and symmetric.

Multicast class is used in high-speed LANs with a large number of workstations. The highest level of precision isn't sought in this case. The servers running in multicast mode regularly send NTP timestamp packets. Based on an expected delay of a few milliseconds, peers in client mode calculate the accurate time. Clients receive synchronization from the server in multicast mode, but the server does not receive any messages from the clients.

The procedure-call class is intended for use with file servers where great precision is required. The client sends an NTP message to the corresponding NTP server in the procedure-call. The server then takes the following steps:

- Swaps the addresses.
- Necessary timestamps are inserted.
- Performs the recalculations of checksum and optional authenticator, and sends the message (return back) promptly.

Symmetric active mode is intended for servers that operate at or near the top of the stratum. The servers that communicate with a huge number of peers regularly but on an irregular basis use the passive symmetry mode. These servers operate at low stratum levels.

A loosely linked connection is established when two symmetrically functioning servers exchange messages for the first time. Each server instantiates the NTP machine with persistent state variables; nonetheless, the protocol machine's primary goal is to preserve timestamps and related data, not to guarantee delivery. As each message is received in synchronic mode, the server updates the reachability status

every time, and if this status has not been updated for a long time, the server dissolves the association and restores state storage (Mills and Member, IEEE 1991).

NTP v4 Features

NTPv4 features quick synchronization at startup and after a network failure, which reduces network delay in time synchronization. The clock discipline algorithm in this version has been redesigned. It also allows clients to use the automatic server discovery feature, which aids in the discovery of live servers. It also includes updated and new reference clock drivers. It also supports new platforms and operating systems, allowing it to work with a wide range of new platforms. Public key cryptography is used. It works with the nano-kernel.

Advantages of NTP Synchronization

Event synchronization and server log file forensics both benefit from accurate timekeeping. The time on the Internet must be precise and consistent to support both of the responsibilities mentioned above. The Coordinated Universal Time is used to synchronize the clock on a server. A list of NTP's numerous benefits are as follows:

Accurate Time

The delay introduced due to communication over Internet is improved (for time) by the time server. This inaccuracy is generated due to the time taken by the synchronized signal to reach the user. If this inaccuracy is not removed, it may lead to bad results.

Reliable Time

To ensure accurate time delivery to all network clients, the time server uses multiple sources and a high-speed NTP processor. A local time server also ensures network reliability.

Security and Verifiable Audit Trail

For securing the operations over the network, secure timestamps play a major role. NTP servers provide security features like keypad lockout which gives controlled access to the server. Client authentication and independent network ports are the features considered for network deployment and are available with NTP servers with associated software.

Ease of Use

Network time servers are simple to set up and maintain. Their upkeep is simple. IPv4 and IPv6 are both supported by time servers (Amtest-TM Kft 2021).

Time Dissemination Using the Internet: Precision Time Protocol (PTP)

In 2002 PTP was established as IEEE 1588 standard. This is the standard established to provide precise (better than milliseconds as was provided in NTP) synchronization of networked clocks which is also required for control synchronization applications (Mills and Member, IEEE 1991). Ethernet is a competent technology for transporting data over a LAN and WAN. However, putting it into practice in mobile backhaul is a huge difficulty. Nanosecond accuracy is required for synchronizing base stations in mobile backhaul. Due to the high precision, the radio spectrum is not distributed into neighboring cells. As a result, if phase synchronization is not strictly enforced, most of the signals will get cancelled themselves in LTE-MIMO design. The IEEE 1588v2 standard was developed specifically for this purpose.

A computer network's clock is synchronized via the Precision Time Protocol. On a LAN, it achieves sub-microsecond clock accuracy, making it useful for measurement and control systems. Financial transactions, mobile phone tower transmission, and networks that are not connected to satellites but require accurate time can all benefit from PTP. For time distribution and clock synchronization, the architecture supported by PTP is a hierarchical master-slave one. Many slave/boundary clocks with single or multiple communication networks comprise a dissemination system of time in hierarchical architecture. To ensure master and slave device synchronization, timestamps of incoming and outgoing packets must be recorded (Fig. 12).

An ordinary clock has only one networked connection and serves as either a master or a slave for the synchronization reference. One section of a network is precisely synchronized with another section with the help of a boundary clock. It has

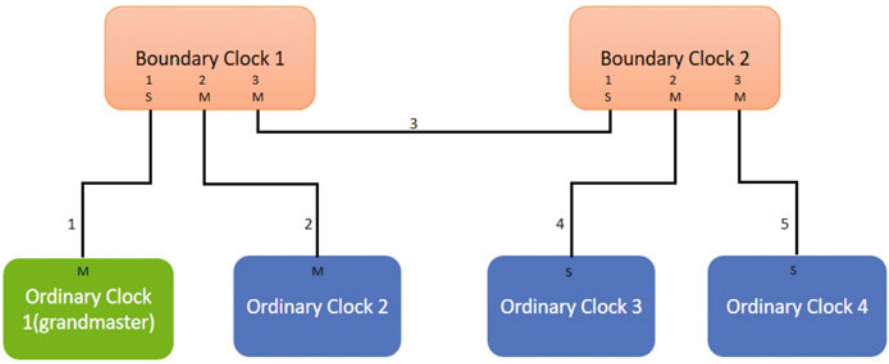


Fig. 12 Hierarchical structure of PTP time synchronization

many connections. A simple PTP network comprises ordinary clocks connected in the same network, and there are no boundary clocks. It's a networked clock system with a master-slave topology. An ordinary clock can only be a source or a receiver and has one network. There are five kinds of PTP clocks: transparent clocks include conventional clocks, boundary clocks, end-to-end transparent clocks, peer-to-peer transparent clocks, and management nodes (Laird 2012).

Ordinary clock is any equipment with single port which is capable of functioning as a master as well as slave clock.

A boundary clock is a multi-port device that can function as both a master and slave clock. A boundary clock is typically composed of a built-in slave clock that recovers a clock. This clock is then used to power the built-in master, which in turn supplies the clock to the next node.

End-to-end transparent clock is a multi-port device that is neither a master nor a slave clock, but rather serves as a bridge between the two. Its role is to forward and add correction. The bridge residence time is corrected by adding it to a correction field in the message's header.

Transparent peer-to-peer clock is a multi-port device that is neither a master nor a slave clock. It serves as a link between the slave and master clocks. Sync and follow-up messages are adjusted and forwarded by this device. Header of the message is updated with the delay incurred and this is how adjustments for delay are accomplished.

Management Node: It is a device that performs two main functions: configuration and monitoring of clocks. The round trip of PTP is shown in Fig. 13.

PTP selects the master clock/time source by employing the BMC algorithm. An ordinary clock computes the master-ordinary clock offset based on the relationship between the ordinary clock and the master clock:

$$\mathrm{del(t)} = \mathrm{Ord(t)} - \mathrm{Mas(t)} \tag{3}$$

Here, del(t) is the offset between the time of the slave clock and the time of the master clock, Ord(t) is the ordinary/slave clock time, and Mas is the time of the master clock (t). The master clock broadcasts the correct time to the slave clocks.

At time $t1$, the master clock sends a sync message to all slave clocks, kicking off the broadcast. When the slave clock receives the sync message, it records the internal time $t1'$. The master sends a follow-up message with the timestamp t1. To be accurately synchronized, the clocks must calculate the transit time of the sync message independently. Calculating the round-trip delay between each clock and its master can be used to determine the transit time. The slave clocks initiate a conversation with their master to determine the transit time k. Let us assume at an instance t2 ordinary/slave clock queries Delay_Req message to the master. This query is received at the master clock at instance $t2'$. In response to the slave clocks query, the master clock replies with a response message as "Delay_Resp." The corresponding timestamps generated are t1, $t1'$, t2, $t2'$. Let us assume that if the time taken by sync message is k and the difference of time between the master clock and slave clocks "del′" is uniform, in that case

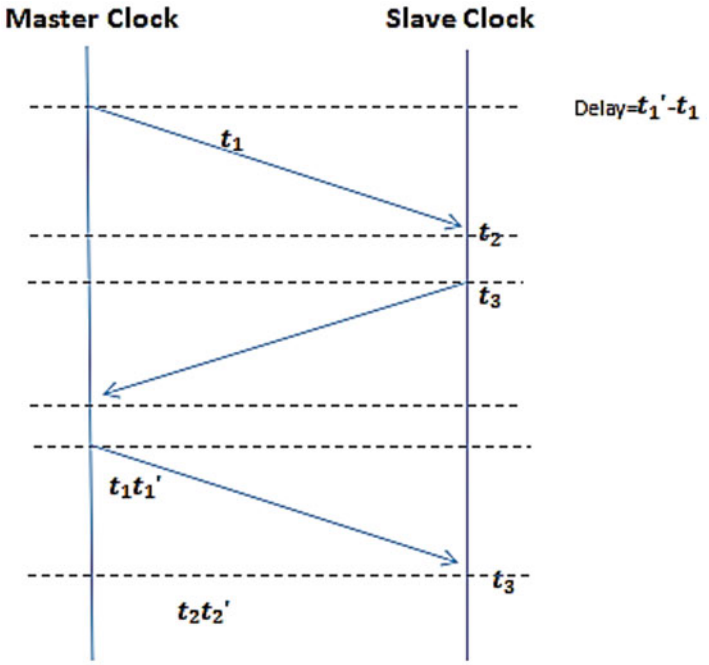

Fig. 13 Round trip of PTP

$$t1' - t1 = del' + k \tag{4}$$

$$t2' - t2 = -f' + k \tag{5}$$

By combining Eqs. (4) and (5), the findings are

$$f' = \frac{1}{2}(t1' - t1 - t2' + t2) \tag{6}$$

The clock can now synchronize itself with the master clock by calculating the offset. It has a grandmaster clock as its primary timing reference. Each of the system's Internet segments has its own synchronization master. The timestamp is transmitted via the network by this grandmaster clock. The timestamp provided by the grandmaster clock is then compared to all of the slave clocks. Then, based on the obtained timestamp, adjust their time.

PTP Messages: The PTP messages are used to synchronize the slave clock with the master clock. There are two kinds of messages in the PTP: event messages and general messages. Event messages are timed messages that generate an exact timestamp during transmission and reception. A timestamp is not required for a general message, but it may include timestamps for the event messages with which it is associated. The messages used in PTP are shown in Table 1.

Table 1 Communication massages used in PTP synchronization

Event messages	General messages
Sync message	Announce message
Delay_Req message	Follow_Up message
Pdelay_Req message	Delay_Resp message
Pdelay_Resp message	Pdelay_Resp_Follow_Up message
	Management
	Signaling

Best Master Clock Algorithm: The best master clock (BMC) algorithm chooses the best candidate clock by considering the clock properties.

Identifier – All devices have a specific identifier for the clock. This is usually derived from the MAC address of a device.

Quality – In PTP data field stratum computations are mentioned in its version1. However, both versions define the quality of the clock depending upon the methodology adopted for clock configuration, a stratum of the clock, and many other features. The two parameters, clock accuracy and clock class, specify clock's quality as per PTPv2. PTPv1 corresponds to IEEE1588:2002 and PTPv2 corresponds to IEEE1588:2008.

Precedence – Grandmaster precedence is assigned by using BMC. A Boolean inconstant is used to mention priority in PTPv1; however, two 8-bit fields are used in PTPv2 for the same.

Stability – In PTP, stability/variance is computed in comparison with the reference clock.

IEEE 1588–2008 utilizes hierarchical selection algorithm, as per the features (IEEE 2008) listed as:

First priority definition – Proactive precedence definition of the user is done with the help of prioritizing every clock in the PTP network. The lower the value, the better the priority.

Class – Every clock belongs to a particular class, with each class having its priority.

Accuracy – Expressed in nanoseconds, the offset value of clock and UTC is defined.

Variance – It defines the jitter value.

Second priority definition – In some situations when normal priority definition doesn't help, a backup order also termed as final priority is defined. Again as mentioned in first priority definition, smaller priority has higher weightage.

Unique identifier - There can be many clocks that are equally capable and match in every respect with another clock, but time selection of the clock is very difficult. That time as a selection criteria, MAC address is considered as the basis. When all other properties are similar, the selection based on MAC address is used as a tiebreaker.

PTP Message Header Format

Figure 14 depicts the PTP message's header, which is 34 bytes long. The messageType field indicates which type of message is contained in the message body, such as Sync, Delay Req, Delay Resp, and so on. The message length field indicates the total length of the PTP message, including the header, body, and any suffix (but excluding any padding) (Calnex Solutions Ltd 2009). The domain number field identifies the domain to which the PTP message belongs. Domains are logical groups of clocks that use the protocol to synchronize with one another but may or may not be synchronized with clocks in another domain. The flags field contains various flags that indicate status.

A correction field includes a correction value in nanoseconds for the residence time of a transparent clock as well as a path delay for peer-to-peer transparent clocks. The source or identity field specifies the port from which this message is originated. The sequence field contains a sequence number for each message type (with a few exceptions). The control field is historical, and its value is determined by the message type; it complies with the standard's version 1 specification. The messageType field is identical, but it has fewer options. The type of message influences the logMessageInterval field.

Announcement Message – When two clocks are in the same domain, the announcement message is used to show the capabilities of one clock to the other

clocks. This enables the establishment of the master-slave hierarchy. Figure 15 depicts the format.

Sync Message

When the sync message was sent, a master clock sent a sync request message containing the master time. If the master clock is a two-step clock, the timestamp in the sync message is set to zero, and the actual sending timestamp is sent later in the associated follow-up message. Both types of PTP delay measurement mechanisms redirect synchronization messages (Fig. 16).

Delay_Req Message

The Delay Req message uses the same format as the sync message. A Delay Req message is sent by the slave clock, which included the slave time at the time the Delay Req message was sent. Delay Req messages are only sent in the delay request-response mechanism (Fig. 17).

Follow_Up Message

A master clock may send a follow-up message that contains the master time at the time the sync message was sent. When the master clock is a two-step clock, sync and

follow-up messages are used. Both types of PTP delay measurement mechanisms send follow-up messages (Fig. 18).

Delay_Resp Message

When the master clock receives a Delay Req message, it sends a Delay Resp message containing the master time. Only Delay Resp messages are sent during the delay request-response process (Fig. 19).

The requestingPortIdentity field contains the source or identity field of the slave that requested this Delay Resp message.

Pdelay_Req Message

A "delay requester" peer-to-peer clock transmits the Pdelay_Req message and includes the time of "delay requester" peer-to-peer clock when the Pdelay_Req

message was transmitted. Pdelay_Req messages are only sent in the peer delay mechanism. The bridge message length may vary due to asymmetry errors caused by networks with different transmit times. Therefore, the reserved field is used to make the message length the same as the Pdelayrespmessage (Fig. 20).

Pdelay_Resp Message

A "delay responder" peer-to-peer clock sends the PdelayResp message. It keeps track of the "delay responder" peer-to-peer clock time when the PdelayReq message was received. Only the peer delay mechanism sends PdelayResp messages. The source or identity field of the "delay requester" peer-to-peer clock that sent the Pdelay Request message is contained in the RequestingPortIdentity field in the PdelayReq message header (Fig. 21).

Pdelay_Resp_Follow_Up Message

A "delay responder" peer-to-peer clock can send the Play Resp Follow Up message, which includes the time of "delay responder" peer-to-peer clock when the PdelayResp message was delivered. It is used when the "delay responder" is a two-step clock with two stages – PdelayResp and Play Resp Follow Up message. Instead of a sending timestamp, this message can send a turnaround time: the time it takes from receiving a PdelayReq to receiving a Pdelay Resp. Only in the peer delay mechanism are PdelayResp Follow Up messages sent (Fig. 22).

Management Message

PTP management messages are used to send information from a clock to a node manager and from a node manager to one or more clocks.

The targetPortIdentity field contains the address of this message's target port/the number of boundary clocks by which this message can be retransmitted, as specified in the starting message. Parameter BoundaryHops.

The boundaryHops field indicates how many boundary clock retransmissions are still available for this management message request or response. This field has the

same value as the startingBoundaryHops field for the first transmission from the issuing clock/node. The action field of this management message specifies the type of action that must be taken. The various types of commands are Get, Set, Response, Command, and Acknowledge. Figure 24 depicts the management fields.

Figure 25 shows how to set the type field to MANAGEMENT (0x0001). The length field specifies the length of the TLV. The format is 2 + N, where N is an even number. The management field specifies the class of management message. Initialize, Enable Port, and Disable Port are some examples.

Applications of PTP Time Transfer

There is a wide range of PTP applications in the digital and cyber world. PTP is a protocol for effective communication between devices utilized in various digital IT applications. It synchronizes PCs and digital devices such as ATMs, IoT devices, routers, and switches by providing timestamping. PTP is found in a variety of microprocessors, network interface cards, and protocol stacks. It's also utilized in

radio frequency instrumentation, aircraft monitoring instruments, and GPS-linked clocks (https://www.geeksforgeeks.org/precision-time-protocol-ptp/. Accessed 20 Apr 2022).

Advantages of PTP

PTP provides several advantages that are very beneficial for digital networks and devices (https://www.artel.com/blog/the-benefits-of-ptp/. Accessed 21 Apr 2022).

Multiple Media Formats – The PTP synchronization method can calculate the precise current phase of any media signal, even if the signals have different time bases. There is no need to have one flavor of PTP for US media networks and another for European media networks; both systems can operate on the same precision timing signal.

No Sync Overlay Network – Ethernet connections are used to disseminate the PTP clock signals, and they are also used for media signals, so an overlay network is not necessary to distribute synchronization. The complexity of cabling systems that connects the cameras to the control units can be greatly reduced.

Suitable for Any IP-Connected Device – There are various interface cards and modules are present in the market that provide timestamping over PTP. These cards are suitable for almost all devices and provide timestamping over PTP.

Highly Accurate for Media Applications – As PTP has an accuracy of better than 1 microsecond, it provides very precise time synchronization for video and audio applications.

Synchronization of Multiple Locations - The PTP grandmasters utilize GPS signals to get their clock synchronized; therefore, they can deliver accurate clock signals to multiple locations.

Time and Frequency Transfer: White Rabbit

CERN created White Rabbit, a time distribution system that can provide nanosecond precision. White Rabbit can distribute time with greater than 1-nanosecond accuracy and frequency with greater than 10-picosecond stability (Diaz et al. 2018). Optical filters and regular Ethernet connections are used to reach this level of accuracy. White Rabbit standards are achieved by enhancing many technologies, such as the Precision Time Protocol, which is utilized for clock synchronization, and the use of the L1 synchronization mechanism (inspired by the SyncE protocol).

PTP services were created to provide an alternate method of synchronization with great precision. However, PTP has challenges with precision over long distances, so the farther a network node is from a master clock, the less confident you may be that high accuracy will be maintained. The White Rabbit was created to address the issue of precision, allowing an Ethernet network to attain sub-nanosecond accuracy across a vast region. Using White Rabbit, networks can run tens of thousands of nodes all

on the same master clock. Telecommunications, financial services, smart grids, and air traffic control are among the commercial sectors that employ it for time synchronization because of its sub-nanosecond accuracy. The White Rabbit is flexible enough that it is compatible with many time transfer application that needs to work over some distance. It is increasingly used in time labs and commercial sectors to ensure sub-nanosecond accuracy (https://www.netnod.se/blog/what-white-rabbit-and-why-does-it-matter-high-accuracy-time-services, Accessed 21 Apr 2022).

The White Rabbit differs from other existing technology in several ways. Satellite-based time transfer systems such as GNSS and GPS all give accurate time at a reasonable cost. They are, nevertheless, quite sensitive. They are easily spoof-able and do not work indoors. PTP, on the other hand, offers a higher level of accuracy that is suitable for practically all current digital devices and applications. The chromatic dispersion of the fiber is compensated with the White Rabbit. Long-distance fiber connections between a master atomic clock and network nodes can be affected by this dispersion. The White Rabbit is designed to provide sub-nanosecond precision over vast distances. It is an open standard. It has open-source software and hardware designs.

NIST disseminated time using White Rabbit. NIST employs WR-LEN modules manufactured by Seven Solutions. A WR time link consists of a grandmaster module with a local 10 MHz and a pulse-per-second (PPS) reference and a slave module with a remote 10 MHz and a PPS, both connected by a single (bidirectional) fiber. The NIST connection's master and grandmaster modules communicate at 1310 nm, while the slave modules communicate at 1550 nm. The NIST time scale room is approximately 100 m away from the time transfer room, which houses the time transfer equipment. A WR grandmaster module in the time scale room receives data directly from the UTC (NIST) signal plane using a 10 MHz and a PPS signal. Through Fiber Link 1, the grandmaster module is connected to a slave module in the time transfer room that reproduces the UTC (NIST) PPS and 10 MHz signals (FL1). These signals will be used to power a TWSTFT Earth station and GPS (Global Positioning System) receiver for UTC (NIST) distribution. By connecting Fiber Link 2 (FL2) to a local slave module in the time scale room, the second fiber port on the remote WR module becomes the master. The outputs of this module are used to monitor and measure WR link stability. Figure 26 shows the setup at NIST.

An optical fiber network was successfully deployed to send precise time signals. A time signal with an 8-ns error was transmitted over an optical fiber link between Delft and Amsterdam. NIKHEF (National Institute for Nuclear and High-Energy Physics) in Amsterdam receives a timing signal from the VSL Time laboratory's atomic clock via an optical connection. A 137-kilometer optical line transports the NIKHEF timing signal back to VSL. In VSL, the received signal and the original signal are compared. After accounting for instrument delays on the Delft-Amsterdam-Amsterdam-Delft link, the received time signal reproduces the broadcast signal with an 8-nanosecond error, as shown in Fig. 27. White Rabbit Precision Time Protocol (WR-PTP) is used to send the time signal. This protocol employs the use of Ethernet. It is possible to measure and compensate for delay (caused by the glass fiber's limited light speeds) by routing Ethernet packets back and forth through the same fiber. By passing the Ethernet

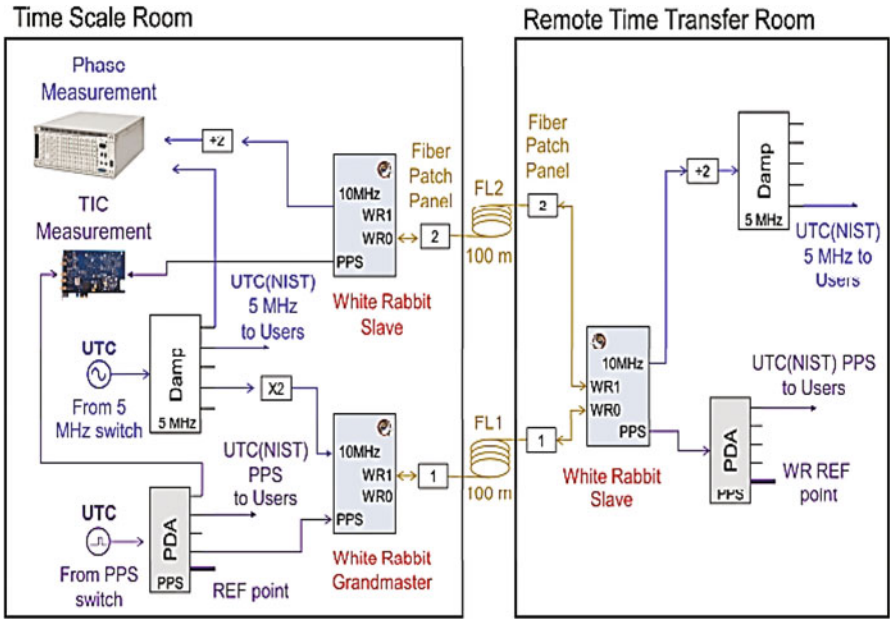

Fig. 26 Layout of the White Rabbit time transfer system used to disseminate time and frequency from the NIST time scale room to the remote location

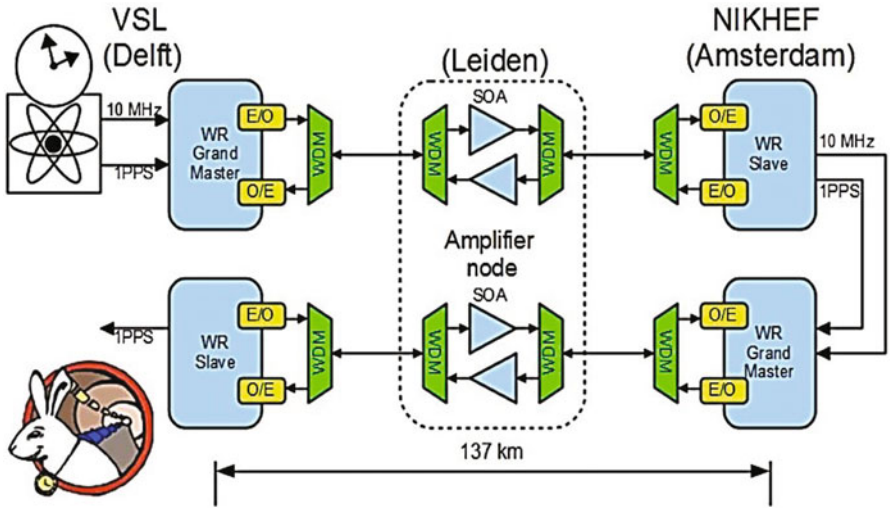

Fig. 27 WR-PTP Delft-Amsterdam-Amsterdam-Delft experiment link

packages back and forth across the same cable, the delay (caused by the glass fiber's limited light speed) can be monitored and adjusted. Because data in fiber typically flows in only one direction, delivering Ethernet packages in both directions over the same fiber is significant in standard telecommunications networks. The Eindhoven University of Technology created a special quasi-bidirectional amplifier to make the WR-PTP possible. They are now focusing on improving the connection calibration approach to further reduce the uncertainty of the time transfer. WR-PTP should be able to achieve sub-nanosecond uncertainty. This means that a timing signal can be disseminated with high precision (i.e., precision of an atomic clock) using the optical fiber, even in case of large distances. In the Netherlands, investigations have begun to roll out a larger network based on WR-PTP for precise time distribution (https://www.vsl.nl/en/about-vsl/news/accurate-time-dissemination-white-rabbit-precision-time-protocol, Accessed 21 Apr 2022).

Time Dissemination over Long-Wave Radio Waves

Long waves of the radio spectrum have a longer wavelength than the medium wave broadcasting band in the case of radio. Radio wavelengths greater than 1000 m are used in this band (frequencies up to 300 kHz). The highest limit is sometimes thought to be higher than 300 kHz, but not higher than 520 kHz. AM broadcasting is carried out across Asia, Africa, and Europe on frequencies spanning from 148.5 to 283.5 kHz. Long wave is a word used to describe a low-frequency broadcasting band that is part of the radio spectrum's frequency in the range of 30–300 kHz.

The radio waves can go beyond the horizon due to their enormous wavelength. Typically, they follow the earth's contour. Long waves propagate mostly via the ground (Seybold 2005). At lower frequencies, the ground absorption losses encountered are smaller compared to higher-frequency signals. The attenuation decreases as frequency lowers. The transmitter can send out low-frequency radio waves as farthest as 2000 km away.

The military employed these waves to communicate with submerged submarines since their penetration power allows them to go deep through saltwater for multitudes of depths. Low-frequency waves are reflected from the ionosphere, which is why they travel such long distances (the real mechanism is refraction), though this method, known as sky wave or "skip" propagation, is not as common as at higher frequencies. The ionospheric E or F layers reflect light. Sky wave signals can be detected up to 300 km (190 miles) away from the transmitting antenna (Melia and G3NYK 2009).

Long-wave receivers fitted inside radio-controlled clocks receive the time calibration signals. The delay encountered and corrected from transmitter to receiver is the same for any location in long-wave time dissemination as in this the signal always travels along the earth's surface. Long waves, unlike medium and short waves, are ground waves that travel along the earth's surface. Higher-frequency signals do not go beyond a few kilometers above the earth's surface, but they can travel as sky waves, bouncing off different levels of the ionosphere at different times

of the day. The time lag for each signal received can vary due to the various propagation pathways. The terrestrial distance of the receiver and transmitter along with the speed of the light through air defines the offset between transmitted and received long-wave signal.

As the time lag in signals received from the same signal station is roughly similar, a single constant shift forward from the time code in the signal may adjust for all long-wave signals received at any one location.

Long-wave transmitters are used to spread timing signals in numerous areas, including the USA, Japan, and Germany. For example, the German Telekom operates the DCF77 long-wave transmitter near Frankfurt (Mainflingen), Germany, at 50 01′ north and 09 00′ east, and the *Physikalisch-Technische Bundesanstalt* (PTB) supervises it. The time signals of the transmitter are guided by commercial Cs atomic clocks at the plant's location. A 77.5 kHz carrier frequency transmits time and frequency, with the amplitude modified by second markers.

The success of the radio-controlled clock is largely due to the features of long-wave emission. Long-wave signals have a significant advantage over time transmission through satellites: they penetrate structures and are unaffected by impediments such as trees or tower block buildings. They can be received without the use of external antennas, particularly with small ferrite antennas included in radio-controlled clocks. Compact radio-controlled clocks powered by batteries or solar cells can be created and operated without the need for a cable connection to an external antenna, thanks to the capability of the long wave. In contrast, receiving signals from the GPS navigation system, as well as the European equivalent Galileo in the future, necessitates the use of an external antenna with a clear view of the sky. If this antenna is deployed, time transmission will have undeniably lower uncertainty. As a result, satellite time transmission and long-wave time propagation will complement rather than replace one other.

By receiving a time signal from radio stations all across the world, an RCC may synchronize its local time to an atomic clock. The majority of radio-controlled clocks pick up signals from the low-frequency band of the radio spectrum (Depari et al. 2015), i.e., 40 to 80 kHz. Long-wave transmitters for time dissemination will continue to be useful in the future, despite the growing relevance of GPS. Prices are lower, power consumption is lower, and the receivers can be used indoors. The LF signal has a coverage larger than that of a radio frequency signal amidst low power, and it is also capable of performing in case of unavailability of line 0f sight with the following advantages:

Reliability on Every Front: Long-wave transmitter can transmit their signals in the kilohertz range. Long-wave radio is used not only for receiving international radio programs but also for transmitting national information.

Superior Performance: With various modes of communication channels available, it is quite difficult to choose the fastest and cheapest mode of communication. Long wave is the robust and reliable channel of communication to disseminate time worldwide.

Mechanical Robustness: The systems have a long-running life and have a low maintenance cost.

Most Economical: Radio transmission is a less expensive way to communicate with a large number of receivers without the need for costly infrastructure such as cables (IFR India 2021). Synchronizing phases in power plants, controlling traffic lights and guiding air traffic, and synchronization of computer and telecommunication networks are among the applications. Furthermore, the time transmitted over long wave is used for accurate phone billing, stock trading, and radio-controlled wristwatches.

Long radio waves are used by NIST to broadcast time and frequency as shown in Fig. 28. Millions of people across North America watch WWVB broadcasts. It transmits the time to digital clocks, clock radios, and wristwatches, among other devices. On a carrier frequency of 60 kHz, WWVB continually broadcasts digital time codes. The time codes are synced with the carrier frequency of 60 kHz and are continually disseminated in two forms at a rate of 1 bit/second utilizing pulse width modulation and phase modulation. The north and south antennas used by WWVB are identical. The north antenna was designed for WWVL broadcasting, whereas the south antenna was designed for WWVB 60 KHz broadcasting. The transmitted signal has a frequency uncertainty of less than one part in 10,000. If the route delay is taken into account, the WWVB may produce UTC with a 100-μs uncertainty. If correct receiving and averaging procedures are applied, the uncertainty can be lowered to the same level as the broadcast signal's uncertainty (https://www.nist.gov/pml/time-and-frequency-division/time-distribution/radio-station-wwvb, Accessed 20 Apr 2022).

Receiving the WWVB signal in ordinary household and official settings has some difficulties. Some regions receive high levels of on-frequency interference from the

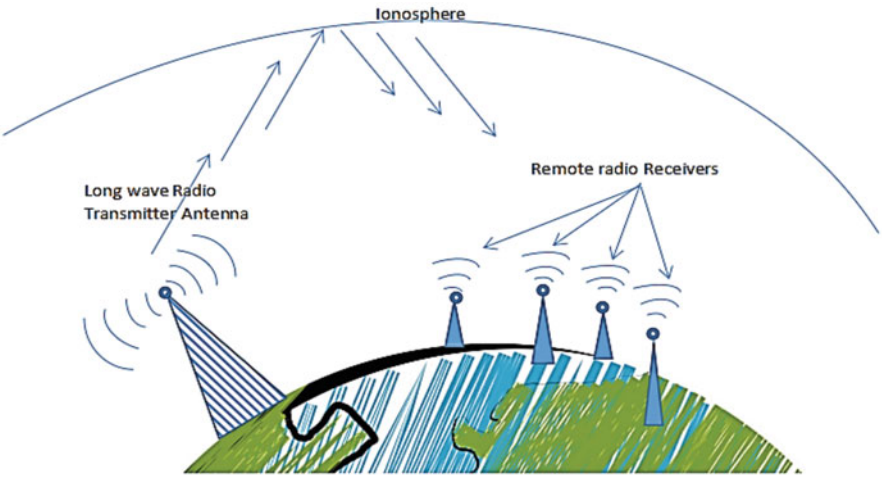

Fig. 28 The long-wave radio broadcast

MSF station in the UK. To address these issues, NIST developed a new protocol and modulation scheme (Eliezer et al. 2007). The enhancements made to the WWVB broadcast increased reception without harming the existing devices. Phase modulation adds several new capabilities while keeping the AM characteristics, allowing for backward compatibility. The new technique enhances timing resolution, but it was meant primarily to improve system robustness by lowering the signal to interference and noise ratio (SINR). The National Institute of Standards and Technology (NIST) began broadcasting a 30-second test signal every 8 min starting November 15, 2021, and every 48 min starting November 16, 2021, on WWV. The Ham Radio Citizen Science Investigation (HamSCI) and NIST have created this signal to assist in ionospheric research.

For weather forecasting, Japan employs the long-wave radio broadcast method. Radio wave broadcast forecasts, which give current and future conditions of radio wave propagation for telecommunications, are the source of Japanese space weather forecasts. In the year 1940, this service began. Because of advancements in rocket and satellite technologies, the significance of radio wave communications has diminished throughout time. NICT's space weather and environment informatics laboratory now provides Japan's operational weather forecast (Nagatsuma 2013).

In LORAN-C, demonstrated in the year 1957, permanent radio beacons transmitted signals to help in identifying the receiver's location. These are low-frequency radio broadcasts. It has a hyperbolic coverage area. It benefited by providing wider coverage with great accuracy which was previously incompatible qualities (Frank 1982). The cost of the equipment required to decipher the signals was a disadvantage. Hence, it was used only for defense purposes initially. The original LORAN was proposed by Alfred Lee Loomis in 1940.

Each LORAN station has a set of specialized equipment that produces precise time signals. The modulation/driving of the transmitting equipment is accomplished using these signals. To create 5 MHz and pulse per second signals, up to three commercial cesium atomic clocks are used. The timing equipment uses these signals to generate GRI-dependent transmitting instrument drive signals. LORAN-transmitter Cs has a max power of 100–4000 kW. The mast radiators in LORAN-C are typically 190–220 m long. The ground is kept away from these radiators. The output power of some LORAN-C (Frank 1983) transmitters reaches 1000 KW and greater. The mast radiators on these transmitters are 412 m tall.

The omnidirectional pattern is radiated by all LORAN-C antennas. As precise positioning is the base for the navigational calculations, using backup antennas is conceptually not possible in the stations of LORAN-C. A backup antenna's slightly altered physical location would result in lines of position that differed from the primary antenna's. LORAN-C has some limitations, such as electronic weather impacts and sunrise-sunset triggered ionospheric impacts. A ground wave following across the surface of the earth proves to be the utmost precise signal (Samaddar 1979). Due to the ionosphere, the ancillary radio wave is reflected on the earth's surface at night. This issue arises because several signals may arrive via various routes.

Results

PTB's telephone time dissemination service operates with three systems (TDS1, TDS2, and TDS3). AS TDS2 works as primary maximum calls are routed to TDS2, e.g., in January 2016, almost 1400 calls were received by TDS2, and TDS which is serving as backup has received approximately 400 calls.

Various results are shown in figures 29, 30, and 31.

Figure 32 shows the results displayed in the number of calls per day averaged over 1 month and their division to TDS1 and TDS2 for the period January 2016–December 2017. The service is mainly used in Germany by utility providers (gas transport sector), to get secure legal time information without the use of the Internet. The number of calls received by TDS2 and TDS1 from 2016 to 2018 is nearly about the same.

Almost 1800 calls per day were received almost every year from 2013 to 2017. The number of calls was averaged over a year. Figure 33 shows that there is a slight decrease in the calls in 2017.

NIST has received 2000 calls per day in telephone time-of-day service in 2019 and 2000 calls in 2020; however, it is reduced to half, i.e., 1000 calls per day in 2021. The service outage duration has also increased in these years as shown in the results below (Fig. 34):

The users can hear the audio portions of the WWV and WWVH broadcasts service using their phones. The delays in time dissemination vary when different mediums are used in communication. The time announcements are delayed by less than 30 ms when landlines are used. It gives stability (delay variation) of less than

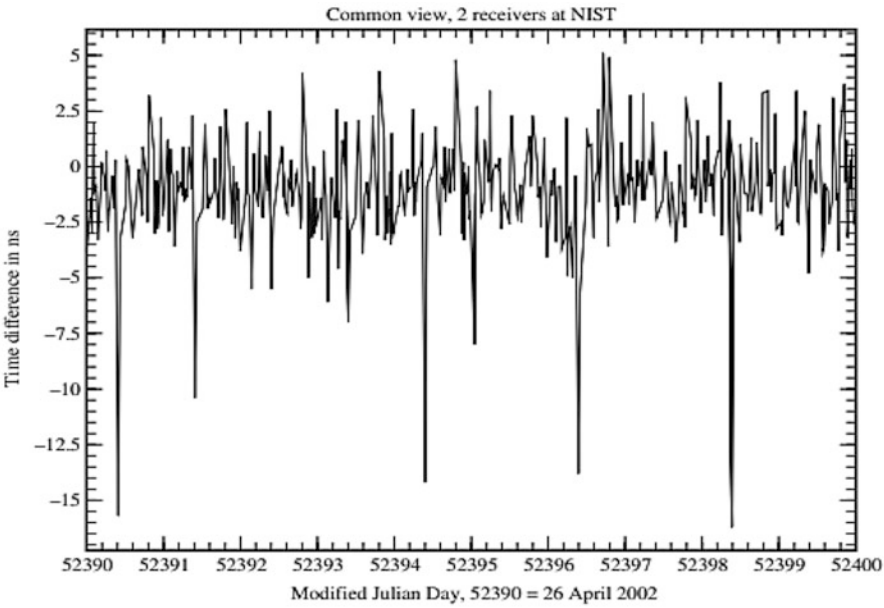

Fig. 29 Bidirectional communication-common view of GNSS receiver at NIST

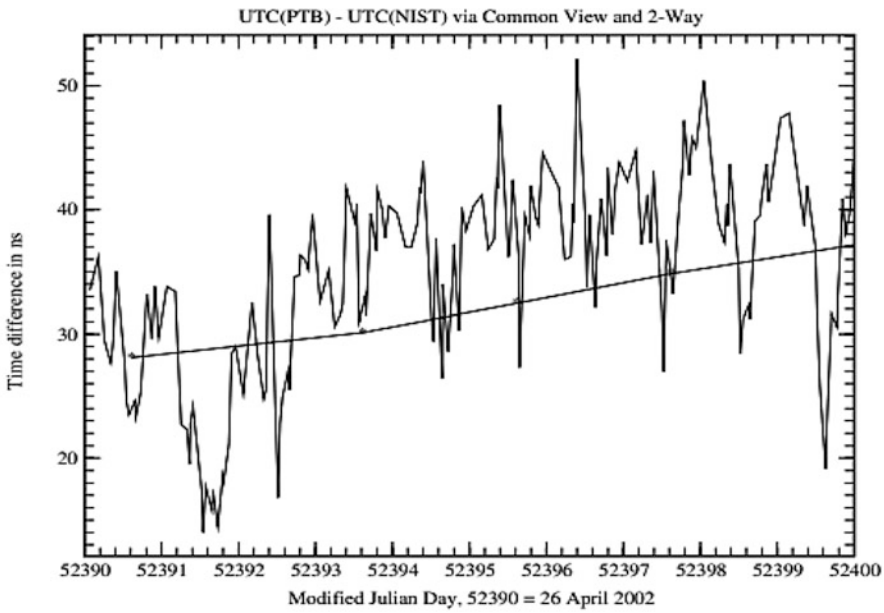

Fig. 30 Results of bidirectional time dissemination: common view and two-way communication offset between UTC (PTB) and UTC (NIST)

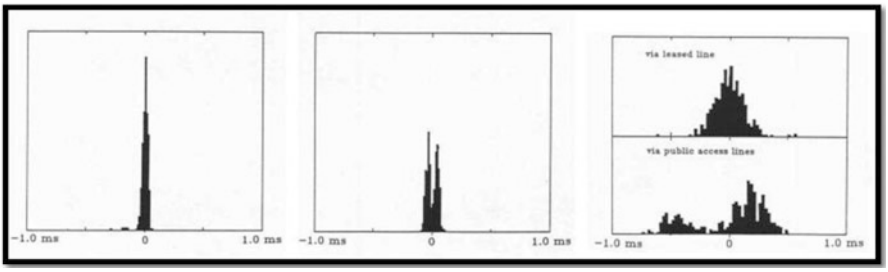

Fig. 31 Histogram depicting precision of NRC telephone time service over 500 calls

1 ms. The delays can be as much as 150 milliseconds in the case of mobile phones or voice over IP networks. The time is delayed by more than 250 ms if the connection is made via satellite phones.

In terms of data reliability received by the receiver, the NPLI Teleclock service has produced extremely good results. Figure 35 shows that by checking and comparing at least three sets of received data, more than 99% confidence in data reliability can be obtained.

Similarly, Teleclock service was able to synchronize the computer clock in real time using GPRS modem. In Fig. 36 results displayed show IST synchronization of computer clock using NPLI's Teleclock service.

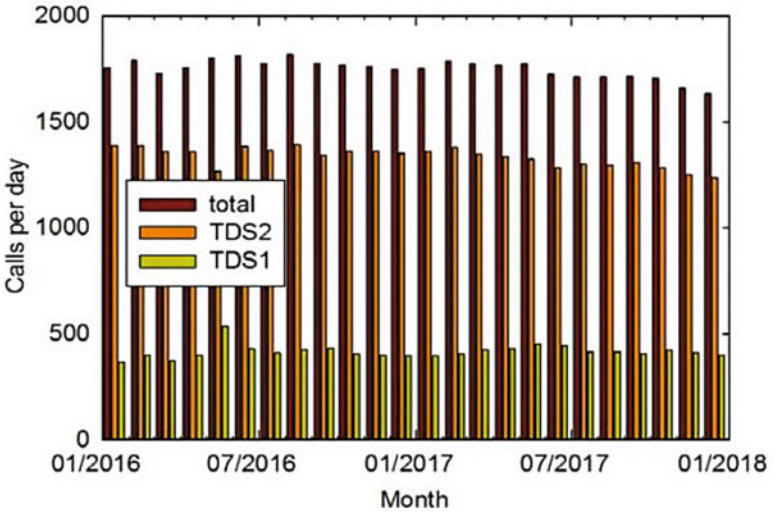

Fig. 32 Histogram demonstrating the usage of PTB's telephone time dissemination service over 2 years

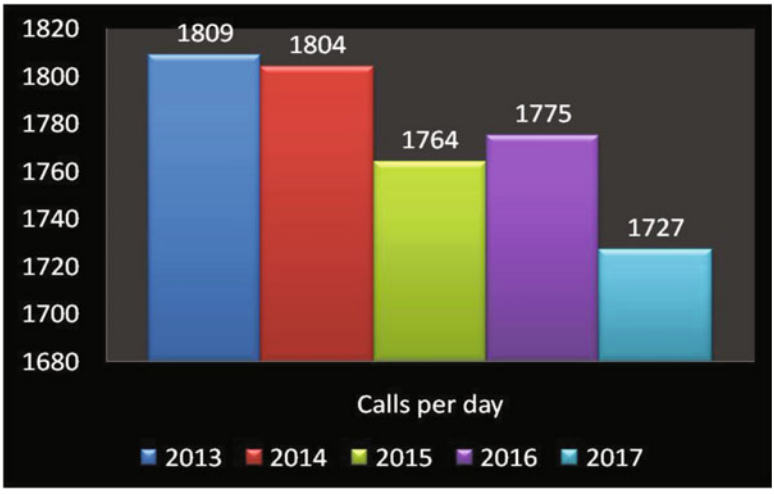

Fig. 33 Histogram depicting usage of telephone time service of PTB from 2013 to 2017

NTP services can be easily accessed by an inbuilt NTP client in Windows systems. The same is displayed in the results shown in Fig. 37.

NTP time dissemination service at NPLI is very popular, as the number of requests received every day is ranging from 12,000 (May 26, 2017) to 142,000 (June 10, 2017) as depicted in the results shown in Fig. 38.

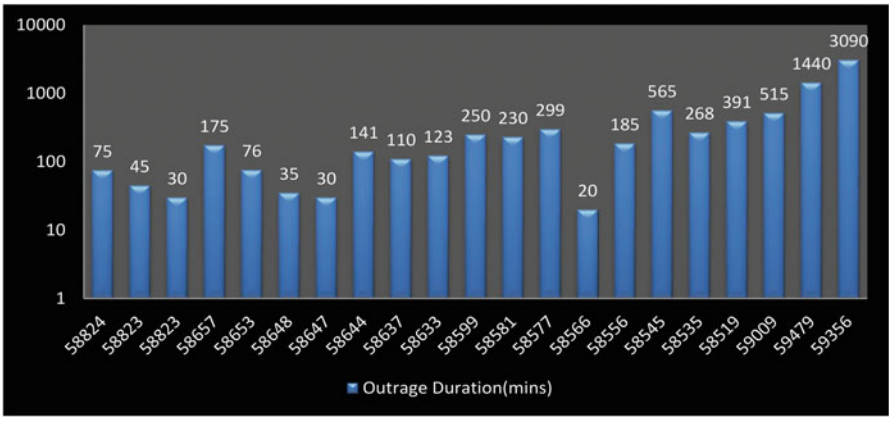

Fig. 34 Results displaying service in minutes of telephone time-of-days service of NIST, USA, from 2019 to 2021

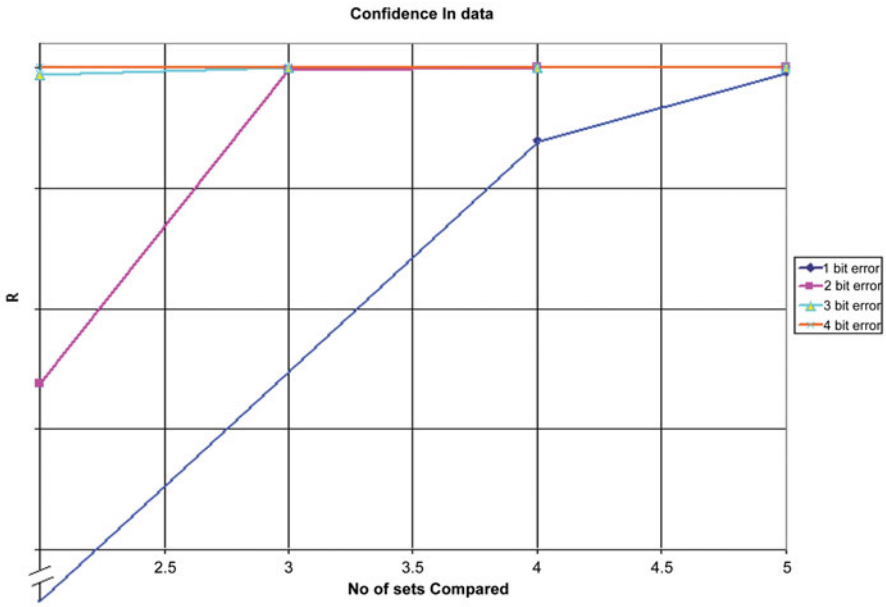

Fig. 35 Results depicting confidence in Teleclock-telephone time dissemination service by NPLI data

NTP services by NPLI are used extensively by many users and some of them are the major ones. For example, IP 110.172.171.194 who have accessed NTP service 249,813 times over a month and IP 203.101.52.55 used this service 3019 times in 1 month as shown in results displayed in Fig. 39. Various stratum-1 NTP servers are

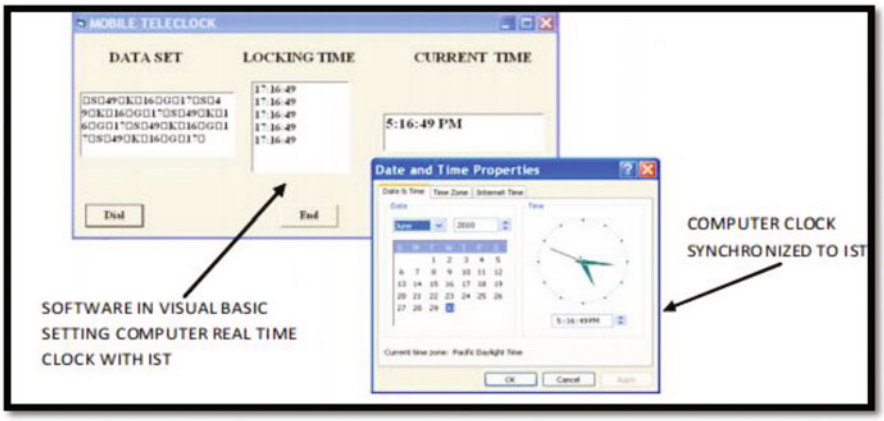

Fig. 36 Results of real-time synchronization of computer time using Teleclock service of NPLI

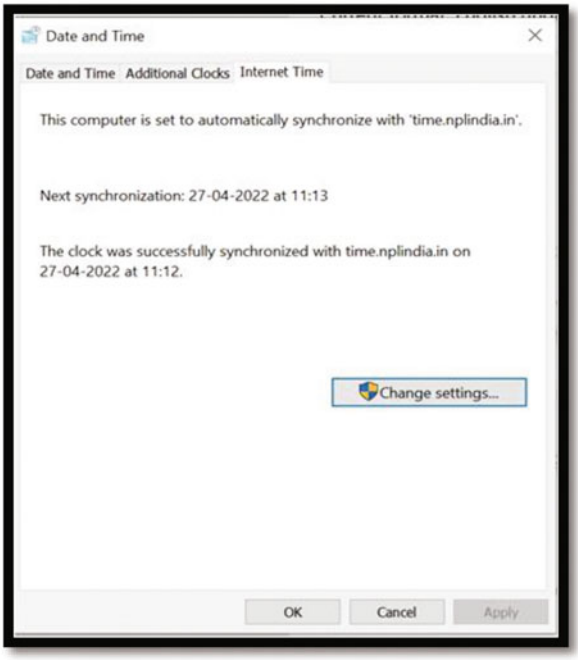

Fig. 37 Results of Windows-based PC synchronization using NTP time dissemination of NPLI

available worldwide now. The performance of geographically diversified NTP services over WAN in terms of RTT is shown in Fig. 40.

Figure 41 shows the NTP service of NPLI used worldwide. However, major portion, i.e., 81.8%, of this service is used by Indian users, 15.5% is used by the USA, some 3.3% are reserved users, and 1.1% are other users.

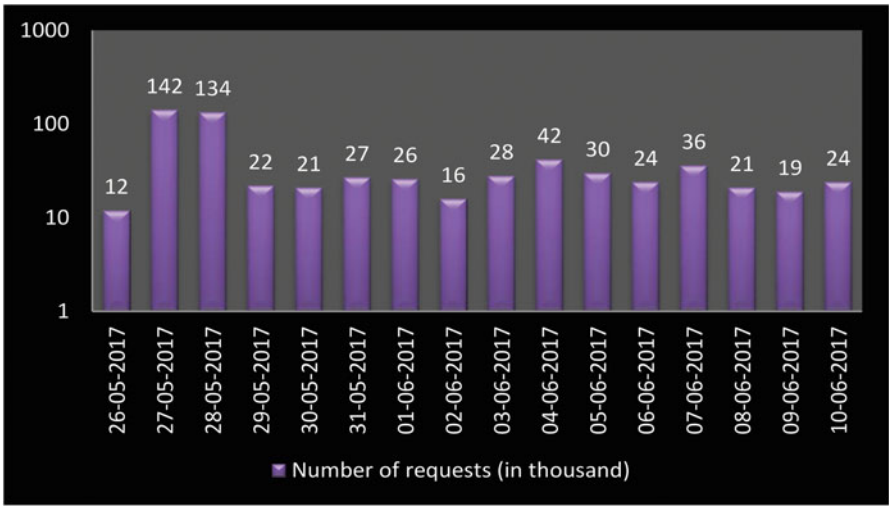

Fig. 38 Histogram depicting the popularity/usage of NTP service of NPLI

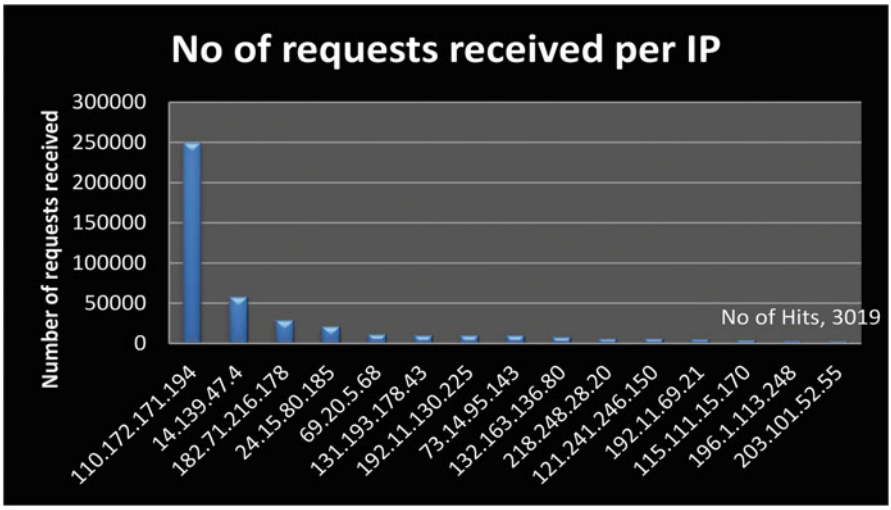

Fig. 39 Histogram depicting the usage of NTP time dissemination service of NPLI by various public IPs over a month

In the experiments, the following configuration is used (refer to Fig. 42). The laboratory experiments' purpose is to provide a better understanding of the field synchronization error behavior and to investigate the PTP clock and/or network parameter settings that can result in an improvement in overall synchronization performance. The experiments in this section are carried out using PTP slave and

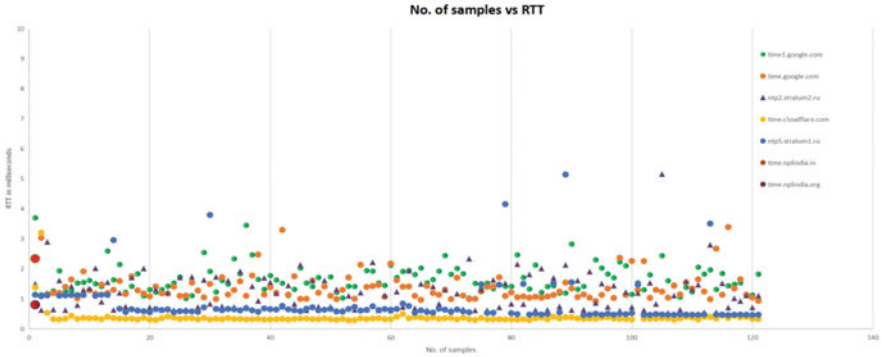

Fig. 40 Results of no. of samples versus RTT of global NTP servers

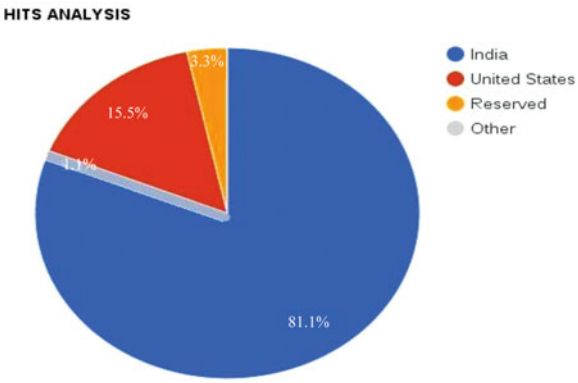

Fig. 41 Countrywide usage of NTP service of NPLI over 1 month

one-step grandmaster prototypes produced by the same manufacturer and referred to as SP and GMP, respectively.

Figure 43a and b show the WAN experimental results (b). The GMP and SP clocks are deployed in remote sites of Hydro Québec's WAN, and the SP clock is synchronized to the GMP via PTP messaging. The local reference clock is a GPS receiver that is synchronized to UTC and is installed in the same room as the SP. The offset between the GPS receiver's 1-PPS output signals and the SP clock corresponds to the synchronization error and is collected every second using an oscilloscope. We conduct two field trials, with the SP clock in Site H and Site R, respectively. For both trials, the rate of the PTP Sync (and Delay_Req/Delay_Resp) messages is set to 64 packets/second (Kassouf et al. 2013).

The low-frequency transmitter DCF77 by PTB, Germany, is by far the best-known service to disseminate legal time for Germany and can also be received in most of Central Europe. A standard frequency of 77.5 kHz is transmitted, as well as

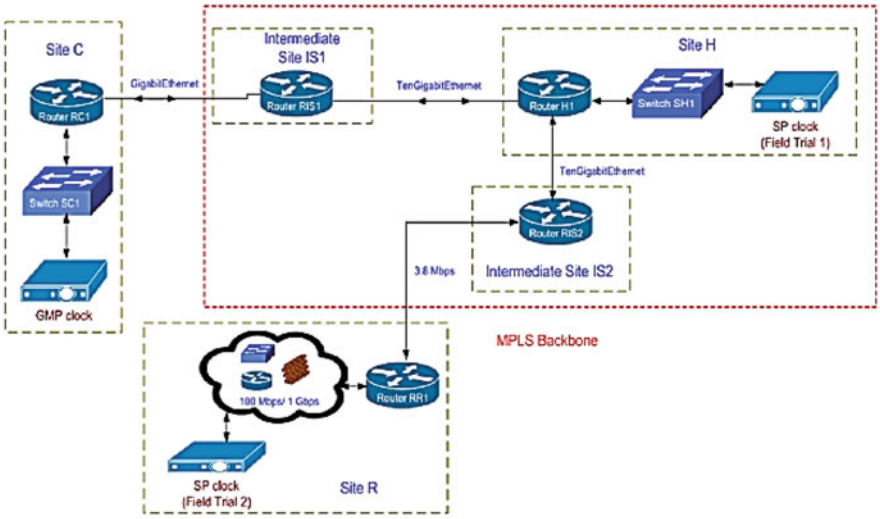

Fig. 42 Hydro Québec's WAN configurations for field trials

coded time information. The Allan deviation was used to calculate the output clock frequency stability, which is depicted in Fig. 44. On the ADC clock signal (ADC RATE), the Allan deviation estimation has been performed. The results indicate how much averaging is required to remove phase noise and achieve the desired stability. Comparable results can be obtained by connecting the DCF77 IN signal to a counter with a gate time that is compatible with the IIR LPF time constant (i.e., 100 ms). The stability of the reference (Levine 2002)-PPS clock signal has been assessed and is depicted in Fig. 45.

Lightning causes powerful noise in low-frequency time dissemination in the LF band or lower frequencies. Figure 46 depicts the effect of this in disseminating a 60 kHz signal. At 60 kHz, atmospheric noise levels are typically 100 dB higher than thermal noise if a theoretical antenna with a gain of 0 dB is assumed. The electrically and physically small receiving antennas used in commercial RCC products are very lossy, and the level of atmospheric noise received in them is less than the thermal noise in the receiver's front end. Lightning from nearby locations can still act as an impulsive interference source, corrupting part of a reception.

Similarly, electromagnetic interference is caused by noises produced by electronic devices and appliances. Figure 47 depicts the effect of this EMI on a WWVB signal at 60 kHz. The effects of EMI caused by office equipment such as computers are also depicted in Fig. 47.

The performance of the LORAN-C signal is evaluated with 100 kHz signal, 100 kW radiated power, sky wave delay of 100 kHz signal, and secondary and additional-phase-factor, smooth earth model for 100 kHz signal, as shown in Fig. 48.

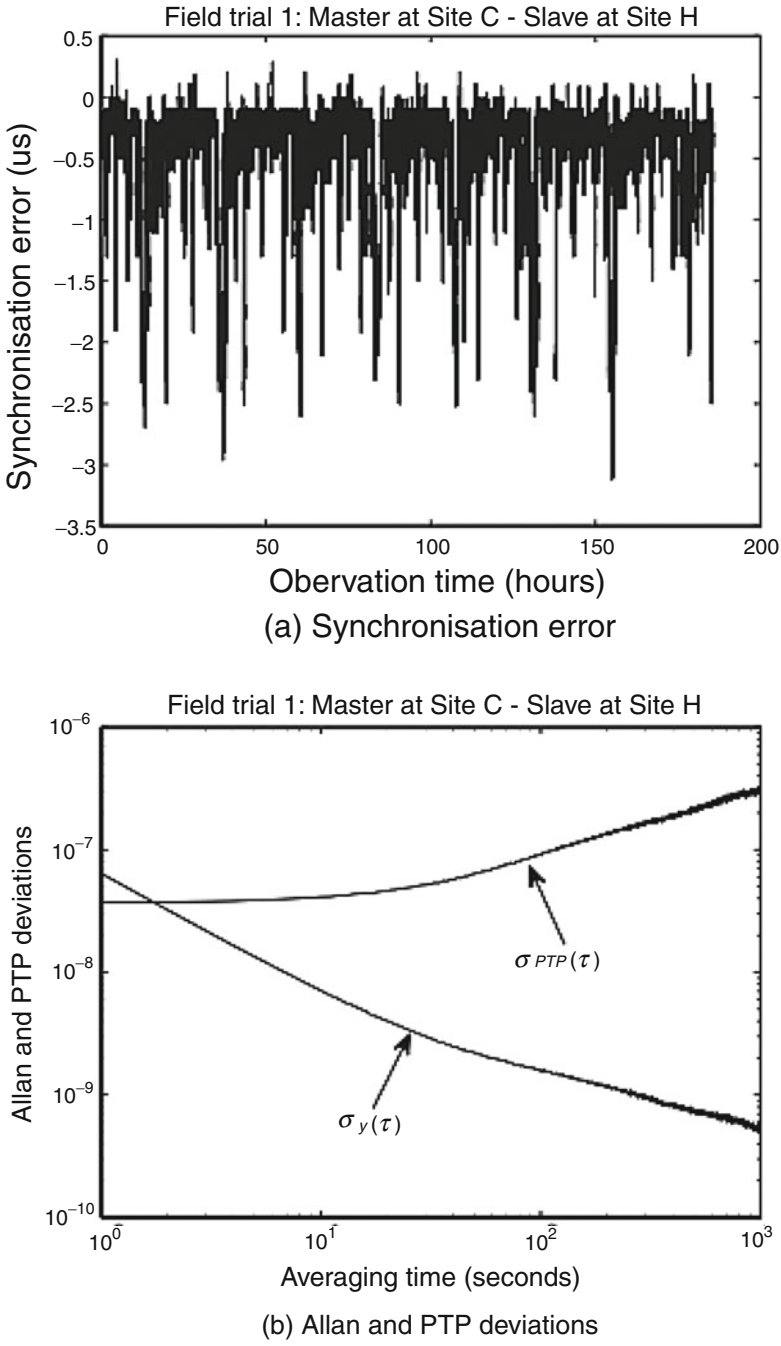

Fig. 43 Field trial 1 using a synchronization messages rate of 64 packets/sec

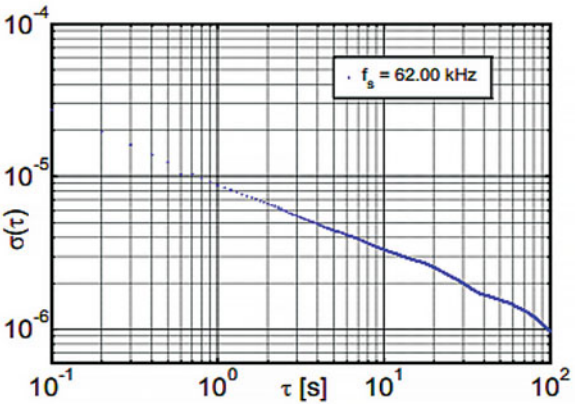

Fig. 44 Output clock frequency stability in LWR time dissemination

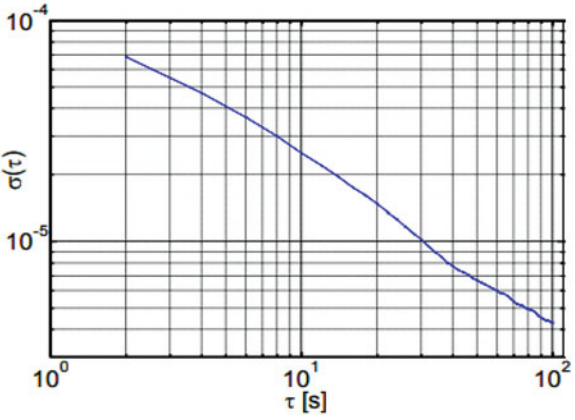

Fig. 45 Reference clock signal (1PPS) stability for LWR of NPL

Various time dissemination services run by various NMIs as per BIPM circular are given in Table 2. This depicts that NTP time dissemination is the most widely used technique.

Conclusion

Over the centuries, precise time dissemination techniques have grown in popularity. Regardless of their nature, all dissemination techniques were equally important. The telephone time dissemination technique was widely used at the time and

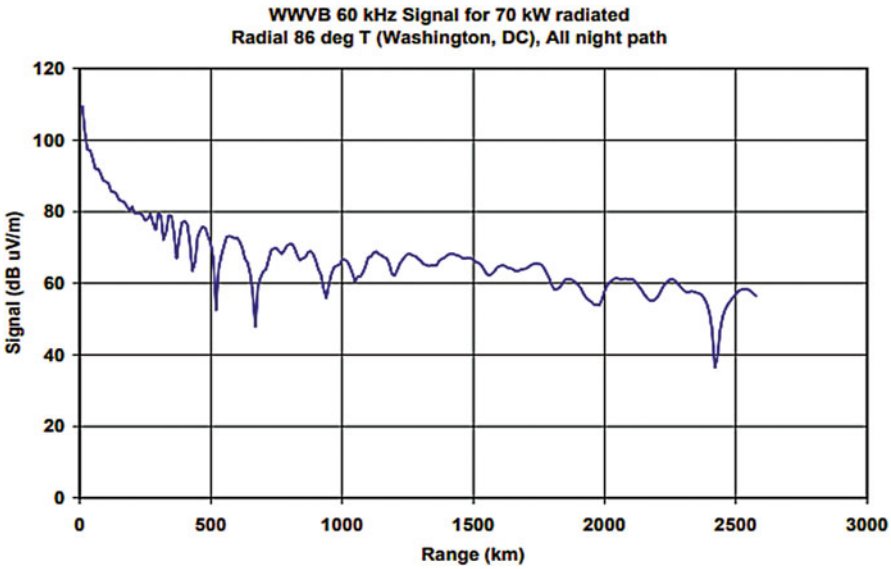

Fig. 46 Distance versus signal strength of WWVB

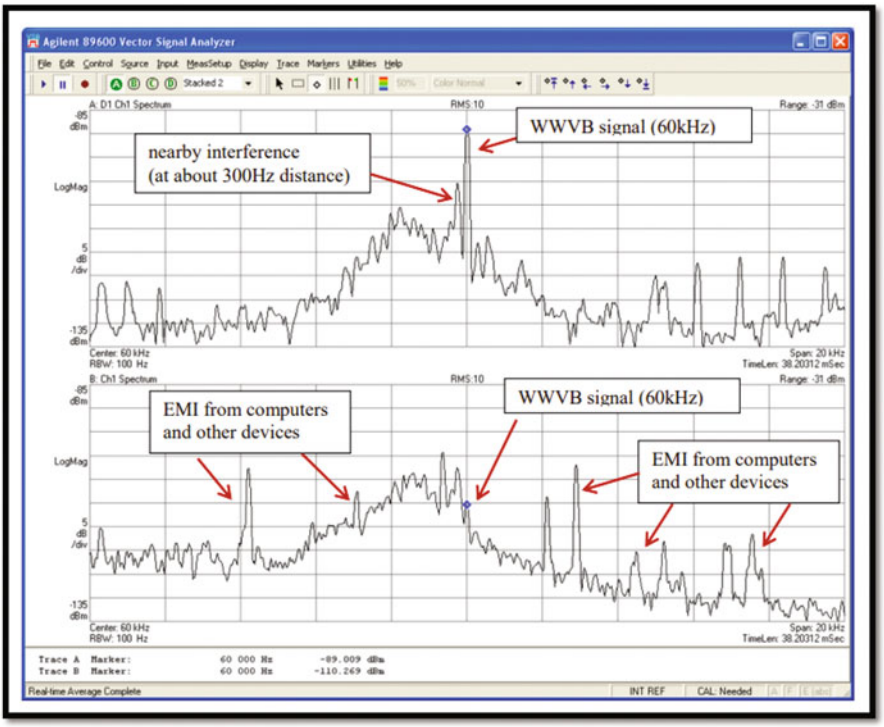

Fig. 47 Signal analysis of WWVB signal

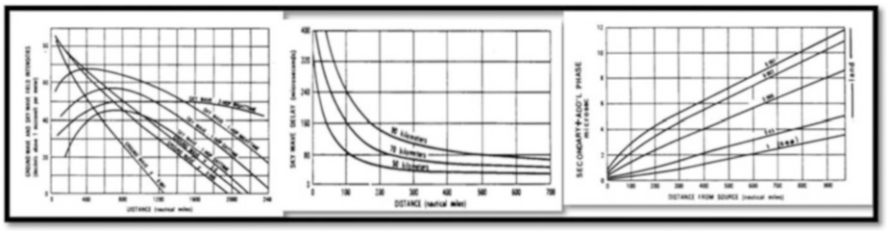

Fig. 48 Performance of LORAN-C 100 kHz signal strength, sky wave delay, and phase factor plotted against distance

made use of the existing telecommunications infrastructure. It was enormously popular because it served the common man's dissemination needs in society to a large extent. Some countries, such as the USA (NIST), Japan (NICT), and Germany (PTB), have upgraded their systems for telephone time dissemination from PSTN to packet-switched networks with infrastructure upgrades. Long-wave radio time dissemination has been critical and continues to be extremely useful for applications such as radio clocks, disaster warnings, etc. The accuracy of this dissemination technique is up to 1 s, but only five NMIs are running this service, including Japan, Thailand, Canada, Brazil, Germany, and the USA, because the installation cost for this service is enormous, and there are now many alternative dissemination techniques available that provide the same benefits. The Internet dominated the nineteenth and twentieth centuries, as did the time dissemination technique. Internet time dissemination via NTP is the most popular dissemination technique because it provides unrivaled simplicity and ease of operation with millisecond accuracy over WAN. Almost all NMIs support this method of dissemination. In some controlled environments, NTP could also support microsecond accuracy. NTP, on the other hand, is incapable of dealing with network asymmetry issues. This is handled very well in the Precision Time Protocol for time dissemination over the network. PTP has evolved from a control system protocol to a network time synchronization protocol over the years and has proven to be very efficient in the process. PTP provided synchronization accuracy on the order of a few nanoseconds. This accuracy is also improved in White Rabbit PTP to sub-nanosecond levels with more than 10-picosecond stability. GNSS time dissemination and two-way time dissemination methods are typically only useful for high-end applications, limiting their use. Even though most countries have not adopted optical cable-based infrastructure, the optical time transfer technique has made tremendous progress. One can conclude that time distribution over the network has been updated regularly to meet the most recent techniques and synchronization requirements. This field has been constantly expanding and improving, and it is expected to do so in the future.

Table 2 Summary of time dissemination services provided by various NMIs with their accuracy as per the latest Cir T

	Common dissemination services for masses *Accuracy: from a few seconds to milliseconds*			**Specialized time services** *Accuracy: from microseconds to picoseconds*		
Time and frequency service (Accuracy)	**Radio wave time transfer** (<1 s)	**Time transfer using NTP/web clock** (0.2–0 ms)	**Telephone time transfer/ speaking clock** (<1 s)	**Satellite time transfer/ TWSTFT** (10 ns)	**Time transfer over PTP** (0.2–10 μs)	**Time transfer over optical links** (6–7 ps)
NMIs	NIST, NIMT, NRC, ONRJ, PTB	NIST, NICT, NPL, NPLI, NMIJ, NIM, PTB, BIPM, INPL, INM, AOS, AUS, BelGIM, BEV, BoM, CENAM, CENAMEP, DMDM, EIM, GUM, HKO, ICE, ILNAS, IMBH, INACAL, INRIM, INTI, JV, KRISS, KZ, LNE-SYRTE, LRTE, LT, MASM, METAS, MIKES, MSL, NAO, NIMB, NIMT, NMISA, NMLS, NRC, NSC IM, NTSC, ONBA, ONRJ, ORB, RISE, ROA, SG, SIQ, SL, SMD, SNSU-BSN, TL, TP, UME, USNO, VMI, VNIIFTRI, VSL, NMIA	NIST, NICT, NPL, NPLI, NIM, PTB, BIPM, INM, AUS, BEV, CENAM, CENAMEP, GUM, HKO, INRIM, KRISS, MSL, NRC, ONRJ, ORB, RISE, ROA, TL, USNO, NMIA	NIST, NICT, NPL, NPLI, NMIJ, BIPM, INPL, AUS, IGNA, IMBH, USNO, NMIA, PTB, NIM	NICT, JV, MIKES, NSC IM,	NIST, NICT, NPL, NMIJ, BIPM, INRIM,NIM

Abstract

With the advent of satellite, accuracy of time transfer has seen significant improvements to nanoseconds and sub-nanoseconds. The major event in the direction is the implementation of GNSS being initiated by the USA and followed by Russia, European Union, China, Japan, and India. This chapter describes the various aspects of GNSS configuration as fielded by the respective countries. One may access time from a normal GNSS receiver with an accuracy of around 30 nanoseconds. But for timing applications, a special GNSS receiver is also available in the market. With these receivers, time accuracy may be improved. In order to do so, various techniques have been evolved. They are mainly common view, all-in-view, carrier-phase technique, P3, and precise point positioning (PPP) methods. These techniques basically identify sources of error and take due measures to eliminate or mitigate them leading to an accuracy of a nanosecond or better. All these aspects have been elaborated in this chapter.

Introduction

Time transfer verbally means giving access of correct time to users. Since 1335 time telling to the public started through chiming/tolling of church bell every hour in Europe. This was followed by the dropping of "time ball" at specified time by NPL, UK, since 1800 and by USNO, USA, since 1845. There was a real breakthrough of time transfer during the early twentieth century when synchronized time pulses were transmitted via electromagnetic wave. So, this technique of time transfer via electromagnetic wave was explored. Soon, the time dissemination via HF, VLF, OMEGA, and Loran was initiated in different parts of the world. Through these methods (few of them has been covered in Chap. 22), an accuracy of milliseconds, microsecond, and even to sub-microseconds could be achieved with some special effort.

After the advent of Earth artificial satellites in the mid-twentieth century, supported by rapid technological advancement and innovation, the technique of the navigation through satellites ushered in a new era of positioning, navigation, and time (PNT) service providing a scope of positioning and time transfer with unprecedented accuracy. Over the years GPS has matured to be fully effective in its utilization. Thus, the last three decades (prior to 2021) have seen explosive improvement in accuracy of PNT. The first operational satellite system for PNT service was ensued by the USA in the name of Global Positioning System very widely known as GPS with the launch of its first satellite on February 22, 1978. Though originally GPS was planned for the USA's armed forces around the globe, this service was soon globally released for a wide range of civil applications. The GPS ultimately became a blueprint for a whole family of global navigation satellite systems (generically called GNSS) subsequently established. It is beyond the scope of this chapter to elaborate on the full technical aspects of GNSS (Hofmann-Wellenhof et al. 2001; El-Rabbany 2002). But the brief description of the working function of GNSS is a necessary prelude for comprehensive discussion of time transfer via GNSS.

GNSS system

The past decade has seen a dramatic change in the landscape of satellite navigation. Economic, political, and strategic considerations have led to the buildup of independent satellite navigation systems by four nations or federations for global service. They are GPS by the USA, GLONASS by Russia, BeiDou by China, and Galileo by the European Union. Of course, there are other systems like NavIC by India and QZSS by Japan. But they are basically meant for regional application.

To explain the basic operation of GNSS briefly, let us concentrate on the description of configuration of each constellation, signal characteristics, types of clocks on board the satellite, and reference system for geodetic and time. This would be followed by operational principle of the GNSS scheme. Whatever has been discussed in this section has been summed up in Table 1 for a quick overview.

Configuration of Constellations

For designing the constellation, it was kept in mind that a minimum of four (to be explained later) satellites of every constellation should be visible everywhere all the time. To achieve this, all constellations have been configured almost in a similar way but necessarily with minor changes for obvious technical reasons. All the constellations for global operation satellites are designed in MEO orbit with zero eccentricity (circular).

The *GPS constellation* has been planned for 32 satellites in three orbital planes. Each is inclined to the equatorial plane by 56°, and the planes are offset from each other by l20° in longitude. Eight satellites are in a circular prograde l2-sidereal-hour orbit in each orbital plane.

GLONASS constellation has 6 orbital planes with a plan of 24 satellites, each plane inclined to equatorial plane by 64.8°. The orbital period is 11 h16 m.

The *Galileo satellite constellation* has circular orbits (with altitude of 23,222 km) and orbital inclination of 56°. It has three equally spaced orbital planes, each with eight operational satellites.

The global *BeiDou-3* system comprises 24 satellites in medium Earth orbit (MEO) distributed over 3 orbital planes. These MEO satellites take 12 h53 m to complete one revolution. The MEO satellites are, furthermore, complemented by three satellites in inclined geosynchronous orbit (IGSO) and three satellites in geostationary orbit (GEO) for regional service.

Clocks

At the heart of the GNSS, there are more than one (for the sake of redundancy) atomic clocks (see Chap. 21) onboard each satellite. GPS and GLONASS constellations have normally cesium and rubidium clocks, whereas Galileo and BeiDou constellations have opted for rubidium and hydrogen masers.

Table 1 Comparative description of GNSS

Parameters		GPS	GLONASS	Galileo	BeiDou
Launch of first satellite		February 22, 1978	12 October 1982	21 October 2011	30 March 2015
Constellation specifications (see Fig. 1.)	Orbit	MEO (circular)	MEO (circular)	MEO (circular)	MEO (circular), GEO, IGSO
	Altitude	20,180 km	19,130 km	23,222 km	21,150 km
	Inclination	56°	64.8°	56°	55°
	Eccentricity	0°	0°	0°	0°
	Orbit planes	6	3	3	3
	Period (h)	11h58m	11h16m	14h05m	12h53m
	Period (rev/sid)[a]	2/1	17/8	17/10	13/7
Number of satellites	Planned	24	24	30	27, 5, 3
	Current status	31 (sept. 01, 2021)	23 (sept. 19, 2021)	21(Sept.04. 2021)	26 (Sept.11,2021)
Signal characteristics	Frequency (MHz) (refer Fig. 2)	L1 1575.42 L2 1227.60 L5 1176.45	L1 1602.00 L2 1246.00 L3 1202.025	E1 1575.42 E5a 1176.45 E5b 1207.14 E6 1278.75	B1 1561.098 B2 1207.14 B3 1268.52
	Spread spectrum	CDMA	FDMA (L1/L2) CDMA(L3)	CDMA	CDMA
Clock on board	Clock type $	Cs, Rb	Cs, Rb	Rb, H	Rb, H
Reference	Geodetic reference	WGS-84	PE-90	GTRF	CGS2000
	Time reference	Steered to UTC (USNO)	Steered to UTC (SU)	Steered to a set of UTC (k) of the European Union	Steered to a set of Chinese UTC (k)

[a]A period of n/m revolutions (rev) per sidereal day (d/sid) results in a ground-track repeat track after m rotations of the Earth (approximately m ×23 h 56 m)
$ *Cs* cesium clock, *Rb* rubidium clock, and *H* hydrogen maser

Each constellation follows a different independent timescale.

GPS time is steered to UTC (USNO). It is continuous timescale implying that GPS time does not introduce leap seconds. GPS time was set to match UTC in January l980 but has since diverged. Thus [TAI – GPS time] = 19 s and is maintained.

Galileo time is steered to a set of UTC (k) of the European Union. Like GPS time, Galileo time follows the same relation with TAI as [TAI – Galileo time] = 19 s.

BeiDou time is steered to set of Chinese UTC (k). BeiDou time maintains constant relation with TAI as [TAI –BeiDou time] = 33 s.

Unlike these three constellations, *GLONASS time* is steered to UTC (SU) with leap seconds.

Unlike the year, month, and day format of the Gregorian calendar, the GNSS date is expressed as a week number and a second-of-week number.

For example, the week number in GPS data is transmitted as a ten-bit field in the navigation messages, and so it becomes zero again every l,024 weeks (l9.6 years). GPS week zero started at 00:00:00 UTC on January 6, l980, and the week number became zero again for the first time at 23:59:47 UTC on August 2 l, l999. To address this concern, the modernized GPS navigation messages use a l3-bit field, which only repeats every 8 l92 weeks (i.e., l57 years), and thus, the week number will not return to zero until near the year 2 l37.

Signal Characteristics

Each satellite system has specific signal characteristics, but each system attempts to be compatible with the others in order to prevent the interferences and attenuation between the signals.

Frequency bands used by GNSS according to ITU frequency allocations are confined to transmitting signals in only two frequency bands like the upper L-band (1559–1610 MHz) and the lower L-band (1164–1300 MHz) which have been established for worldwide satellite navigation use. S-band is also used in few cases of navigation system. Details of frequencies used by four constellations have been given in the Fig. 1 and also in Table 1.

Each satellite of GPS, BeiDou, and Galileo constellations broadcasts spread-spectrum-coded information in *code division multiple access (CDMA)* mode in which each satellite uses a distinctly different ranging code. But GLONASS uses a *frequency division multiple access (FDMA)* modulation, in which the individual satellites transmit at slightly different frequencies. However, similar to other GNSS, the L3 signal of GLONASS will make use of CDMA modulation which will be available with the next generation of K2 satellites expected by 2022.

Binary offset carrier (BOC) signals became a kind of standard in GNSS signal design besides using BPSK and QPSK. BOC signals are applied in GNSS in order to

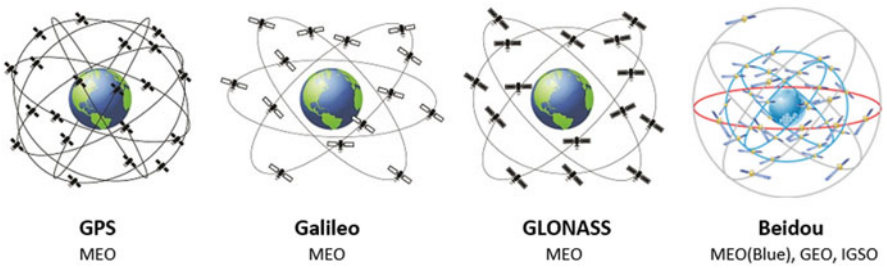

Fig. 1 Orbit configuration of four GNSS constellations

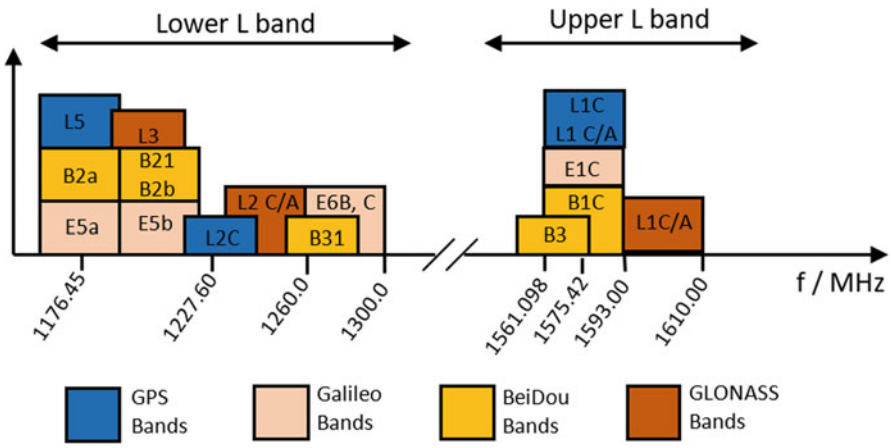

Fig. 2 Frequency bands used by global satellite navigation systems according to ITU frequency allocations

fulfil spectral separation requirements between different noninteroperable signals of different GNSS and to enhance synchronization performance. Galileo uses a composite binary offset carrier (CBOC) modulation for reduced ranging noise and improved multipath resistance.

Signals of all constellations are necessarily superimposed with navigation data, including satellite ephemeris data, an atmospheric and propagation message, and satellite clock bias information. These data are refreshed by the respective ground control station at a regular interval of time.

Relativistic Effects on Clocks in Orbit

While the satellites are in the orbit, the movements and height change relative to the Earth-centered inertial reference frame. According to the special and the general theories of relativity, the clocks on the satellites are thus affected by their speed, as well as by their gravitational potential, respectively. The fractional frequency offset ($\Delta f/f_0$) in GNSS clocks caused by these effects is covered by the following relation:

$$\frac{\Delta f}{f_0} = -\frac{1}{2}\left(\frac{v}{c}\right)^2 + \frac{\Delta U}{c^2} \tag{1}$$

where ΔU is the change in the gravitational potential at the satellite, v is the velocity of the satellite, and c is the velocity of light. Thus, the atomic clocks at the GNSS orbital altitude will tick more rapidly because they are in a weaker gravitational field than are atomic clocks on the Earth's surface. Atomic clocks moving at the orbital speeds of GNSS satellites will tick more slowly than stationary ground clocks. These combined effects lead to a frequency offset in clock.

Let us take the case of GPS constellation. The frequency of the base oscillator in a GPS satellite is l0.23 MHz, from which all other signals coherently are derived. Note that for GPS at the height of ~26,562 km and (v/c = 2.7×10^{-5}), the combined effect of offset comes out to be of 4.46×10^{-10}. Thus, to account for the relativity effect, the frequency of the base standard on board each satellite is set at l0.22999999543 MHz, instead of l0.23 MHz, prior to launch. Similar corrections in clock frequency are applied in the case of all other three constellations before launch.

Working Principle of GNSS

The basic principle of GNSS is based on measuring the range of the satellites at the receiving end. In fact, the receiver measures the travelling time of the signal with respect to its internal clock. By multiplying this time by the light velocity (c), we get the range between the satellite and the receiver. Code correlation technique is used to measure the time difference between the received and generated replica code. The measured range is different from the true range and so is called the pseudo-range (Pi) of the ith GNSS satellite which may be formulated as follows:

$$P_i = \rho_i - c\left(t_{rec} - t_{ref}\right) + c\left(t_i^{sat} - t_{ref}\right) + \left[d_{ion} + d_{trop} + d_{multi} + d_{rec}\right] \quad (2)$$

where:

ρ_i is the true range of ith satellite.
t_{ref} is the GNSS time.
t_{rec} is the time of receiver internal clock.
t^{sat}_i is clock time of ith satellite.
d_{ion} is delay error caused by ionosphere.
d_{trop} is delay error caused by troposphere.
d_{multi} is delay error caused by multipath effect.
d_{rec} is delay error caused by receiver noise.

Terms in parenthesis [] of RHS of (2) are error terms that equivalently become responsible for the deviation of the signal from the line-of-sight mode.

Please note the ($t^{sat}_i - t_{ref}$) is modelled as follows:

$$\left(t_i^{sat} - t_{ref}\right) = a0 + a1 \times \Delta t + a2 \times \Delta t^2 \quad (3)$$

The coefficient a0, a1, and a2 are transmitted in the navigation message. These coefficients are uploaded to the satellite and refreshed at a regular interval of time by the control center at the ground. Δt represents the time elapsed from the time of last update.

The true range may be expressed in cartesian coordinates as follows:

$$\rho_i = \sqrt{(x_{rec} - x_i)^2 + (y_{rec} - y)^2 (z_{rec} - z_i)^2} \quad (4)$$

Where:

x_{rec}, y_{rec}, and z_{rec} are the coordinates of the receiver.

x_i, y_i, and z_i are instantaneous coordinates of the ith satellite.

Please note that instantaneous satellite coordinates are determined from the satellite orbit parameters transmitted through navigation message.

So, if we carefully look at the Eq. (2), there are four unknowns to be determined (ignoring the error terms). This implies that for getting solution for four unknowns, four simultaneous measurements are required. *This necessitates the availability of minimum four satellites at a time.*

Limitation of GPS Accuracy

There is always a propagation delay when the time signal travels from the transmitting end to the receiver. The accuracy of time transfer largely depends on the degree of correctness of this delay assessment. GNSS signals are transmitted in L-band. At this frequency, signals travel from satellites to the receiver in a line-of-sight mode. But in practice, signals do deviate from the line of sight to some extent. So, it is important to identify the sources of the error of this deviation. Six major factors (Langley 1997) are normally identified as the major sources of error such as ephemeris error, satellite clock error, ionosphere error, tropospheric error, and errors caused by multipath and by receiver noise. They are explained in the following subsections.

Ephemeris and Satellite Clock Error

GNSS satellites broadcast navigation message that provides satellite orbit and clock parameters. Receivers use these messages in order to solve the equations. Through the navigation message, the coefficients (a0, a1, and a2) of clock prediction model are transmitted to the receiver. These are used to estimate the satellite clock offset with respect to the GPS system time. However, predictions may not be perfect causing some error in the estimate of the clock offset.

Similarly, parameters to define the current orbit status are sent to the receiver though navigation message. These are used to estimate the instantaneous position coordinates of the satellite. It may not be possible to correctly estimate the instantaneous position of the satellite due imperfection in prediction of ephemeris data.

Further, the parameters (clock coefficient and orbit parameters) that are sent through navigation message are continuously estimated at the control segment but only periodically uploaded to individual satellites. Once uploaded, the satellite position and clock prediction errors increase until the next upload refreshes them.

Ionospheric Error (d_{ion})

The ionosphere is the layer of the atmosphere between around 80 km and 600 km above the Earth. Electromagnetic wave signals are perturbed when travelling through the ionosphere.

The GPS navigation message includes values of the parameters of a simple ionospheric model known as the Klobuchar model. NeQuick-G, the ionospheric model is adopted by the Galileo system. A Klobuchar-like model is also used by the BeiDou system.

In GLONASS, there is no ionospheric model applied, and thus, there is no broadcast of any parameter. However, any of the GPS or Galileo ionospheric models could be used for GLONASS signals, by applying a correction factor given by their relative squared frequencies ratio.

Nevertheless, these models can give rise to some error.

Tropospheric Error (d_{trop})

The troposphere is the lowest layer of the Earth's atmosphere (10–15 km). Refraction in the troposphere has a dry component and a wet component. The only way to mitigate tropospheric effect is to use models. Tropospheric models depend on empirical models by considering all values of temperature, pressure, relative humidity, and mapping function. Examples of such models are the Hopfield and Saastamoinen models.

Multipath Error (d_{multi})

Multipath describes what happens when reflected GNSS signals arrive at a receiver's antenna along with one coming directly from the satellite. When a circularly polarized wave is reflected from a surface such as a wall or the ground, the sense of polarization is changed. The multipath affects the pseudo-range measurement. This effect can be mitigated by special antenna design, by processing the data, or by weighing the measurements according to the elevation angle.

Receiver Noise (d_{rec})

GNSS signals are very weak. Typically, less than 100 watts is transmitted from a distance of 20,000 km to 25,000 km. When received at the surface of the Earth, the signal strength may be as low as -160 dB W (1×10^{-16}) watts. Inherent noise within the receiver causes jitter in the signal.

Table 2 The standard error model: L1 C/A (the values are very rough estimates as indicative, so they vary slightly from one literature to another)

Source	Position error (1σ)	Time error (1σ)
Ephemeris	2.5 m	7.5 ns
Satellite clock	1.5 m	4.5 ns
Ionosphere dion	7 m	21 ns
Troposphere dtrop	0.7 m	2.1 ns
Multipath dmulti	1.2 m	3.6 ns
Receiver noise drec	1.5 m	4.5 ns
Total	7.85 m	24.0 ns

Combined Error

The dilution of precision (DOP) or geometric dilution of precision (GDOP) is a term used to describe the effect of the geometric strength of a satellite configuration on accuracy. The degradation of time and position solutions due to a suboptimal geometric arrangement of observable satellites is termed dilution of precision (DOP). The higher is the value of DOP, the lower is the accuracy.

Table 2 summarizes the values of the error contributed by individual sources. Time error has been calculated from the estimate of position error by multiplying it with the velocity of light. Let us note that 1 m range error corresponds to 3 ns time transfer error. Assuming that each component of errors is uncorrelated, the total error may be found by root of square of sum (RSS) of all these components. Of course, this total value needs to be multiplied by the DOP factor to take care of the effect of satellite geometry with respect to the receiver location. Refer to Table 2, where if we assume the TDOP to be 2, the time error amounts to about 48 ns.

However, one may achieve an accuracy time transfer *much better than this* by averaging over reasonably good number of observations.

Direct Access to Time from GNSS Receiver

All four GNSS constellations are by now fully operational. So, GNSS receivers capable of receiving signals from all constellations and generating solutions for PNT are already available in the market. All GNSS receivers not only show position coordinates but also have a hardware output of one pulse per second. With the help of these GNSS receivers, one can get direct access of time but with a limited accuracy to about 30 ns. An absolute calibration of the GNSS receiver delays is required for this technique.

A GNSS disciplined oscillator (GNSSDO) (Banerjee et al. 2007, 2008) can generate time and frequency signals by controlling its own oscillator with the precise time provided by the GNSS receiver. GNSSDO is already available in the market at a reasonable cost. For many applications requiring precise and stable frequencies, the expensive purchase of an atomic clock can be substituted by the use of GNSSDO.

Improving Accuracy of Time Transfer

It has been seen that the user can always find a time and position solution if a minimum of four satellites are simultaneously visible. But if one needs to know the time at a static location whose precise coordinates are known, then one can get the time by receiving the signal from a single satellite only. Special timing receiver that are designed to work on this principle are already available in the market. A few models for multichannel dual-frequency timing receiver are Septentrio PolaRx3eTR, MESIT GTR55, TTSx-EMDE Electronics, PikTime, and SPECTRACOM SecureSync (see Fig. 3.).

For the useful operation, such receivers should be configured in the way as shown in Fig. 4. The receiver should be fed with a second pulse (1PPS) and frequency of the receiver which is to be compared with the time of GPS of the receiver. It is important to determine precise coordinates of the antenna location in advance. Irrespective of the type of receiver, it is important to feed the values of coordinates to the receiver. These receivers have a time interval counter with high resolution (~20 ps) built into them. The output of this receiver is available in one common GNSS generic time transfer standard (CGGTTS) format as defined by the Consultative Committee for Time and Frequency (CCTF) (Defraigne and Petit 2015; Allan and Thomas 1994). The common output format has been devised for the convenience of exchange of data between the comparing clocks.

Fig. 5 Sample of CGGTTS format of NPLI dated 02-23-2018 (MJD 58172)

In the sample of CGGTTS format shown in Fig. 5, tenth column "REFSYS" contains the offset "reference user clock – system timescale," i.e., the offset between the user clock and the GNSS time.

With the help of the special timing receiver, it has been possible to compare two distant clocks with much better accuracy. By using this receiver, it has been possible to improve the time transfer accuracy by eliminating or reducing the effect of the sources of error. Many techniques have been conceived to achieve this.

Common View (CV)

Common view technique started since the early 1980s. In this method, two comparing stations have to observe only those satellites that are in common view. Measurements with common view satellites are also to be made simultaneously. Let us discuss the common view between station A and B as comparing sites (see Fig. 6). We may write the following equation:

$$TA - TB = \frac{1}{N} \sum w_i \left[(G - t_A)_i - (G - t_B)_i \right] \tag{5}$$

TA and TB are time difference between the two clocks; $(G\text{-}t_n)_i$ is the observed time difference between the GNSS time (G) and the reference clock at that site (t_n, i.e., t_A or t_B), as determined from GNSS satellite i measurements at site n (e.g., $(G\text{-}t_n)$ shown in tenth column of Fig. 5).

The Bureau International des Poids et Mesures (BIPM) used to publish tracking schedules (see Table 3) for single-channel common view every 6 months so that observations between pairs of stations could be made simultaneously on the same satellite.

The GPS common view technique has been used for many years by the BIPM as one of its main techniques for international time comparisons.

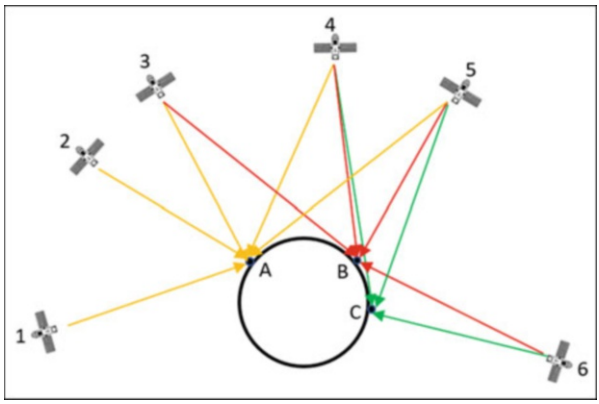

Fig. 6 Common view technique: satellites 3, 4, and 5 are in common view between station A and B, though satellite 1 and 2 are also visible from A and satellite 6 is also visible from B. No satellite is in common view between A and C

Table 3 Typical sample of GPS Schedule No. 49

India				
		Start		
Class	PRN	h	m	Connects
38	31	0	10	H
D4	31	0	26	H
A0	23	0	42	ME, EA, E
A4	20	0	58	SAF
AC	03	1	14	A
AD	03	1	30	A
AE	03	1	46	A, EA
AC	19	2	2	A
A0	13	2	18	ME, EA, E
F1	03	2	34	I
AD	19	2	50	A, EA
A0	25	3	6	ME, EA, E

The accuracy of common view GPS is better than for one way since the stability of common view is better, and also only a differential calibration is required between the two receiving stations. A differential calibration is made by carrying a portable GPS receiver between the two stations. This provides information on the difference between the delays of the receiving equipment at the two stations. An absolute calibration of the equipment delays at each station is not required. The accuracy of common view time transfers is typically in the 1 to 10 ns range.

Satellite clock errors are nearly equal in common view, so they are nearly cancelled out.

Orbit error is also attenuated but with increasing distances, the number of simultaneously observed satellites decreases, and the number of high-elevation satellites becomes low. But ionosphere and troposphere are different for different sites. Ionosphere error may be cancelled over a short baseline. So, the improvement

in ionosphere and troposphere errors depends on the baseline length. Ionosphere errors do not cancel over long baseline.

Local effects like multipath reflections and temperature sensitivity of receiver are not common in common view-mode and thus are not cancelled.

GPS CV had been used for the calculation of UTC at the BIPM until 2006. It is still in use, particularly for short baselines, as it is simple to use (Matsakis et al. 2014; Defraigne et al. 2007).

One main disadvantage of common view is that few of all visible satellites at the respective ends may be in common view. For example, though satellite 1 and 2 are also visible from A and satellite 6 is also visible from B in Fig. 6, they are not in common view between A and B. Further, the number of satellites in common visibility reduces with the increase of baseline distance. Thus, all visible satellites are not fully utilized. Common view cannot be applied for two widely separated stations like station A and station C as shown in Fig. 6.

Concept of All in View (AV)

Considering that CV has the constraint of using all visible satellites, All in view (AV) (Petit and Jiang 2008) has been proposed where all satellites in view are used to compare the local clock to a reference timescale through the satellite clocks at the two comparing stations. Difference between averages of the timing solutions of two station is subtracted to get the final result as shown in the following equation.

At each station using all visible satellites, one gets the difference between the combined results of two sites:

$$TA - TB = \frac{1}{N}\sum w_i(G - t_A)_i - \frac{1}{M}\sum w_i(G - t_B)_i \tag{6}$$

N is the number of observed satellites at station A and M is number of satellites at station B.

AV eliminates the constraint of simultaneous observations, so that two observing stations can be linked whatever their distance.

Improving Accuracy of AV through IGS Network

The errors from satellite clock estimate and the ephemeris estimate do not cancel in AV as they do at least partially in CV technique. To improve the accuracy of AV method, some of the IGS products are utilized.

Conceived in the early 1990s, the International GNSS Service (IGS) is a self-governed, voluntary federation of more than 300 contributing organizations from more than 100 countries around the world (see Fig. 7.). IGS provides satellite orbit and clock products (see Table 4) and other resources with the highest possible precision and accuracy. The IGS products are provided openly for the benefit of all scientific, educational, and commercial users. Though the service was started for GPS, in course of time, all GNSS constellations are covered under this umbrella.

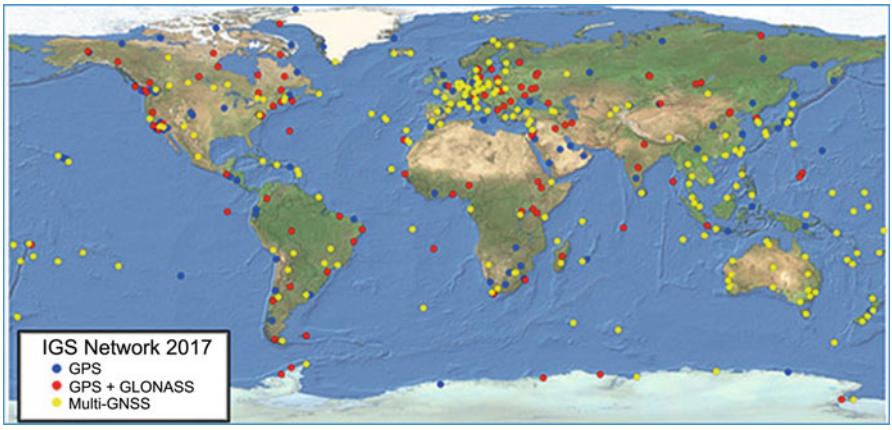

Fig. 7 IGS network. (Source: https://www.gpsworld.com/the-international-gnss-service-25-years-on-the-path-to-multi-gnss/)

Table 4 Specifications of IGS products

Type	Parameter	Accuracy	Latency
Broadcast (navigation message)	Orbits	~100 cm	Real time
	Sat. clocks	~5 ns RMS ~ 2.5 ns S dev	
Ultra-rapid	Orbits	~5 cm	Real time
	Sat. clocks	~3 ns RMS ~ 1.5 ns S dev	
Rapid	Orbits	~2.5 cm	17–41 hours
	Sat. clocks	~75 ps RMS ~ 25 ps S dev	
Final	Orbits	~2.5 cm	12–18 days

Using IGS rapid products, the uncertainties due to satellite orbits and clock average get significantly reduced.

The availability of IGS products made it possible to use the AV method instead of the CV method, resulting in improved performance of the time links independent of the distance. With wide availability of multichannel receivers, AV was implemented in place of CV since Sept. 2006 for all UTC links.

Concept of P3

The traditional GPS common view technique uses single-channel C/A code for computation in which the ionospheric delay can be reduced by an ionosphere model (as discussed in section on "Common View"). Over the years, most GPS receivers have become dual frequency. Keeping this in mind, better ionosphere removal can be achieved in modern receivers by using the fact of the frequency dependence of the ionosphere delay.

P1 and P2 are the pseudo-range measurements on two frequencies (say, L1 and L2 for GPS). These measurements are available in modern geodetic receiver.

Noting that ionospheric error $I_i = \frac{40.3}{f_i^2}$ (ignoring higher-order terms), one may prove that:

$$P_3 = \frac{f_{L1}^2}{f_{L1}^2 - f_{L2}^2} \times P_1 - \frac{f_{L2}^2}{f_{L1}^2 - f_{L2}^2} \times P_2$$

For GPS, where L1 is 1575.42 MHz and L2 is 1227.6 MHz:

$$P_3 \approx 2.55 \times P_1 - 1.55 \times P_2$$

P3 is the ionosphere-free code measurements.

Instead of using standard model, this method can be used to minimize the ionospheric error significantly.

Figure 8 clearly shows the improvement in P3 technique. In fact, P3 code removes 99.9% of the ionosphere delays, and Klobuchar models remove only 60%. By linear combination of L1 and L2 frequency, corrected range is more noisy by a factor of 3 as shown below:

$$Factor \approx \sqrt{2.55^2 + 1.55^2} \approx 3$$

With the help of GPS P3, sub-nanosecond statistical uncertainty for the time transfer could be achieved.

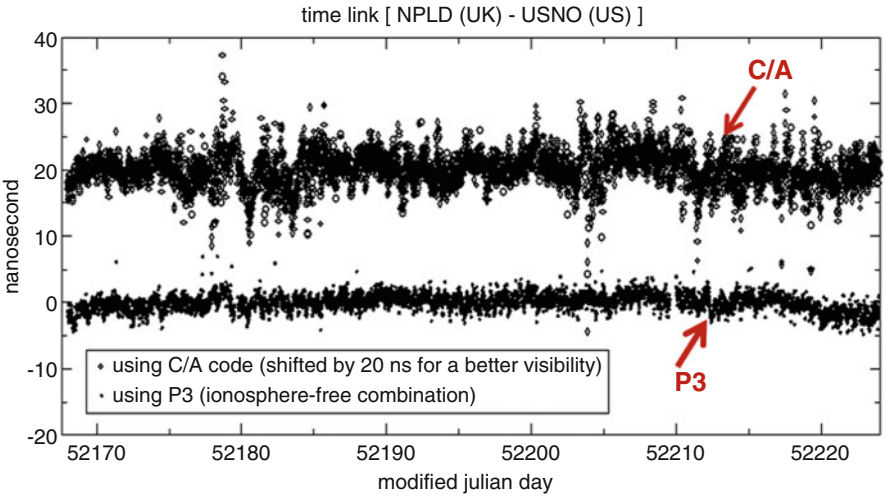

Fig. 8 The improvement in jitter in P3 over C/A code. (Source: Defraigne et al. 2007)

Concept of Carrier Phase

GNSS signals offer two types of observables. The pseudo-range code observable is one type, and the carrier phase that it modulates is the second. The pseudo-range's code length is about 1 ms, implying a wavelength of 300 meter; the carrier has a wavelength of around 20 cm (for GPS L1 carrier of 1.575 GHz has wavelength of 19 cm). The wavelength of carrier of GNSS signal is much shorter than code length. The resolution available from these carrier signals depends on the signal to noise and is typically around 2 mm, approximately 1% of its wavelength. So, the carrier-phase measurement noise and multipath error are about 100 times lower than the noise of the code measurements.

For this reason, the potentiality of GNSS carrier phases for time and frequency transfer is studied and demonstrated by different researchers (Ray and Senior 2003). The modern geodetic GNSS receiver measures the carrier phase and also code range.

So, the phase difference between two receivers p and q is as follows:

$$\varphi_p^i - \varphi_q^i = -f\left(\tau_p^i - \tau_q^i + \Delta t_{pq}\right)$$

$$+iono(p) - iono(q) + tropo(p) - tropo(q) + N_p^i - N_q^i$$

Δt_{pq} is the clock offset between two receivers p and q. Due to the cycle ambiguities, it is not possible to determine the absolute value of Δt_{pq}.The carrier-phase observable can thus be used for very precise determination frequency transfer by the determination of the rate of change of Δtpq (Fig. 9).

A combined analysis using both carrier phase and code observations is necessary to get the absolute value of the clock offset, with a precision limited by the code noise level (depending on the receiver type, but smaller than 1 nanosecond).

Concept of PPP

Code-only techniques like CV and AV have the limitations in performance due to multipath effects and errors in the tropospheric model and code noise. The effects of these error sources can be fairly minimized by phase measurements from geodetic-type receivers (Ray and Senior 2003; Kouba and Heroux 2001).

Precise point positioning (PPP) for time transfer is the technique that uses GNSS dual-frequency carrier phase and code measurements to get a better accuracy. The satellite orbit and clock data from IGS network solutions are used in addition to find the solutions for timing and positioning.

To facilitate the functioning of PPP time transfer, several online software services, using packages like Atomium, NRCAN, JPL, and Bernese, have been developed and are available for use. For performing PPP, one requires a dual-

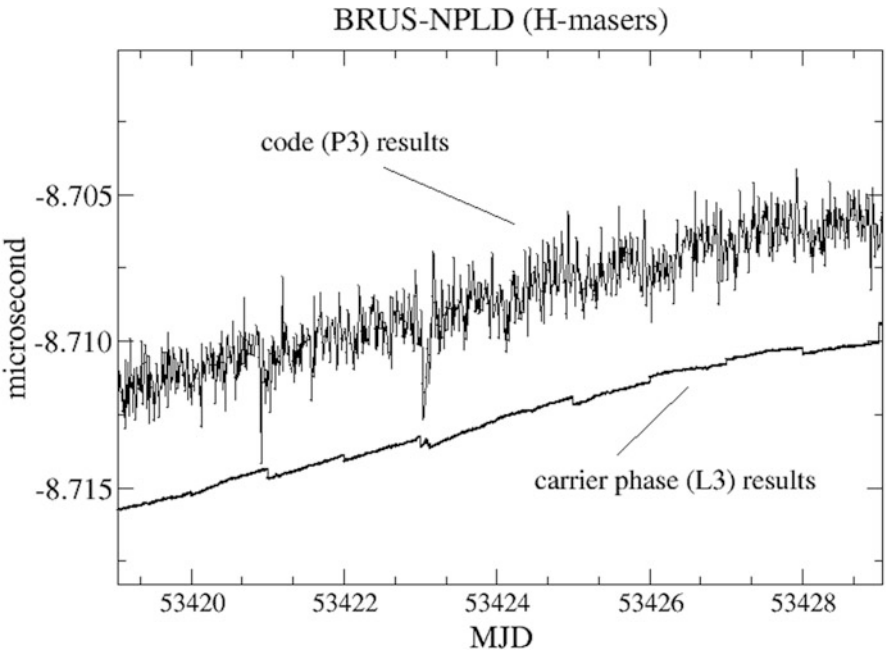

Fig. 9 Comparison of P3 and carrier phase through Δt_{pq} between labs. (Source: Defraigne et al. 2007)

frequency geodetic receiver which can generate both C/A code pseudo-range and carrier-phase observations, typically in RINEX format. These data are to be fed to any of the available software packages that subsequently generate the final output. This includes the time difference between a local clock and the timescale maintained by IGS with the precision of the carrier phase and the accuracy of the code. PPP technique has the potentiality of achieving time comparison with an accuracy of 500 ns. BIPM regularly publishes data of IGRT-UTC (k) through using PPP. NPLI is one of the laboratories that contribute to PPP link.

Comparison of GNSS Techniques

Table 5 includes the conservative estimate of the performance of different time transfer methods through GNNS system. It has been shown that GNSS can easily give 30–20 ns accuracy of time transfer, but by the improved method like PPP technique, GNSS promises to push accuracy to as good as 500 ps. There is a Two Way Satellite Time Transfer (TWSTFT) (see Chap. 24) technique which has capability a shade better that by GNSS techniques.

Table 5 Tabulation of GNSS time transfer methods describing the relative performance

Method	Uncertainty	Remarks
Direct access GNSS	50 ns–20 ns	Ephemeris and ionosphere error dominate
CA code CV/AV	1–1.5 ns	Ionosphere and troposphere do not cancel for long baseline. IGS product should be accessed for AV
GNSS P3	700 ps	Ionosphere error minimized
GNSS PPP	500 ps	Better uncertainty but requires significant post-processing, IGS data for orbits

NavIC on Timing Applications

Navigation with Indian Constellation (NavIC) or Indian Regional Navigation Satellite System (IRNSS) is a constellation of seven geosynchronous (GSO) satellites with coverage over the Indian landmass and in the region extending to 1500 km beyond the Indian geopolitical boundary. Three of the NavIC satellites are in GEO (32.5°E, 83°E, and 129.5°E), while four of the satellites are in two inclined geosynchronous orbits (IGSO) having inclination of 29 degrees each. While one of the IGSO planes crosses the equator at 55°E longitude, the other crosses at 111.75° E longitude. NavIC system has been realized by the Indian Space Research Organization (ISRO) and has been operational since 2018. It broadcasts NavIC system time which is realized at IRNSS Network Timing facility (IRNWT) and is steered to UTC (NPLI). NavIC, thus, provides reliable and precise dissemination of UTC (NPLI) and UTC.

Already many GNSS receivers that are available in the market have the provision to receive signals from NavIC constellation in addition to other GNSS constellations. Potentiality of NavIC service for precise timing applications through these receivers is being demonstrated through experiments and publications of the outcome of these efforts (Bhardwajan et al. 2021; Santra et al. 2022).

Concluding Remark

Combining multi-constellation GNSS can increase the number of available satellites and thus can improve the redundancy of the receiver clock parameters. Many laboratories contributing to UTC operate multi-GNSS receivers, allowing the computation of time links using not only GPS but also the other GNSS such as GLONASS, Galileo, and BeiDou, which have all reached operational status.

Various methods to combine the data from all four GNSS constellations have been studied (Verhasselt and Defraigne 2019) to improve the time transfer performance with respect to any single-GNSS solution. The optimal use of satellites of all GNSS constellations supplemented by the regional constellation is still being explored so that maximum benefit can be accrued out of such a good number of available satellites.

Abstract

TWSTFT (Two Way Satellite Time and Frequency Transfer) technology was developed over decades and has become one of the most precise and accurate techniques for comparison of the frequency standards located at remote sites. Since 1999, TWSTFT has been used in TAI (International Atomic Time) generation. More than two-thirds of TAI clocks and almost all the primary frequency standards are transferred using TWSTFT. The advantages of TWSTFT are its small calibration uncertainty and its long-term link stability. To further improve the time transfer precision and stability, several calibration methods have been

developed and the possible instability-inducing sources were investigated. Although many instability sources of TWSTFT were studied, we still have not identified all sources since the observed instabilities in real TWSTFT links are larger than expected and the causes of diurnal effect (Diurnal effect is the daily variations, with peak-to-peak amplitude could be up to 2 ns in extreme cases, which periodically appear in the TWSTFT measurement results) still cannot be explained well. Further investigations are necessary. For the future development, the SDR (software-defined receiver)-based TWSTFT methods show competitive performance with the GPS PPP and much less diurnal effect than the conventional TWSTFT. Some of them are very promising methods for the next generation of TWSTFT. This chapter gives a review and brief introductions of the above topics.

Introduction

The concept of Two Way Satellite Time and Frequency Transfer (TWSTFT or TW) was proposed about 50 years ago, and several TWSTFT experiments, using small on-site earth stations and pseudonoise sequence, have been performed around 1970 (Jespersen et al. 1968; Chi and Byron 1975). In the beginning, only two or three measurements a week were performed, and now many single-links with more frequent measurements per day have constructed a worldwide network. Since 2003, TWSTFT has been used as a primary time transfer technique for the realization of coordinated universal time (UTC) and is currently one of the most precise and accurate techniques for comparison of the frequency standards located between remote sites. More than two-thirds of TAI clocks and almost all the primary frequency standards are transferred using TWSTFT.

By using TWSTFT method, frequencies can be compared with an uncertainty in the 10^{-15} range at an averaging time of 1 day, and time scale differences can be compared at the nanosecond level (Bauch et al. 2006; Piester et al. 2008). The achieved performances are based on the reciprocity of the propagation path that many delay variations of the transmitted signals cancel out in TWSTFT. However, the reciprocity is not completely fulfilled in practical situation. This is mainly due to: (1) the different signal paths through different electronic components in the ground stations and generally in the satellite; and (2) the different frequencies used for uplink and downlink to and from the satellite. Especially for the cases of long baselines, phase variations with amplitudes of 1 ns and more seem to limit the time and frequency transfer precision. Besides, as more and more timekeeping institutes use very stable maser clocks as their references, the diurnal fluctuations of about several hundred picoseconds appear in the continuous or hourly two-way time transfer results (Parker et al. 2003; Parker and Zhang 2005). In order to increase the accuracy and stability of TWSTFT, there is a keen desire to develop new technologies for time and frequency transfer. Moreover, the TWSTFT system should be calibrated and the sources of instabilities also need to be investigated.

Conventional TWSTFT is based on pseudorandom noise (PRN) codes, which are generated by commercial modem, to perform the measurements. The PRN occupying 2.5 MHz of up/down satellite link in usual case provides its resolution of 1 nanosecond. Increasing the bandwidth may get better time-transfer resolutions but will also increase the operational cost. Therefore, it becomes an important issue to develop some novel technique to improve the resolution without increasing the operational cost. Considering this, some new SDR (software-defined receiver)-based methods were proposed. National Institute of Information and Communications Technology (NICT) has developed software-based two-way time transfer modems (Amagai 2006; Amagai and Gotoh 2008; Gotoh and Amagai 2008), and their ability in improving the time transfer precision by using a Dual Pseudo-random Noise (DPN) signal has been demonstrated in the experiments between NICT(Japan) and TL(Taiwan) (Gotoh et al. 2011; Huang et al. 2011a; Tseng et al. 2012). In comparison with the conventional TWSTFT data, the DPN time transfer results of NICT-TL experiment have higher precision and less diurnal effect**.** Afterward, TL proposed the SDR transfer technology with the open-loop method. This technology has been verified in the pilot study organized by the CCTF WG on TWSTFT, and the comparison results have been utilized in the UTC generation. Recently, NICT has further devoted to develop the SRS (software ranging system) modem which allows the code and carrier phase measurements, with the goals of carrier-phase frequency transfer with instability below 1.0E-16 and time transfer by the code phase with lower than 1 ns uncertainty. These SDR-based TWSTFT technologies will be introduced in section "SDR-Based TWSTFT."

The precision of the TWSTFT highly depends on the residual nonreciprocity delays. Kirchner (Kirchner 1991) has discussed many causes of nonreciprocity. Several studies have also tried to evaluate all the potential sources of time delay instability and eliminate them (Parker and Zhang 2005; Piester et al. 2007). Nevertheless, we still have not identified all instability sources, since the observed instabilities in real TWSTFT links are larger than expected and the causes of the obvious diurnal effect still cannot be well explained. To obtain more precise and stable time transfer results, further investigations for evaluating all potential sources of time transfer instability are necessary.

In this chapter, we will review the basic principle of TWSTFT first, then introduce the conventional method and the SDR based technologies, the current adopted calibration methods, and finally explain the possible instable sources of TWSTFT technique.

Basic Principle of Conventional TWSTFT

The schematic of basic setup and signals propagation of TWSTFT is illustrated in Fig. 1. The equipment used for a TWSTFT Earth station includes the following:

1. A satellite terminal called VSAT (Very Small Aperture Terminal) type which usually consists of a dish antenna of 1.8 m ~ 3.6 m, a power amplifier, a low noise

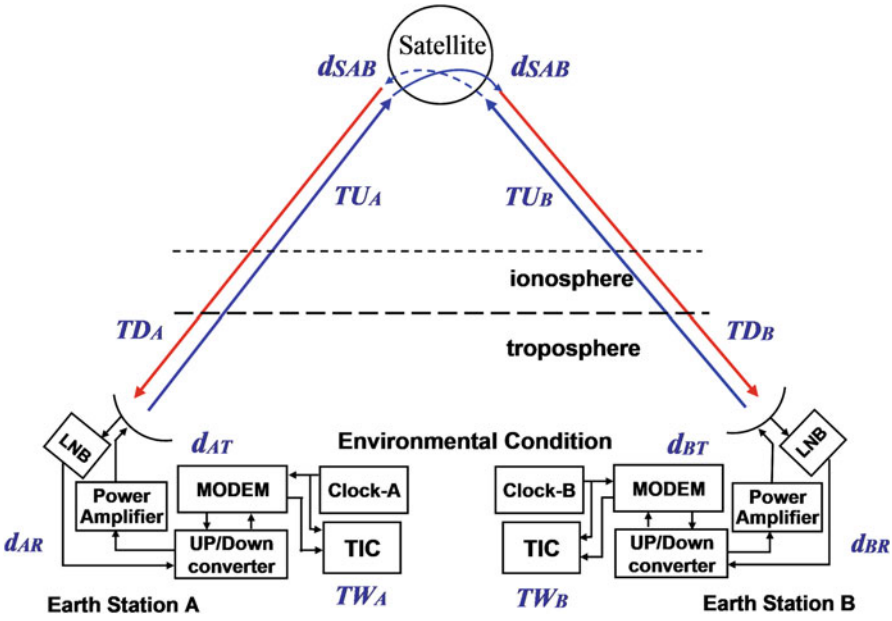

Fig. 1 The schematic of basic setup and signals propagation of TWSTFT

amplifier, and up/down converters. Most of the present TWSTFT links use Ku-band signal of the commercial communication satellite, and the up and down link frequencies are around 14 GHz and 12 GHz, respectively.

2. The other important equipment is the special designed time transfer "modem," which usually adopts the pseudo random noise (PRN) code modulation technique using the same frequency band of the satellite transponder to minimize the delay variation in the satellite. Currently, SATRE (Satellite Time Transfer and Ranging Equipment) modems, developed by a German company, are commonly used in Europe, Asia, and USA.

In Asian TWSTFT links, a different type of modem has been developed by the NICT in Japan (Imae et al. 2001; Imae et al. 2003), and used for conventional TWSTFT comparisons. This type of modem can perform the TWSTFT operation up to 7 stations simultaneously. Afterward, it was replaced by the newly developed DPN and SRS modems, which will be introduced in a later section of this chapter.

To perform the TWSTFT experiment, a pair of Earth stations transmit and receive pseudorandom noise (PRN)-coded signals via communication satellite. In each Earth station, the clock signal (typically 1 pulse per second, 1PPS) is modulated at an IF carrier frequency, up-converted to the up-link frequency, amplified by a high-power amplifier (HPA), and then radiated to the satellite by the antenna. The signal from the counterpart station clock is received at the satellite down-link frequency by the same antenna, amplified by a low-noise amplifier (LNA), and then down-converted to the

IF frequency and demodulated to the received clock signal. At the same time as the local clock pulse is starting the TIC, the pulse is also transmitted to the counterpart station. So the time interval counters (TICs) are started by a pulse from the local clock and stopped by the received pulse from the clock of counterpart. The same process goes on at both stations. The time interval information that is recorded at each station contains the clock differences as well as various delays as shown in the equations below.

$$TW_A = T_A - T_B + d_{BT} + TU_B + d_{SBA} + TD_A + d_{AR} + \Delta\tau_{BA} \quad (1)$$

$$TW_B = T_B - T_A + d_{AT} + TU_A + d_{SAB} + TD_B + d_{BR} + \Delta\tau_{AB} \quad (2)$$

where $\boldsymbol{TW_A}$ and $\boldsymbol{TW_B}$ are the time interval counter readings, $\boldsymbol{T_A}$ and $\boldsymbol{T_B}$ are the respective clock times, and the $\boldsymbol{d_{XY}}$s are the, respective, delays of the transmit and receive parts (equipment delays) of earth stations A and B. ***TUx*** and ***TDx*** are the up and down propagation delays illustrated in Fig. 1. $\boldsymbol{\Delta\tau_{BA}}$ and $\boldsymbol{\Delta\tau_{BA}}$ are Sagnac corrections, and $\boldsymbol{\Delta\tau_{BA} = -\Delta\tau_{BA}}$.

Since the time up to and back from the satellite is on the order of a quarter of a second, TW_A and TW_B are always positive for reasonably well synchronized clocks.

Assuming that the transmission and reception paths are almost the same, the atmospheric and geometrical delays between the Earth station and the satellite are canceled. Then calculation for the timescale difference between station A and station B by the TWSTFT can be simplified. However, the reciprocity is not fulfilled, so the equation for calculating the timescale difference contains all the delays terms. From Eqs. (1) and (2), the time difference between clocks at A and B sites can be determined by:

$$\begin{aligned} TA - TB = {} & (TWA - TWB)/2 \text{ (TIC readings)} \\ & +[(dAT - dAR) - (dBT - dBR)\,]/2 \text{ (Earth station equipment)} \\ & +[(TUA - TDA) - (TUB - TDB)]/2 \text{ (Propagation delay)} \\ & +(dSAB - dSBA)/2 \text{ (Delay in satellite)} \\ & +2\Delta\tau\text{RAB (Sagnac effect)} \end{aligned} \quad (3)$$

Figure 1 shows a model of the paths of the 1pps signals propagating between stations A and B and also gives a concept for analyzing the possible reasons for the time transfer instabilities of the TWSTFT technique. The sources of instability may include the following:

1. Atmospheric effects: troposphere, ionosphere.
2. Satellite motion effects: Sagnac effect, path delay difference.
3. Environmental conditions:

Ground station's internal delays affected by temperature, humidity, pressure.
Satellite transponder delays affected by heating due to solar radiation.

To further increase the precision of TWSTFT and reduce the related uncertainties, it is very important to evaluate all potential sources of time transfer instability, and then reduce or eliminate them.

SDR-Based TWSTFT

By using TWSTFT method, two clocks at two earth stations, with their distance very far away but within a common satellite's footprint, can compare to each other to get their time difference with its uncertainty up to nanoseconds or better within high levels of confidence. Convential TWSTFT relies on the hardware "commercial Modem" to perform sigal modulation and de-modulation in T/F transfer. PRN codes with code rate of 2.5 Mcps were usually used to achieve a measurement precision of 1 ns.

However, there has been a rapid development of lab-type atomic clocks and optical clocks in recent years, and their stabilities have greatly improved. That is why there is a keen interest to improve the precision of time and frequency transfer. The usage of broadband PRN codes could achieve more precise time transfer, but it requires a wider bandwidth of the satellite transponder and will lead to the increase of connection fees of commercial communication satellites. In order to improve the time transfer precision without increasing the operational cost, the development of novel techniques becomes an important issue.

In this section, some SDR-based methods are introduced. The SDR was originally designed for implementing the dual pseudorandom noise (DPN)-based or carrier-phase (CP)-based TWSTFT measurements for improving their short-term stabilities (Tseng et al. 2012; Piester et al. 2007; Fujieda et al. 2014).

DPN Method

The National Institute of Information and Communications Technology (NICT) has developed the Dual PRN (DPN) signal method, which is based on the Binary Offset Carrier (BOC) signal that will be further used on Galileo and GPS civil navigation systems. The DPN is realized by modulating a PRN with two different subcarriers. Measuring the DPN group delay is equivalent to measuring the propagation delay. Because the frequency period between DPN's separated subcarriers can be regarded as a wider operational bandwidth, it was expected that higher resolution could be achieved. Piecewise bandwidth is the most notable advantage that the DPN signals do not really occupy wider bandwidth of satellite transponder, so the operation costs will not increase.

The DPN test was first proposed and evaluated around 2006 (Gotoh and Amagai 2008). In August 2008, NICT conducted the common clock test (Gotoh et al. 2011).

The test was successful, and the TDEV reached 20 picoseconds at 1-second averaging, as expected. In Oct. 2008, NICT compared national standard with the free-running Hydrogen Maser (Huang et al. 2011a) by using DPN method with 20 MHz bandwidth. The TDEV reached 18 picoseconds (MDEV = 5.2E-14) at 10-mimute averaging, and the results agreed with the GPS PPP ones.

The first international DPN experiment has been successfully performed between NICT and TL and lasted for several months in 2010 (Gotoh and Amagai 2008; Gotoh et al. 2011; Huang et al. 2011a) and 2011. In summary, the numerical results show that DPN results of NICT-TL experiment have higher precision and less diurnal compared with the conventional TWSTFT results. It is also comparable to GPS PPP in the short term. Moreover, the DPN technology can adopt real-time processing and will enable the cost-effective utilization of the limited satellite bandwidth in TWSTFT systems.

SDR Transfer with the Open-Loop Method

The precision of TWSTFT was limited by the so called diurnal effect, which is the daily variation of about ±0.5 ns periodically appearing in the measurement results. To investigate the diurnal effect, several articles have indicated that the daily variations may be caused by atmospheric, environmental condition, and so on. However, the diurnals cannot be completely explained by anyone of these factors, so the diurnal effects are regarded as the combination of these non-reciprocities in TWSTFT.

Based on the cooperation experience on TWSTFT DPN technlogy between NICT and TL, TL further developed the SDR receiver with the open-loop method trying to mitigate the diurnal effect.

A. The Concept of The Open-Loop Method (Huang and Tsao 2015)

The principle of two-way time difference measurement can be simply expressed as Fig. 2. The earth station A sends its on-time tick to station B and vice versa based

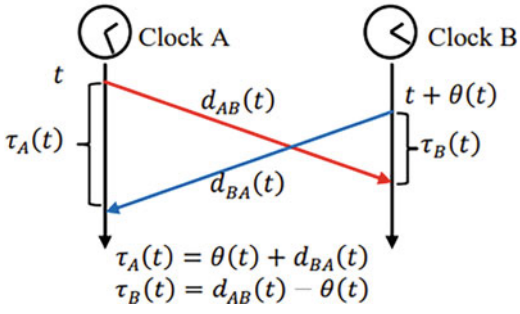

Fig. 2 The principle of two-way time difference measurement method

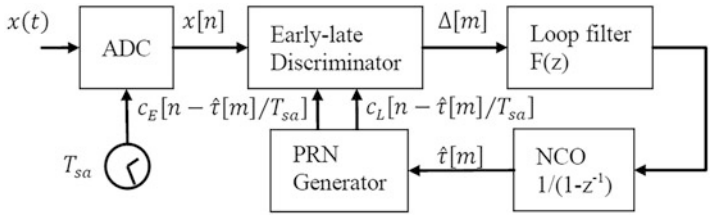

Fig. 3 Conceptual representation of the DLL with an E-L discriminator (Huang and Tsao 2015)

on their clocks, where we assume A leads B by (t) seconds at time t. Then the TOAs, $\tau_A(t)$ and $\tau_B(t)$, are measured and exchanged. If the forward and opposite paths between A and B are reciprocal (i.e., $d_{AB} = d_{BA}$), the time difference can be obtained by $\theta(t) = (\tau_A(t) - \tau_B(t))/2$.

For conventional TWSTFT modem, the most common method used for time-of-arrival (TOA) measurement was the delay-locked loop (DLL). As shown in Fig. 3, the error signal Δ[m], which is introduced to identify the code phase mismatch between the measured and true values, is fed into a loop filter F(z), to remove high-frequency components. Then by accumulating the filtered error signal using a numerical controlled oscillator (NCO), the TOA measurement is obtained. According to the TOA measurement, PRN generator updates the early and late PRN waveforms for the next cycle. It was found (Huang and Tsao 2015; Huang et al. 2016) that adopting the DLL method may cause error accumulation, and the TOA measurement will also be affected by input signal power.

In previous study (Huang and Tsao 2015), a first-order DLL was emulated and the common clock experiment was evaluated. The results showed that the first-order DLL with different loop gains will result in different TOA measurements, so that the reciprocity may depend on some parameters, such as loop order or bandwidth, used in the DLL.

For conventional receivers, a second-order DLL was also widely implemented to continuously track the PRN signal. The DLL following the correlator output will filter out the high-frequency terms of TOA measurement and reduce the measurement noise. However, it was found that the transfer behavior of the second-order DLL depends on parameters such as C/N_0 value, code-phase velocity, and code-phase drift (Holmes 2007). In the situation of multiple transmitting stations in a TWSTFT network, the C/N_0 values of all the participating Earth stations may be different due to satellite coverage or antenna pattern. Different transfer behaviors caused by DLLs would lead to different biases in TOA measurements. The biases cannot be canceled out and thus will cause an error in time-difference results. Besides, the errors caused by low quality of receiving signal will be accumulated and propagated by the closed-loop behavior of DLL.

To avoid the effects of DLL character and error accumulation, a parameter-free measurement scheme, the so-called open-loop (OL) method, was proposed to remove the loop filter and the feedback mechanism of DLL.

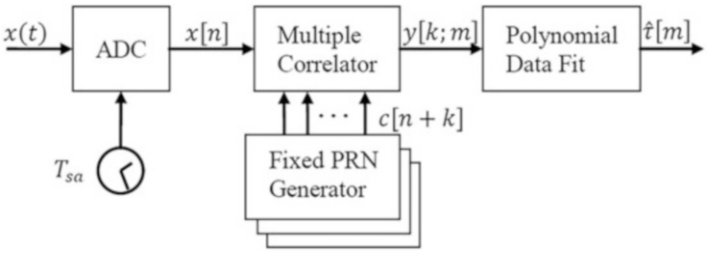

Fig. 4 Proposed open-loop TOA measurement method (Huang and Tsao 2015)

The concept of the Open-Loop(OL) method is shown in Fig. 4 that the local codes with predetermined code phase differences were generated, and they were cross-correlated with the input PRN code to get multiple correlation results. Then, these results were fitted to a second-order polynomial. The input code phase was then determined by finding the global maximum of the polynomial.

The results of previous common clock experiment, performed between two OL-based SDR and two SATRE modems, showed that the OL-based SDR could have higher reciprocity than SATRE modem. Therefore, receivers with OL method may reduce the TWSTFT uncertainties including the diurnals (Huang and Tsao 2015).

B. Implementation of SDR Receiver.

The composition of the SDR receiver and the procedure to obtain TOA will be introduced in this section.

The hardware of the SDR receiver includes an Analog-to-Digital Converter (ADC), some RF components, and a computer. To sample the receiving signal, the VSSP32 (Nitsuki 2016) and N210 (Ettus n.d.) were adopted as the ADC. The sampling frequency of ADC should set to be higher than twice of the PRN code-chipping rate, so that the PRN signal could be completely described and have better time resolution. Therefore, VSSP32 was set with a maximum sampling frequency of 64 MHz and a voltage resolution of 4 bits, and N210 was set with a maximum sampling frequency of 50 MHz and a voltage resolution of 8 bits. To avoid quantization error, an amplifier and an attenuator were used to make the signal level fulfill the dynamic range of the ADC input. Then the digital signal processing (DSP) algorithms were run in a high-performance personal computer (PC) to measure the TOA from the samples.

Besides, some previous works indicate that the effects of multipath interference and multiple access interference (MAI) would lead to diurnals (Zhang et al. 2009; Zhang and Parker 2013), so the high-resolution correlator (HRC) (Van Dierendonck et al. 1992; McGraw and Braasch 1999) and successive interference cancellation (SIC) algorithms (Pateland and Holzman 1994) were implemented on the SDR to reduce these effects.

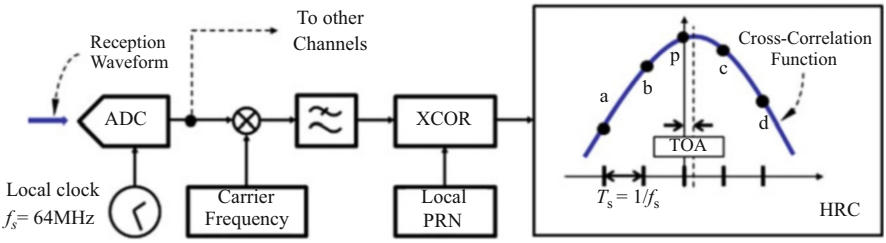

Fig. 5 The TOA measurement procedure using proposed SDR, where fs and Ts are sampling frequency and sampling period, respectively (Huang et al. 2016)

As mentioned in the previous section that the SDR is designed with the open-loop concept, so the possible errors caused by DLL could be avoided. Furthermore, the samples used for determining adjacent TOAs do not overlap. For example, using N210 with 50 MHz sampling rate, the PRN code length of 4 ms would be equal to 200,000 samples. The first 200,000 samples are used to derive the first TOA, and the following 200,000 samples will determine the next TOA. This procedure makes all TOA measurements independent, so that anomalies do not cause error propagation. Therefore, some anomalies due to low signal quality would merely affect time-difference performance, since the unusual results can be easily detected and removed.

The TOA measurement procedure by the SDR is shown in Fig. 5 (Huang et al. 2016). Conventional algorithms (Holmes 2007) are still used for the implementation of some functions, such as PRN acquisition, frequency tracking, and carrier phase locking. The received signal is first sampled and quantized by an ADC, e.g., VSSP32, and then the samples are down-converted to the baseband by mixing the carrier frequency with them and filtering out the high-frequency components. The baseband samples and desired PRN codes with different time delays are then correlated to yield the cross-correlation function (CCF). This cross-correlation procedure (XCOR) is performed once per code period, and the peak location of CCF is defined as the TOA. However, the location of the peak cannot be determined exactly due to signal processing in the discrete-time domain. Therefore, for precisely estimating the peak location, five largest CCF samples around the peak, denoted in order as p, c, b, d, a, are used on the SDR. By using HRC algorithm, the TOA measurement can be obtained with Eq. (4) from these CCF samples.

$$\mathrm{TOA} = \left(\frac{b-c}{b-2p+c} - \frac{a-d}{a-2p+d}\right) Ts \tag{4}$$

It was found that the experment results using SDR receiver showed similar long-term stability and better short-term performance in comparison to those results using conventional SATRE modem. Adopting insensitive earth station could further reduce the Diurnal effect. In 2016, the International Bureau of Weights and Measures (BIPM) and the Consultative Committee for Time and Frequency (CCTF) working

group (WG) on TWSTFT launched a pilot study on the application of SDR receivers in the TWSTFT network for UTC computation.

The first results of the pilot study, demonstrating that SDR TWSTFT shows superior performance compared to that of SATRE TWSTFT for practically all links between participating stations, were reported to the CCTF WG on TWSTFT annual meeting held in May 2017. In particular, the use of SDR TWSTFT results in a significant suppression of the diurnals. For the very long inter-continental links, e.g., the Europe-to-USA links where the diurnals are less pronounced, SDR TWSTFT achieved a smaller but still significant gain of 30%. These findings were also supported by the evaluation of some of the links with an alternate technique based on GPS signals (GPS IPPP). Stimulated by these results, the CCTF WG on TWSTFT prepared a recommendation for the 21st CCTF meeting for proposing the introduction of SDR TWSTFT in UTC generation.

After the calibration of the OP-PTB link, and an observation period which ensured the reliability of the data transmission and processing chain, SDR data was used in UTC calculation for the first time in March 2020 (https://www.bipm.org/en/-/2020-twstft-sdr).

The SDR is an open platform for the operators of the TWSTFT ground stations. The interested researchers may make deeper studies, e.g., by taking out the carrier phase information for various applications (Jiang et al. 2018).

TWSTFT Carrier Phase (TWCP) for Frequency Transfer

The precision of conventional TWSTFT is limited to signal bandwidth and is inversely proportional to the code chip rate. It was demonstracted in previous studies that, in comparison with conventional TWSTFT that adopted the code modulation technique, using carrier phase information (TWCP) could further improve the precision of TWSTFT. Sch¨afer et al. introduced the use of the carrier phase to TWSTFT (Schäfer et al. 1999), and Fonville et al. demonstrated an intercontinental test result for a few hours (Fonville et al. 2004).

The principle of TWCP is briefly introduced as the following: (Fujieda et al. 2014).

To conduct the TWCP experiment, two Earth stations A and B work as a pair. In addition to the time difference between A and B, there are three more unknown values that need to be solved. These unknown values are the phase fluctuations induced by the translation of the received to the transmitted signal at the satellite and two geometrical distances between the satellite and the two stations.

The TWCP technique requires that each site observes both its own satellite-transfered signal and the signal of its counterpart site, so that the phase information from A to B, from B to A, from A to A, and from B to B could be expressed by four equations. The Doppler frequency shift due to the satellite motion and the phase noise of the onboard oscillator could be canceled out by using the delay measurement information of earth station's round-trip signal.

Let us denote the uplink and downlink signal angular frequencies as w_u and w_d, respectively, and angular frequency of the translation onboard oscillator could be expressed as $w_s = w_u - w_d$.

Due to the Doppler effect, a signal $\sin(w_u t + w_u \tau_a(t))$ transmitting from station A can become $\sin(w'_u t + w_u \tau_a(t))$ when it arrives at the satellite, where $w'_u = w_u\left(1 - \frac{v_a(t)}{C}\right)$ and c is the speed of light.

With the onboard signal $\sin(w_s t + w_s \tau_s(t))$, the transmitting signal is further down-converted to $\sin[(w'_u - w_s)t + w_u \tau_a(t) - w_s \tau_s\,(t)]$. Due to the Doppler effect, this signal shifts to $\sin(w''_d t + w_u \tau_a(t) - w_s \tau_s(t))$ when it arrives at station B. Then with the local signal $\sin(w_d t + w_d \tau_b(t))$ at station B, the received signal is finally down-converted to

$$\sin\left((w''_d - w_d)t + w_u \tau_a(t) - w_s \tau_s(t) - w_d \tau_b(t)\right). \tag{5}$$

With the radial velocity from station B to the satellite being denoted as $v_b(t)$, the angular frequency received at station B with the Doppler shift is expressed as:

$$w''_d = (w'_u - w_s)\left(1 - \frac{v_b(t)}{c}\right) = w_d - w_d \frac{v_b(t)}{c} - w_u \frac{v_a(t)}{c} + w_u \frac{v_a(t)}{c}\,\frac{v_b(t)}{c} \tag{6}$$

The fourth term on the right hand is negligible, as it is less than 10^{-16}.

According to the above discussion, the phase information $\varphi_{ab}(t)$ in radian of the signal transmitted from station A and received at station B could be expressed as:

$$\begin{aligned} \varphi_{ab}(t) &= w_u \tau_a(t) - w_s \tau_s(t) - w_d \tau_b(t) - (w_u \nu_a(t) t + w_d \nu_b(t)\, t)/c \\ &\quad + w'_u I_{ua}(t) + w''_d I_{db}(t) + w'_u T_a(t) + w''_d T_b(t) \\ &\quad + w_u \frac{v_a(t)}{c}\,\frac{v_b(t)}{c} t \\ &\approx w_u \tau_a(t) - w_s \tau_s(t) - w_d \tau_b(t) - (w_u \rho_{as}(t) t + w_d \rho_{bs}(t))/c + w_u I_{ua}(t) + w_d I_{db}(t) \\ &\quad + w_u T_a(t) + w_d T_b(t) \end{aligned} \tag{7}$$

where T_a and T_b are tropospheric delays in seconds which are frequency independent over stations A and B, respectively. ρ_{as} and ρ_{bs} are the geometrical distances between the satellite and stations A and B. I_{ij} is the ionospheric delay correction term in seconds with frequency f_i (i = u or d) at position j which can be represented as follows:

$$I_{ij}(t) = \frac{40.3 \cdot TEC_j(t)}{c \cdot {f_i}^2} \tag{8}$$

here TEC_j (t) is the total electron content, i.e., the total number of free electrons along the signal path at position j, which is conventionally measured in TEC units. f_{u} and f_{d} are the uplink and downlink frequencies, respectively.

The phase information from B to A, from A to A, and from B to B, can be similarily represented by:

$$\begin{aligned}\varphi_{ba}(t) =& w_u\tau_b(t) - w_s\tau_s(t) - w_d\tau_a(t) - (w_u\rho_{bs}(t)t + w_d\rho_{as}(t))/c \\ &+ w_uI_{ub}(t) + w_dI_{da}(t) + w_uT_b(t) + w_dT_a(t)\end{aligned} \tag{9}$$

$$\begin{aligned}\varphi_{aa}(t) =& w_u\tau_a(t) - w_s\tau_s(t) - w_d\tau_a(t) - (w_u\rho_{as}(t)t + w_d\rho_{as}(t))/c + w_uI_{ua}(t) \\ &+ w_dI_{da}(t) + w_uT_a(t) + w_dT_a(t)\end{aligned} \tag{10}$$

$$\begin{aligned}\varphi_{bb}(t) =& w_u\tau_b(t) - w_s\tau_s(t) - w_d\tau_b(t) - (w_u\rho_{bs}(t)t + w_d\rho_{bs}(t))/c + w_uI_{ub}(t) \\ &+ w_dI_{db}(t) + w_uT_b(t) + w_dT_b(t)\end{aligned} \tag{11}$$

Since the geometrical distance from station A to the satellite and the corresponding distance from station B to the satellite are not symmetrical, there is a difference of about a few milliseconds in the arrival times of signals from stations A and B to the satellite. Let us assume that the onboard translation oscillator signal is stable during this time difference, and thus the induced phase jitter is negligible.

By subtracting Eq. (7) from Eqs. (9), and (10) and (11), one can obtain that:

$$\begin{aligned}&\varphi_{ab}(t) - \varphi_{ba}(t) = w_+(\tau_a(t) - \tau_b(t)) - w_-(\rho_{as}(t) - \rho_{bs}(t))/c \\ &+w_-(T_a(t) - T_b(t)) + w_u(I_{ua}(t) - I_{ub}(t)) - w_d(I_{da}(t) - I_{db}(t))\end{aligned} \tag{12}$$

and

$$\begin{aligned}&\varphi_{aa}(t) - \varphi_{bb}(t) = w_-(\tau_a(t) - \tau_b(t)) - w_+(\rho_{as}(t) - \rho_{bs}(t))/c \\ &+w_+(T_a(t) - T_b(t)) + w_u(I_{ua}(t) - I_{ub}(t)) + w_d(\,I_{da}(t) - I_{db}(t))\end{aligned} \tag{13}$$

Here $w_+ \equiv w_u + w_d$ and $w_- \equiv w_u - w_d$, and the terms related to the onboard signal are canceled.

In TWCP, the geometrical distances $\rho_{as}(t)$ and $\rho_{bs}(t)$ in Eqs. (12) and (13) are unknown, and we can further subtract the above intermediate results to cancel them to obtain:

$$\begin{aligned}&w_+(\varphi_{ab}(t) - \varphi_{ba}(t)) - w_-(\varphi_{aa}(t) - \varphi_{bb}(t)) \\ &= \left(w_+{}^2 - w_-{}^2\right)(\tau_a(t) - \tau_b(t)) \\ &+2w_uw_d[(I_{ua}(t) - I_{ub}(t)) - (I_{da}(t) - I_{db}(t))]\end{aligned} \tag{14}$$

The time difference between stations A and B could finally be obtained by using the following equation:

$$\tau_a(t) - \tau_b(t) = \frac{w_+\alpha(t) - w_-\beta(t)}{{w_+}^2 - {w_-}^2} + \frac{2w_u w_d}{{w_+}^2 - {w_-}^2} \times [(I_{da}(t) - I_{ua}(t)) - (I_{db}(t) - I_{ub}(t))] \quad (15)$$

where

$$\alpha(t) \equiv \varphi_{ab}(t) - \varphi_{ba}(t)$$

$$\beta(t) \equiv \varphi_{aa}(t) - \varphi_{bb}(t)$$

On the right hand of Eq. (15), the first term is derived from the four observed phases, the second one is for ionospheric delay correction, and the tropospheric delays are canceled. Since the uplink and downlink frequencies of TWSTFT are around 14 GHz and 12 GHz, the coefficients $w_+/({w_+}^2 - {w_-}^2)$ and $w_-/({w_+}^2 - {w_-}^2)$ are about 7.0E−12 and 8.0E−13, respectively. Thus, a measurement precision of 1.0E-13 seconds could be expected when the phase detection has a resolution of less than 0.1 radians.

Besides, the ionospheric correction term can be calculated, when $TEC_j(t)$ is obtained by theoretical model or actual measurement. The ionospheric delay needs to be considered carefully because of the frequency difference between uplink and downlink and the TEC difference between the ionospheres at stations A and B. Since the TWCP frequencies are higher than those used in GPS, the effect due to the ionosphere is smaller than that encountered in GPS time transfer. However, the amplitude of the ionosphere effect could be up to a few hundred picoseconds, so it cannot be neglected in TWCP, even though it is usually assumed to be negligible in conventional TWSTFT.

Some TWSTFT experiments using TWCP technique in recent year have showed encouraging results. One of these TWCP experiments was performed between NICT and PTB (Fujieda et al. 2014), with it ranging up to about 9000 km, and it confirmed that TWCP is applicable over very long baselines. The experimental results showed a good agreement with those measured by TWCode and GPSCP and clearly demonstrated that the measurement precision of TWCP is superior to that of TWCode and GPSCP.

Later study confirmed again that TWCP can provide higher stability than that obtained by conventional TWSTFT (Fujieda et al. 2016). The advanced TWCP technology had also been applied to optical clock comparisons between NICT and KRISS. It was demonstrated that the satellite-based techniques have the potential to realize uncertainty at the 1.0E−17 level, when optical clocks are continuously operated for a week or more (Fujieda et al. 2018).

"Software Ranging System (SRS)" Modem Developed by NICT (Fujieda et al. 2019, 2020)

To extend the application of the TWCP, the National Institute of Information and Communications Technology (NICT), Japan, is further devoted to develop the SRS

modem which allows both the code and the carrier phase measurements, with the goals of carrier-phase frequency transfer with instability below 1.0E-16 and time transfer by the code phase with lower than 1 ns uncertainty.

The newly developed SRS modem consists of FPGA (Field Programmable Gate Array), DAC (Digital to Analog Converter), ADC (Analog to Digital Converter), 1-GHz VCO (Voltage Controlled Oscillator), and PLL (Phase Locked Loop). A design consisting of mostly digital components makes the modem cost-effective and reconfigurable.

The performance of time and frequency transfer in a common clock and non-common clock measurements were evaluated, and encouraging results were obtained. Frequency stability of low 10^{-17} level has been achieved in the initial carrier phase measurements performed over domestic distances with a common-clock configuration. The observed delay repeatability also promises a calibration uncertainty lower than 1 ns (Fujieda et al. 2020).

Hopefully, the new SRS modem could be further improved by combining code-phase and carrier-phase measurements to achieve better time and frequency transfer stabilities, and then applied to more TWSTFT links.

Delay Calibration of Twstft Links

Based on the path reciprocity of signals, the TWSTFT technique cancels out the first-order effects. To increase the precision of time transfer, especially when the data of TWSTFT link will be applied to TAI computation, the parameters of nonreciprocal residual effects need to be determined. The possible delay differences due to nonreciprocal residual effects may happen in: (1) the propagation in the atmosphere for up and down links, (2) the transponder path in the geostationary satellite, (3) the earth rotation (Sagnac effect), and (4) inside each earth station including transmission and reception paths. The last parameter seems to be the most important source of error.

Most of the TWSTFT time transfer links were calibrated by using GPS common-view measurement results before 2006, and thus the attainable uncertainty was limited to several nanoseconds. Considering on this, the CCTF Working Group on TWSTFT stimulated to perform calibrations of TWSTFT links using more adequate technique.

According to the guideline (Jiang et al. 2016) proposed by BIPM, there are two major methods as follows:

1. Using a portable earth station (PS), which is in the relative calibration mode, either as an independent time transfer technique or as a reference to determine the relative delays of the earth stations to be calibrated with respect to the PS.
2. Using GPS traveling calibration equipment.

Besides, some other calibration methods have also been developed for the TWSTFT calibration, as follows:

3. Using a satellite simulator in the absolute calibration mode.
4. Using triangle-closure condition of TWSTFT links.

These methods for TWSTFT delay calibration will be briefly introduced in the following sections. Moreover, since the SDR method has been adopted for UTC calibration, the calibration rule proposed for SDR links will also be mentioned.

TWSTFT Calibration Using Portable TWSTFT Station

The differential delays of TWSTFT-participant earth stations can be determined by means of a portable TWSTFT station which is operated in consecutive experiments side-by-side with the participating earth stations in a common clock setup. The use of portable TWSTFT equipment has allowed time transfer with nanosecond accuracy, and the calibration uncertainty is usually uB $\leq$ 1 ns (Galindo et al. 2016; Piester et al. 2014; JCGM 2012; Bauch et al. 2011). All the details about the organization, data processing, uncertainty evaluation to be included in the final report, and the CALR (link calibration result) implementation of the calibration campaign can be found in references (Jiang et al. 2016; Galindo et al. 2016).

In the calibration campaign, TWSTFT will sequentially operate at participant laboratories during the period of the calibration trip. To verify the stability of the portable station during the trip, the measurements at the first site can be repeated again after visiting all other participating institutes in each campaign (Fig. 6) (Piester et al. 2005, 2006).

NICT and TL have performed bilateral comparison campaigns in 2006. An uncertainty of about 1 ns in the differential calibration was achieved. Although calibrating the TWSTFT earth stations by portable station is commonly used

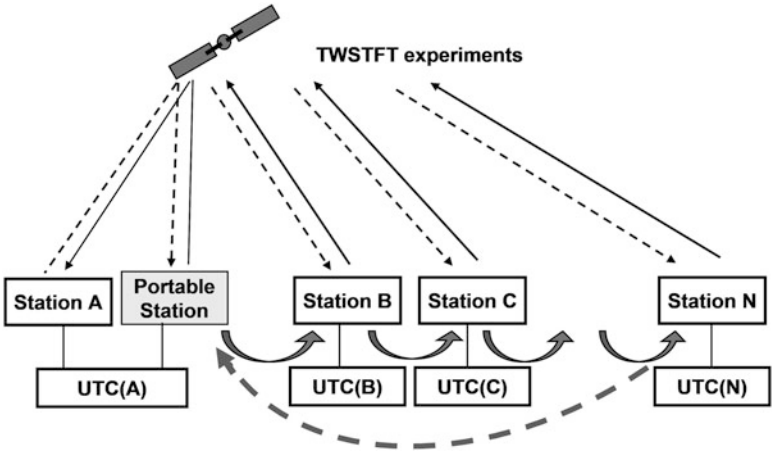

Fig. 6 Schematic set-up of TWSTFT calibration trip by using portable station (PS)

among European labs, it is not convenient for laboratories located in different continents. For example, in Asia-Pacific Rim region, TWSTFT calibration using portable TWSTFT station needs to transport the portable station overseas and thus make it very difficult. Besides, the calibration scheme of circulating a portable TWSTFT reference station is applicable, only in the case that the single satellite transponder is used. This condition is not always fulfilled in the intercontinental links, e.g., between Asia and Europe. In such case, calibration of the TWSTFT link can be achieved by adjusting the TWSTFT results to those obtained with a calibrated GPS link. PTB has proposed a method exchanging two portable TWSTFT stations and two GPS receivers between the two earth stations to be calibrated. The overall uncertainty for the calibration was estimated to be at a level of 2 ns (Fujieda et al. 2007).

TWSTFT Calibration Using GPS Traveling Calibration Equipment (TWSTFT 2012)

When calibration via the portable TWSTFT station is not applicable, the GPS time link calibration can be used as an alternative one, with which the uncertainty of 1.5 ns is attainable (Jiang et al. 2015). The GPS link calibration differs from the GPS receiver calibration. The latter is based upon a common clock difference (CCD) of the two GPS receivers (the traveling and the local receivers). The GPS link calibration measures the double clock difference (DCD) directly, which is calculated by subtracting the GPS link between the traveling calibrator and the remote site master receiver from the TWSTFT link. A link calibration of either TWSTFT or GPS is referred to the UTC pivot point (PTB at present).

Using GPS to calibrate a TWSTFT link is a simple alternative way. However, reporting the results to BIPM is essential and all key points, as what are requested for the calibration using a portable TWSTFT station, should be addressed in an adequate way.

Earth Station Delay Measurement Using Satellite Simulator (SATSIM)

In the past decades, several laboratories and companies have devoted time to the development of satellite simulator for the absolute calibration of TWSTFT station. This method was first proposed by De Jong (de Jong et al. 1989). By using the method and instrumentation developed at NMI Van Swinden Laboratorium (VSL, the Netherlands), six European Earth stations (participating in one TWSTFT experiment) were calibrated in an absolute way in 1994 (de Jong et al. 1995). These six stations have also been calibrated in a relative way by a portable station. Most results of these two methods showed an agreement to the level of 10 ns, although few of the data showed significant deviations of multiples of 100 ns. LNE-SYRTE (France) also had developed a satellite simulator and implemented it into the earth station. Afterward, VSL designed and assembled a dual-stage quad-mixer satellite simulator

(Mubarak and Dierikx 2011). With this satellite simulator, all delays in the TWSTFT station can be determined in absolute terms. The satellite simulator was implemented in the TWSTFT station and can automatically perform the delay calibration measurements. As for most of the newly developed equipment, the optimum transmission power level for each measurement path is underdetermined to achieve an optimal signal-to-noise (S/N) ratio, and then its long-term behavior can be determined.

The SATSIM equipment was mainly used for the Earth station delay measurement (absolute delay difference calibration and monitoring), and the measurement accuracy could be at a level of few hundred picoseconds. SATSIM can also be used to measure the delay fluctuations in earth stations. These fluctuations are the main source of instability that degrades the accuracy of TWSTFT. TL had installed a satellite simulator system, which was developed by a German company, on an earth station for the investigation of signal path delay variations in the TWSTFT earth station (Tseng et al. 2007). The results showed that the long-term and short-term temperature variations have different contributions to the measured delay value of the earth station. Besides, a very high correlation between the delay of earth station and the outdoor temperature data was observed.

Calibration of TWSTFT Links by Triangle-Closure Condition

Although the high accuracy of TWSTFT has a potential subnanosecond uncertainty, it is based on a metrological calibration. The calibration campaign is labor- and cost-intensive, and also limited by the complexity of the organization and the availability of equipment. Therefore, it is not practical applying either of the above calibration methods to all TWSTFT links.

Actually, three TWSTFT links, among three time-keeping laboratories, can make their contribution through the triangle constraint. The sum of three TWSTFT links will form a closed triangle, the so-called the triangle closure. In ideal case, a closure is expected to be zero if there are no measurement errors, namely, the triangle closure condition (TCC). BIPM (Jiang et al. 2008) has proposed a strategy to transfer the existing TW calibrations of the uncalibrated links using the TCC in the UTC TW network. The Europe-America TW network, comprised of 10 national time-keeping laboratories, was calibrated in this way. The related UTC data within the same period was used for the computation. The uncertainties of the TCC are 2 ns or 6 ns, depending on the original calibration uncertainties of TWSTFT or GPS, respectively. This is satisfactory for most of the scientific and metrological applications. By using this strategy, most of the time transfer links in a TWSTFT network can be easily calibrated.

The Calibration Issue of SDR TWSTFT Method (Jiang et al. 2018)

Since SDR TWSTFT shows better performance in comparison to the conventional SATRE TWSTFT, it was considered to apply the SDR TWSTFT results in the

generation of UTC, which required the signal delays along the full propagation path to be fully determined.

The SDR link calibration can be achieved by adopting the following rules:

1. For UTC links:
   (a) If the SATRE link is calibrated, the SDR link should be aligned to it.
   (b) If the SATRE link is not calibrated, both links – the SATRE and the corresponding SDR link – should be calibrated together by using a portable TWSTFT station or GPS calibrator with the "link" method (TWSTFT 2016).
2. The non-UTC link delay should be calibrated by the triangle closure calibration (TCC) method (TWSTFT 2016).

The conventional uncertainties of the UTC SATRE links, with uA and uB being 0.5 ns and 1.0 ns (using TWSTFT portable station calibration) or 1.5 ns (with GPS Calibrator), respectively, are assigned by BIPM. Usually, higher uncertainty values than the estimated ones will be assigned, e.g., the estimated uB for conventional SATRE links is 0.6 ns, while the actual values of 1.0 ns were assigned. These values are derived from a detailed report on the used link data in Section 5 of Circular T and are assigned to time differences UTC-UTC(k) as reported in Section 1 of Circular T at a 5-day grid.

Regarding the SDR TWSTFT links, its corresponding values of uA and uB are 0.2 ns and 1.0 to 1.5 ns, respectively (Jiang et al. 2018). It has been demonstrated that for short baselines, e.g., OP-PTB, a gain factor of two or three is obtained in the stabilities of SDR links in comparison with those of SATRE links. For long baselines, e.g., NIST-PTB, with much smaller diurnal comparing to most of other links, the stability of the SATRE link is already below to 0.2 ns. Therefore, assigning the uA value of 0.2 ns to a SDR link is reasonable.

As for uB, the conventional value is applicable for both the SATRE and the SDR links because the conventional uB of the SATRE link is often higher than the measured one. Therefore, the combined uB of the SDR link could be covered by the conventional uB of the SATRE link.

The conventional value of the uB for the SDR TCC calibration is 2 ns, the same as that when using SATRE data (Jiang et al. 2008). The uB of SDR links may be further improved if a direct SDR link calibration is performed.

Analysis of the Instabilities in TWSTFT

Instability Sources of TWSTFT

Potential causes of nonreciprocity and evaluating the sources of delay instability have been discussed by many researchers . Recently, reference clocks of many TWSTFT stations have changed to hydrogen masers (which provide better short-term stability) and the TWSTFT measurements are performed more frequently (even 24 h a day for Asia-Pacific TWSTFT network comparisons). Therefore, the

influences of instabilities in TWSTFT have emerged from the clock noise and become an important issue. The major instability sources of TWSTFT include (Recommendation ITU-R 2015): the Sagnac effect, environmental temperature, ionosphere, ground station delay (out-door and in-door), and path delay difference due to satellite motion.

Sagnac effect is associated with the Earth's rotation, which causes the relative position of a geostationary satellite to vary slightly over the course of a 24-h period. The variation of Sagnac can be computed from the ephemeris data of the satellite (Parker and Zhang 2005; Piester et al. 2007; Tseng et al. 2011).

The environmental temperature is also an important instability source. Previous studies demonstrated the TWSTFT measurements may show high correlation with local temperature of station sites. The NIST have measured temperature coefficients of group delay for several different TWSTFT sets of equipment (Parker and Zhang 2005). Their data showed that the temperature coefficients of TWSTFT system could be as large as several 10 ps/°C. TL employed a satellite simulator system (SATSIM) to measure the differential path delays (i.e., (TX-RX)/2) in 2005 (Mubarak and Dierikx 2011; Tseng and Lin 2005). By using a high chip rate of 20 Mcps (chip per second), a very high correlation between the delay of earth station and the outdoor temperature data was observed. During TWCP measurements, it is also observed that the transmission power decreased by about 10 dB when the outdoor temperature increased to more than 30 °C. In the case of common clock TWCP measurement, there was a daily variation of the measurement results with an amplitude of about 20 ps, and it had a correlation with the variation of the outdoor temperature (Fujieda et al. 2014). Nevertheless, if the whole TWSTFT equipment could be placed in a well-controlled environment, the influence of temperature could be regarded as a controllable factor.

Since TWSTFT use different frequencies for up- and down- links, the transmitting and receiving signals go through the ionosphere with different delays, which cannot be completely canceled in the two-way difference, and will thus cause instability. The ionospheric delay varies with respect to some factors, such as the change of total electron content (TEC) and the elevation angle of a TWSTFT station. Because the TEC varies with solar activity, the TEC shows both diurnal and annual variations. Besides, for TWSTFT link with long-baseline, its elevation angle will be lower, so longer ionospheric delay will be included and will cause larger ionospheric delay difference in the TWSTFT measurements. For a short-baseline time transfer, the difference for the ionospheric delay is usually less than 100 ps. While for an intercontinental measurement, this delay term could be larger from 150 to 300 ps. (e.g., 300 ps for NIST-PTB link (Parker and Zhang 2005), and 150 ps for NICT-PTB link (Piester et al. 2007)).

There are two other nonreciprocity terms related to the satellite motion. One is the path delay difference with its impact of less than 15 ps. The other term is frequency shift due to the Doppler effect, which is proportional to the relative velocity of satellite motion. Due to the error possibly caused by the imperfection of the TWSTFT receiver, the Doppler shift will cause the additive variation into the measurements (Tseng et al. 2011). A study on multiple access interference between

multiple pseudorandom noise (PRN) coded signals has tried to explain this effect (Huang et al. 2011b). The amplitude of the "measurement error" was estimated as large as 1.5 ns for a chip rate of 2.5 Mcps (chip per second). This term is likely to be eliminated by reducing the interference between PRN codes, and worth further studies.

Regarding the ionospheric delay, since it is inversely proportional to the square of the signal frequency, it cannot be canceled out in TWSTFT because of the frequency difference between the uplink and downlink. In TW Code, the impact of the ionospheric delay is assumed to be negligible (JCGM 2012). However, it should be considerable in the TWCP link taking the high performance into account. Related investigation on the ionospheric delay, along with some other error sources in TWSTFT carrier phase over very long baseline, was obtained in 2014 (Fujieda et al. 2014).

Although previous research investigated many instability sources of TWSTFT, it is clear that we have not identified all sources, since the observed instabilities in real TWSTFT links are larger than expected. Moreover, the causes of the obvious diurnal effect can still not be explained well. Anyhow, the main instabilities summarized from past studies are compiled in Table 1.

The Issue of Diurnals (Jiang et al. 2019)

The major source of statistical uncertainty in current TWSTFT is the daily variations, so-called diurnals, observed in the TWSTFT link data. Although the diurnals have been investigated extensively in the past (Parker and Zhang 2005; Piester et al. 2007; Zhang and Parker 2013; Mubarak and Dierikx 2011), the real causes of this effect are not fully understood and only some strategies for suppressing it have been developed up to now. Based on previous studies, the possible sources that lead to diurnals could be separated into two categories as follows.

The first category is related to the variations of the path delay difference (PDD) of the two signals traveling, in opposite directions, between the pair of TWSTFT ground stations A and B. For example, the Tx signal of station A transmits through the ground station equipment, free space, satellite, and down to station B. The Tx signal of station B also transmits in opposite direction to station A. The PDD of these two signals could be affected by a couple of factors, e.g., those mentioned as the following, typically with a daily pattern and thus cause a diurnal pattern in the TWSTFT results:

(a) The geometrical path delay difference: due to the gravity of the sun and maneuvers for position keeping, the geostationary satellite will swing around its nominal position. In combination with the time offset at which the signals from the ground stations arrive at the satellite, a geometrical path delay difference may be caused. The satellite daily movement data are not available to us, but the geostationary satellite is about 35,786 km above the earth surface, and

Table 1 Summary of instabilities in TWSTFT system

Instable terms and its potential sources	Amplitude of variation (ps)	Comments
Ionospheric delay difference (caused by TEC variation)	<100 (area) 150 ~ 300 (transoceanic length)	TEC varies with solar activity Elevation angle Larger difference for longer baseline
Sagnac effect (caused by satellite motion)	50	NICT-TL link via satellite IS-8
	10 ~ 150	NICT-PTB very long TWCP link (Fujieda et al. 2014)
Path delay difference (caused by satellite motion)	15	Satellite velocity Difference of arriving times of two signals
Doppler shift, and interference between multiple PRN codes (caused by satellite motion)	30 ~ 1500 (for 2.5 Mcps)	May be enlarged in the code-tracking process Depends on chip rates
Ground station delay (caused by outdoor temperature)	120 ~ 350 (variation range of outside temperature: 5 ~ 16 °C	Temperature coefficient: −22 ps/°C for TL's ground station (outdoor up/down converter) Measured by SASTIM in 2006 using a chip rate of 20 Mcps
Indoor equipment (caused by indoor temperature)	40 ~ 150	The variation of the room temperature may be up to 1.5 °C at TL
Troposphere delay difference	3	NICT-PTB very long TWCP link (Fujieda et al. 2014)
Phase jitter in satellite transponder	Unknown	
Phase jitter in instruments	0.2 (frequency converter)	
Phase variation in instruments	100	
2nd-order Doppler shift	2	

thus the related daily change of PDD was estimated to be approximately 200 ps (Zhang and Parker 2013).

The satellite movement also changes the magnitude of the relativistic Sagnac effect, while the nominal Sagnac effect of a baseline has been included in the link calibration.

(b) Temperature changes of satellite's transponders: Different surface parts of the satellite get exposure to radiation from the sun during the day and may cause temperature changes to the transponders and lead to delay changes. The effect could be canceled, if only one transponder is used in the TWSTFT link (such as the Europe-to-Europe links). The PDD change could be significant if two transponders are used (such as the Europe-to-USA links) for long-baseline comparison.

(c) Different frequencies adopted for the up- and down-link signals transmission: different frequencies used for the up- and down-link signals transmission: since the ionosphere is a dispersive medium, the path delays can be slightly different for signals transmitting to and receiving at the satellite. The troposphere is also dispersive but with a much lower level of influences at the adopted frequencies (Hobiger et al. 2013); by using Ku-band frequency, the change of ionospheric delay has been estimated to be less than 150 ps (Zhang and Parker 2013) and the tropospheric delay would be even smaller (Piester et al. 2007).
(d) Environmental condition of TWSTFT stations: Mainly temperature, but potentially also humidity and pressure, may cause variations of the delay between TX and RX signal paths in the equipment of ground station. Dependent on the equipment quality of the earth station, the environmental impact on the PDD could be as large as 1 to 2 ns.

The second category is related to signal interferences and multipath effects. For example, the signal interferences under the situation of multiple transmitting stations (such as Europe-to-Europe TWSTFT links) in a TWSTFT network, and multipath effects that may be caused by impedance mismatch in the equipment. These effects may, depending on the characters of the modem, lead to hardly quantifiable shifts in the time-of-arrival measurements of the RX module at the ground station. The diurnal pattern of the TWSTFT results look similar with those from the rather systematic effects discussed above, while it is difficult to distinguish them from each other.

Based on recent studies, adopting some newly developed TWSTFT technology, e.g., SDR method or SRS modem (carrier phase), could suppress the diurnal effect of many TWSTFT links. For intracontinental TWSTFT results, the improvement by adopting SDR receivers in reducing diurnals is significant, although some residual diurnals still exist. As for the TWSTFT SDR results of the inter-continental links, the diurnals are only slightly suppressed. Therefore, further studies are needed for full understanding of the entire causes of the diurnals.

Part IV

Certified Reference Materials/Bharatiya Nirdeshak Dravya (BND): Need and Boon for Atma Nirbhar Bharat

Certified Reference Materials (CRMs)

22

An Introduction

Nahar Singh

Certified reference materials are required to ensure the quality and metrological traceability of products, validate the test methods/procedures and calibration of analytical instruments (Zakaria and Rezali 2014). Indian institutes/industries/R&D Sectors/accredited labs, etc., are procuring several reference materials for quality assurance. Due to the non-availability of indigenous reference materials, it is not easy to establish the quality of the procured product. The developed nations have their regulations and programs to procure quality products (Trienekens and Zuurbier 2008). The use of certified reference material can establish the quality of the procured product through validation of procedures and calibration of measuring equipment (Guide 2009). The stability, homogeneity and traceability of measurement ensure the quality of the reference material (Bunk 2007). The shelf-life of reference material is also an essential factor, as sometimes it expires even before usage because of low shelf-life, thereby creating an extra burden on users (Pauwels et al. 1998). Procuring from abroad is tedious; extra resources are involved, and the expiry time starts from the time it is dispatched. The transit time is also counted as a lifetime. To cater to the need of institutes/industries/R&D labs/accredited laboratories and avoid import, CSIR-NPL has taken the initiative to develop the certified reference materials (Bharatiya Nirdeshak Dravya: BND®) in-house and in collaboration with Reference Material Producers who are accredited as per ISO 17034: 2016.

Although, CSIR-NPLI has produced more than a hundred BNDs, in-house and in collaboration with RMPs, many more are yet to be developed (Pant et al. 2020). Still, there is significantly less awareness about the BNDs among institutes/industries/R&D labs/accredited laboratories and even the assessors. There is a need to create awareness about BNDs among the stakeholders. In this direction, BIS has taken the step to publish Indian standard specifications equivalent to ISO 17034:2016 (Aswal

D. K. Aswal et al. (eds.), *Handbook of Metrology and Applications*,
https://doi.org/10.1007/978-981-99-2074-7_25

2020). Recently, the Bureau of Indian Standard (BIS) and the National Accreditation Board for Testing and Calibration Laboratories (NABL) has approved and encouraged industries to use Indian reference Materials (BNDs) instead of expensive imported CRMs (Pant et al. 2020). Another way of popularizing the BNDs is bringing out technical publications and publishing handbooks, book chapters, etc. However, these should not be very scientific in content but written in a manner that the accredited laboratory personnel, assessors, and even the common public can understand their utility. Therefore, these chapters are not scientific but presented so the reader can understand the reference material, why it is necessary to develop it, how it can be created, and where it is available. Also, the primary and secondary standards, their needs, and the distinction between them are discussed in the book. Thus, the book chapters will be a guide for the researcher working on reference materials which are required in almost all fields.

BNDs are the primary reference standards that ensure the reliability and comparability of the measurements as a bench-mark for quality. For global visibility, the BNDs produced by CSIR-NPL in different sectors are uploaded to the international database, i.e., COded'Indexation des Matériaux de Référence (COMAR) (Aswal 2020). In addition, Indian Reference Materials (BND) acts as an import substitute and is economically viable for many academic institutions and industries. Some of the major existing industries in India are taking the traceability or reference materials from abroad at a considerable cost. These reference materials have to be procured at a very high cost and need to be procured repeatedly after the validity of the reference material has expired. Thus, there is a substantial recurring loss of national resources. Also, we are procuring many materials, products, and sophisticated instruments and many times, we get substandard products and need to develop an adequately certified calibration facility to check them. These substandard materials are not only causing loss of national resources but also causing various kinds of pollution, as these materials, when thrown, degrade, and most are unusable.

Indian Reference Materials (Bharatiya Nirdeshak Dravya: BND®) division of CSIR-NPL is actively involved in the preparation of various BNDs in different sectors such as petroleum, cement, water, hardness, breath alcohol, pH, minerals, food etc. It may be noted that India faces a massive problem due to poor quality imports on the one hand and rejection of our export at foreign borders, on the other hand, causing a substantial economic loss to the country (Athukorala and Jayasuriya 2003). BNDs are poised to bring a rapid transition of India from a developing state to a developed state by strengthening its quality infrastructure and manufacturing. The CRMs are being procured at a very high cost. India is importing CRMs from other countries to the tune of several hundred crore rupees/annum. It indicates that the availability of indigenous CRMs (BNDs) will save huge import costs, enhance the export and thereby increase the country's GDP by many folds, reinforcing the "Make in India" and "self-reliance" pledge of the Government of India. The reference materials will boost the overall quality and safety of life in the country and international trade. For clarification, the definition of reference materials, certified reference materials, and Bharatiya Nirdeshaka Dravya is presented below:

Reference Material (RM): Material sufficiently homogeneous and stable concerning one or more specified properties, which have been established to fit its intended use in a measurement process (Ulberth-Buchgraber et al. 2011).

Certified Reference Material (CRM): The reference material is characterized by a metrologically valid procedure for one or more specified properties, accompanied by a certificate that provides the value of the specified property, its associated uncertainty, and a statement of metrological traceability (Beauchamp et al. 2020).

Bharatiya Nirdeshak Dravya (BND): A CRM issued by CSIR-NPL characterized by a metrologically valid procedure for one or more specified properties with associated uncertainty and accompanied by a certificate or certificate of analysis, providing a statement of metrological traceability (Pant et al. 2020).

Indian Reference Materials (Bharatiya Nirdeshak Dravya: BND®) division of CSIR-NPL is actively involved in the preparation of various BNDs in different sectors such as petroleum, cement, water, hardness, breath alcohol, pH, minerals, food etc. This reference material will boost the overall quality and safety of life in the country and international trade (Pant et al. 2020).

CSIR-NPL provides measurement traceability by calibrating equipment using its national primary standards and BNDs. BNDs are well characterized using state-of-the-art measurements to determine the chemical composition and/or physical properties. BND ensures the accuracy and reliability of measurement required for controlling the quality of products developed by the industry for discoveries in science, innovative technologies, pharmaceuticals, and monitoring the environment for better health and safety of the people of India.

The section is divided into nine chapters. One of the chapters describes the usage of BNDs for the calibration of the measuring instruments. CSIR-NPL has developed some BNDs related to the calibration of sophisticated instruments such as X-ray diffractometer, FTIR, and scanning electron microscopy, and the list is increasing rapidly. These BNDs are traceable to national standards. The need, how to produce, the market size, etc., have been described in this chapter. CSIR-NPL has also developed 18 nos. BNDs of the primary gas mixture, which are needed for calibrating various environment monitoring equipment. The primary reference gas mixtures of CO, CO_2, CH_4, and N_2 are presently available with CSIR-NPL. Another chapter discusses the role played by RMs and CRMs in standardization, QC and QA and their application for various purposes by the respective bodies – in the manufacturing and services sector – and international trade. The discussion reveals that ISO/IEC 17025:2017 embodies the spirit of the Plan-Do-Check-Act (PDCA) cycle. Taking the case of the Indian cement industry, the requirement of calibrations and RMs at various production and quality control stages is also discussed.

One of the chapters is related to cement and building material BNDs. CSIR-NPL started developing the cement-related BNDs in 2018 in collaboration with the National Council for Cement and Building Materials (NCCBM). It has contributed to the growth and development of the cement and construction industry, quality control, testing, method validation, technology transfer, productivity, and cost-effectiveness. India is the second-largest cement producer globally and has attracted

huge investments from Indian and foreign investors. The cement sector has to play a pivotal role in the Government of India's initiative of developing hundred smart cities, housing for all, dedicated freight corridor, water transport, concrete road projects, etc. In 2020, cement production had reached about 337 million tonnes and was projected to reach 450 million tonnes by 2022 (Karkun 2017). Due to the increasing demand in various sectors such as housing, commercial construction, and industrial construction, the cement industry is expected to reach 550–600 million tonnes per annum by 2025, contributing to a market size of approximately 10 billion USD (Nandamuri et al. 2017). India could become the leading clinker and grey cement exporter to the Middle East, Africa, and other developing nations in the next 10 years (Pareek and Pincha 2015). Therefore, there is a need for more stringent regulations on product quality where BNDs have to play a significant role. The current CRM market in India is approximately INR 5 to 6 crore per annum (Aswal 2020). Twelve BNDs have been developed and released in the market, and the list is multiplying. These BNDs have been sold in India, Nepal, Bhutan, Bangladesh, Africa, Hong Kong, and the Middle East. The details of production, the method of certification, etc., are described in detail in the chapter.

Another area where CSIR-NPL produces BNDs is food, chemical, and biologics. Food and water contamination is a significant concern globally. Unsafe and contaminated food consumption leads to food-borne infections, allergic reactions, and food intoxication (Gallo et al. 2020). Approximately 1.7 billion cases of childhood diarrhea diseases occur every year globally due to unsafe food and water (according to World Health Organization 2020) (Lee et al. 2020). The quality of the laboratory test is a deciding factor and an essential prerequisite that impacts health, the environment, and the economy. The BNDs are pivotal in providing uniform, traceable and reliable measurements. Food, water, and environmental testing laboratories extensively use mass spectrometry, chromatography, and other analytical techniques to check for adulteration, ensure health safety, and require periodic calibration using CRMs.

CSIR-NPL produces BNDs for food, water, and environment sectors with NABL accredited Aashvi Technology LLP, Ahmedabad, Gujarat and Fare Labs, Gurugram, Haryana, for direct benefit to the testing laboratory, educational institutes, R&D centers, industries, in-house labs. CSIR-NPL with Aashvi Tech LLP has developed 27 BNDs for food, water, and environment, and the list is growing fast to minimize the import of CRMs. Currently, the focus is on toxins, contaminants, vitamins, pesticide residue, and some specialized BNDs. BNDs for copper, nickel, lead, arsenic, mercury, cadmium, zinc, iron, and TDS standard solution, potassium hydrogen phthalate, potassium dichromate, sodium chloride, sodium carbonate, calcium carbonate, and pH buffer solutions 4.00, 7.00, and 10.00 are available with CSIR-NPL.

One chapter in the book is related to Petroleum BNDs. India is the second-largest refiner in Asia and the fourth largest globally (Nichols 2014). Its crude oil import was US dollars 101.4 billion in 2019–20. The economic progress of India is closely linked to its energy demand. Therefore, the need for oil and gas is expected to grow more, making the oil sector more attractive for investment. It makes it indispensable

to have a stringent check on the quality of imports and exports of petroleum products. The results from lab tests play a significant role in ascertaining the quality of petroleum products. Using BNDs ensures that laboratory instruments perform to the standard of predefined value, assuring laboratory tests' accuracy. With the non-availability of indigenous certified reference materials, domestic refiners have been importing the materials from other economies. CSIR-NPL has partnered with HPCL and BPCL to produce 29 BNDs, and the list is growing. The petroleum BNDs are expected to save foreign exchange and time, avoiding delays in receiving imported reference materials. Also, with the availability of BNDs to the Middle East, the African continent will love to expand business with us. The petroleum BNDs include BNDs for the various concentrations of sulfur, flash point (PMCC and Able), smoke point, distillation standards, pour point, color saybolt, color ASTM, total base number, total acid number, FIA-aromatics, olefins, saturates, density, kinematic viscosity at different temperatures, freezing point, etc.

Yet another chapter deals with the precious metal BNDs. The Global precious metal market was valued at USD 182.1 billion in 2019 and is expected to grow at a compound annual growth rate of 9% in revenue from 2020 to 2027. Asia-pacific is the primary producer and consumer of gold. The metal is significantly consumed in China and India. As the value of the precious metal is determined from a measurement of fineness, most countries have established laws regulating the manufacture and sale of precious metal items to protect the market and consumer. Different countries have varying standards and regulations that govern the manufacture and sale of good jewelry (Kannabiran and Bhaumik 2005). They differ in the marking systems, allowable tolerances, and fineness standards, among other things. With so much variation, it is easy to see why international trade in gold jewelry can be hampered by the standards and regulations of individual countries.

BND 4201 is India's first high purity (99.99%) gold reference standard manufactured by CSIR-NPL and Government Mint, Mumbai, in collaboration with Bhabha Atomic Research Centre, BARC, Mumbai (Pant et al. 2020). It will benefit the consumer and public to ensure the purity of gold. The BND 4201standard gold bars are 25% cheaper than the imported version. BNDs of other purity percentage gold will be prepared in collaboration with GoI Mint and Jalan and Company. These BNDs are available in the market, allowing jewelers to use instrumental methods rather than the conventional fire assay to ensure purity. The availability of precious metal BNDs at a low cost will enhance the export of precious metals.

One of the chapters deals with the mechanical properties of materials. Metals and the automobile sector are the major contributors to the Indian economy in international trade (Sahoo and Ashwani 2020). The foremost requirement for barrier-free metal and auto parts trade is to meet international quality standards. Material properties, such as strength, ductility, hardness, and wear resistance, are essential parameters for designing a product that needs SI traceable service measurements (Canale et al. 2008). CSIR-NPL with the Global PT provider has started producing BNDs for hardness, strength, and other parameters. Three BNDs of hardness have been released, and others are coming soon. The availability of the BNDs will enhance the capabilities of Indian laboratories and help the automobile, metallurgical

testing lab, steel manufacturing, railway, defense, and aerospace industry in a big way and thereby enhance the export in these sectors.

One of the chapters deals with pesticides. According to a source, 1.2 billion people died worldwide in 2019 due to bacterial resistance (Dadgostar 2019). It was reported that pesticides poison 385 million people and cost 11,000 death every year in India (Boedeker et al. 2020). India also has an unclear picture of the exact burden of all food-borne illnesses arising from pesticide contamination and excessive antibiotic use. Their management is mainly unregulated as unsuspecting consumers freely use their residues. Numbers of pesticides are used in agricultural production to control pests and weeds (Pimentel 2009). Despite having several benefits from pesticides and antibiotics, it is highly essential to monitor and control their amount in the food chains as they are the main culprit for potential toxicity to humans and animals (Okocha et al. 2018). Comparability and the accuracy of the measurement results depend mainly on certified reference materials appropriate for a particular application. To support measurement laboratories, it is urgent to develop cheaper CRMs for pesticide analysis in foodstuffs, serving as a representative material for vegetables or fruits with a high-water content.

One chapter deals with metals and alloys. Alloys are a mixture of pure metals and are mixed to improve their performance and properties (Zhang et al. 2012). A summarized detail of numerous alloy systems is discussed in this chapter. Metal alloys are classified into two categories, ferrous and non-ferrous. Different steels thus fall into the first category, and popular alloys like brass, bronze, invar, duralumin, hindalium, etc., fall into the second category. However, any alloy or material must be checked for its quality, production and performance repeatability; thus, standardization is necessary. Any such standardization involves checking and benchmarking the acceptable composition range of that material. When mixed, many properties depend on the individual metals' crystalline phase, so these also deserve to be bench-marked. In addition, their properties depend on the thermal cycling processes, heat treatment procedures and associated microstructure that result in, i.e., on the thermodynamics of their preparation process. These preparation processes have to be repeatable and, therefore, need to be standardized, i.e., measured, quantified and catalogued. This process will produce standard alloys or certified reference materials (CRMs). They may be compared with any subsequent batch-to-batch product to check the expected properties' consistency. Different National Metrology Institutes (NMIs) worldwide have been thus working on standardizing different alloys of interest to grow their economies (Tzalenchuk et al. 2022). The chapter summarizes the different standard alloy samples available with the major NMI's of the developed world like NIST-USA, PTB-Germany, NMIJ-Japan and NPL-UK or their surrogates. The American Society for Testing of Materials (ASTM), American Iron and Steel Institute (AISI), and Society of Automobile Engineers (SAE) have independently developed a lot of standard data for several alloys, irrespective of whether similar data have been published or not by any NMI (Lingaiah 2003).

Consequently, several alloy makers follow the ASTM standard data for trade purposes when NMIs do not have specific standards of interest. Based on

commercial prospects and demand, they are the ones that are waiting to be standardized in future by any of the global NMI. In the case of emerging economies like India, irrespective of what other NMI have or have not worked on, this write-up discusses how any alloy as a case study can be successfully standardized well for all its parameters. It shall be worth the effort as that knowledge may be commercially exploited for the local and global market and extrapolated to make other alloy standards and quality alloys in due time.

Medical devices can be instruments, apparatus, machines, appliances, implants, and reagents for in-vitro or in-vivo use that are intended to be used, alone or in combination, to address humans' medical requirements (Sharples et al. 2012). When a device or material performs with an appropriate host response in its specific application, it is said to have biocompatibility (Williams 2008). In medical device development, appropriate physicochemical and biological evaluations are devised to establish biocompatibility (Bernard et al. 2018).

Qualified biomaterial with proven safety and efficacy is most important to its functionality in the human physiological environment (Sivakumar 1999). Although critical performance analysis in pre-clinical evaluations can control the risk elements of such materials and devices, the databases of regulatory authorities report a considerable number of complications and adverse events annually (Tarricone et al. 2014). The main factors that challenge the process of biomaterials evaluation for qualifying them for medical use are non-uniformity in regulations, the difference in material development and methods of their evaluation, preconceived post-marketing data, the cost involved, etc. (Herrera Morales 2015). Established biocompatibility characteristics through documented material evaluation matrix within a risk-based quality management platform are essential for clinical acceptance (Vinodkumar et al. 2022). Selecting strategies for evaluating biomaterials could be performed wisely to address the regulatory requirements. Qualifying biomaterials to meet regulatory requirements insist on traceability to international standards in physicochemical characterization and biological evaluations. Appropriate Certified Reference material (CRM) is identified as one of the critical elements to address this requirement.

Abstract

Antibiotics and pesticides have a great impact on human life. However, antibiotics fight against the bacteria and prevent as well as treat infections; on the other hand, pesticides are reasonably essential as they not only help protecting crops from pests, diseases, and weeds but also increase the production to almost double. Without using antibiotics and pesticides, there will be a huge loss in terms of lifesaving and food production, respectively. The excessive uses of both create many acute health problems when disposed of into the environment through sewage and other sources. The worst part of antibiotics and pesticides is that they do not degrade over the period of time and remains in soil, water, and other environmental components. Finally, their residues reach to the food supply chains. The misuse of antibiotics build a resistance against the particular drugs made to help for fighting against the bacteria. In the same way, pesticide excessive uses have resulted in contaminations in food items, soil, and water bodies, leading to serious health implications. To cope with these environmental issues, certified reference material of both can play a very crucial role as it provides reliable measurements and benchmark for the quality assurance. CSIR-NPL has started Bharatiya Nirdeshak Dravya (BND®) program for the development of the certified reference material to mitigate the needs of the country in terms of quality assurance as per ISO 17034.

This chapter describes the importance, national need, and various steps involved in the development of certified reference material (BNDs) of antibiotics and pesticides. The metrological traceability of BNDs established linked to SI units is explained. Further, the metrological perspective, such as testing, calibration, method of validation, repeatability, reproducibility studies, control chart preparation, interlaboratory comparison, quality control, and quality assurance, has been discussed in detail. Further detailed discussion on BND process starting from planning to intended parameter with matrix, homogeneity, stability, assignment of property value with its associated uncertainty, and certification process are highlighted. The synergy among accredited bodies, stack holders, and regulatory bodies with NMIs is emphasized. The impact of BNDs in the formulation of regulations in trade is narrated.

Introduction

Due to rapid industrialization in the sector of agriculture and pharmaceutical, it has put an immense chemical burden on the environment. Pesticide contamination alone causes ≈ 3 million cases of poisoning worldwide, leading to death around 220,000 annually (Organization WH 2009). In the same manner, antibiotics put global burden

and staggering death toll of drug resistance bacteria. According to a source, 1.2 billion people died worldwide in 2019 due to bacteria resistance; it was reported that 385 million peoples are poisoned by pesticides, which causes 11,000 death every year in India (Walker et al. 2013). This is all because of limited understanding of estimates of diseases and deaths from all food safety-related issues. India also have unclear picture on the exact burden of the rise of all foodborne illnesses due to contamination of pesticide and antibiotic excessive uses, and their management is largely unregulated as their residues are freely used by unsuspecting consumers (Fafchamps et al. 2008). A numbers of pesticides are used in agricultural production with the main purpose of controlling pests and weeds (Meissle et al. 2010). Despite having several benefits from pesticides and antibiotics, it is highly essential to monitor and control their amount in the food chain as they are the main culprit of a potential toxicity to humans and animals (El-Shahawi et al. 2010). On account of this, individual maximum residue levels (MRL) for pesticides are regulated in food and feeds (Regulation (EC) No. 396/2005) to ensure that food products are safe and appropriate for consumption (Muhammad 2019). In the same way, MRL limit for antibiotics should also be regulated as per Food Safety and Standards (Contaminants, Toxins and Residues) Regulations, 2011. In a fast-growing country like India, in order to achieve the green growth policies and sustainable development goals, there is an urgent need for the adoption of safe production practices in agriculture. This can be achieved through scientific intervention and management of supply chain systems (Malisch 2017). The literature reveals that more than 2 million tons of pesticides is consumed worldwide; however, we are unable to decrease the net loss around 30% production of total agricultural produce. India has also lost approximately annually Rs 6000 crores due to the impact of pests, weed, insects, and rodents on agriculture produces (Bunch et al. 2003). The negative impact of various microbes on crops is continuously increasing due to resistance developed against several antimicrobial agents (Noyes et al. 2009). The excess use of synthetic pesticides and antibiotics causes detrimental effects not only on the environment but also affecting living organisms through the consumption of contaminated (Mahmood et al. 2016). The prolonged consumption of food and water contaminated by pesticides and antibiotics may cause several diseases like cancer, endocrine disruption, birth defects etc. long-term health effects and also like abdominal pain, loss of appetite, and cancer (Mostafalou and Abdollahi 2013). The Centre for Science and Environment (CSE), India, has reported the presence of several antibiotic and pesticide residues in human tissues of Indian people. Apart from raw agriculture food stuffs, pesticide and antibiotic residues have also been found in packed food items like soft drinks, bottled water, etc. The types of pesticides used in India as per the year 2019 is depicted in Fig. 1.

Food safety and globalization is attracting the attention of the researchers as trade is becoming complicated due to food safety norms across the globe (Johnson and Kumar 2003; Henson et al. 2000). To mitigate these issues, there is an urgent requirement for reliable measurements which will provide quality check for trade barrier and internal consumption (Umali-Deininger and Sur 2007).

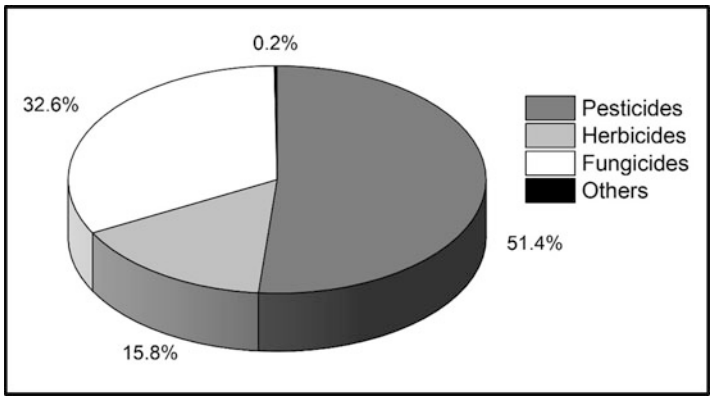

Fig. 1 Composition of pesticide uses in India 2019

Also, the certification of food products and continuous watch of the market are part of the policy. There is a consistent need for the testing of agro-products to evaluate the presence of contaminants like pesticides, antibiotics residues, etc. to ensure the quality of the food products. As a matter of fact, various inspection and testing laboratories associated to check the residues and other toxins persevere to increase rapid growth globally (Feigenbaum 1991). Worldwide, several countries like the USA, Australia, Japan, etc. have developed their own mechanism related to legal and regulatory control on food stuff being procured locally or from other countries (Maskus 2000). Recently Turkey rejects Indian durum wheat, i.e., shipping 56,877 tons consignment, due to phytosanitary concerns. Referring to this, certified reference materials that show their importance in terms of calibration of measuring instrument by providing measurement traceability are the most effective tool to minimize such disputes (Vesper and Thienpont 2009). The CRM plays a crucial role as quality control tools for measurement results (Campana 2001). However, it is important that usage of such matrix should match the reference material worldwide for comparability, accuracy, and traceability and to resolve the dispute during acceptance of the products (Tahoun et al. 2019). CRMs serve also as a lead material for testing and calibration of analytical tools which require to analyze residues of pesticides and antibiotics in vegetables or fruits with a high-water content (Obadina and Olotu 2017). To boost the national quality infrastructure and backing measurement laboratories, it is an urgent need to develop cheaper CRMs for pesticide and antibiotic analysis in agricultural food stuffs and animal food stuffs.

Pesticide's Effect on Human Health

Exposure to pesticides can cause various health effects; the most prominent effect is on the nervous system. General health effect may vary from short term to long term, called acute effects and chronic effects that can happen depending upon the duration

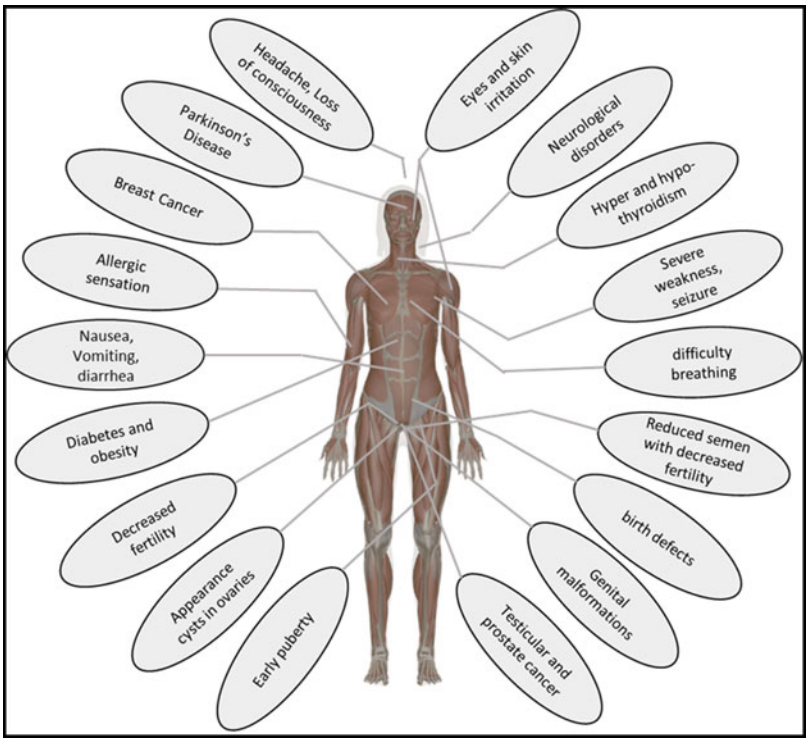

Fig. 2 Pesticides and human health

of the exposure (Damalas and Koutroubas 2016). Several pesticides are banned worldwide, but they exist in the environment and known as persistent organic pollutants (Leino et al. 2013). There are several pathways by which pesticides enter in the human body. Some of the examples of acute health effects are diarrhea, rashes, blisters, stinging eyes, blindness, nausea, dizziness, and death (Bhatia et al. 2014). The short-term and long-term effect of pesticides on human health are shown in Fig. 2. Human being can be exposed to pesticides into two ways: (i) through occupational and (ii) passively through non-occupational (Vera-Herrera et al. 2021). Generally, there are three ways through which pesticides can enter into our body, i.e., through skin, by inhalation, by mouth during mixing, and application. Occupational exposure may be carried out during industrial production, carriage, marketing, and application. The dermal absorption impact depends on the concentration, duration of exposure of pesticides, temperature, and humidity (Moonen et al. 2020). The absorption rate is very high through the skin, groin areas, eyes, ear canal, etc. (Shah 2020). Sometimes, pesticides are kept in food and drink containers, so accidental oral exposure to pesticides may be consumption of water from unlabeled containers. Pesticides may be found throughout the human body through the circulatory system and may be expelled from the body through urine, skin, exhale breath, etc. (Overholt and Castleton 1989). Respiratory exposure in human beings also

occurs due to inhalation of pesticide-contaminated aerosol generated during fumigations. The pesticides change into toxic gas when get contacted with moist air (Dowling and Seiber 2002). Worldwide, several tragic accidents have been reported; one example among them is Pakistan, where around 2800 workers got affected by malathion during spray to control pests (Tariq et al. 2007). The non-occupational exposure has also been reported in human beings by consumption and usage of pesticide-contaminated food, water, air, clothing, and tools because of precautionary fumigation or residual indoor sprays to control pest (Damalas and Eleftherohorinos 2011). The other common sources through which pesticides may enter in human skin are squish, tumble, and during cleaning of contaminated instruments (Organization WH 2020). Besides these, some other example of non-occupational exposure has also been reported through treatment of ectoparasite in pets (Larry et al. 2008).

(a) Types of Pesticides

Pesticides are chemicals and are grouped according to the types of pests which they kill including insecticides (insects), herbicides (weeds), larvicides (larvae), bactericides (bacteria), fungicides (fungi), nematicides (nematodes), and rodenticides (rodent and mice). The literature suggests that pesticides can be classified based on functional groups, chemical classes, mode of action, and their toxicity (Abubakar et al. 2020). Pesticides exhibit potential applications in the area of agriculture, medical, veterinary, etc. to control microbial infection. Pesticides may be organic and inorganic in nature. Organic pesticides further can be divided into natural or synthetic form (Lau et al. 2015). Organic pesticides contain carbon chain and having more complex structure than inorganic pesticides (Weed and Weber 1974), whereas inorganic pesticides may be in metallic and mineral form like copper, sulfur, and sulfates of copper, iron, etc. Pesticides may be further divided on the basis of application like insecticides and miticides which are utilized to control pest in agriculture, forestry, medical, etc., fungicides to control fungal infection, herbicides to control weeds, algaecides to inhibit growth of algae, rodenticides to kill mice and rats, etc.

On the basis of cited literature, it is essential to know the concentration of pesticides in various matrixes. There are several food matrixes, and they may contain numbers of contaminants like organic species (pesticide, antibiotics, fatty acids, dioxins, nutritional constitute, etc.), inorganic species (metal and non-metal element), and microbial (algae, bacteria, fungi, etc.). The reference material is required for the validation of method, calibration of instrument, and traceability compliance. The matrixes matching the reference material is a prerequisite requirement for precise and accurate determination of targeted species. The determination of pesticides in various matrixes can be carried out by using reference material, which may be in the form of high purity or matrix match.

Presently, it is difficult to get matrix match reference material. In such cases, calibration of instrument can be done by using high purity reference material or by adding known quantity of reference material to the test sample of nearly same matrix

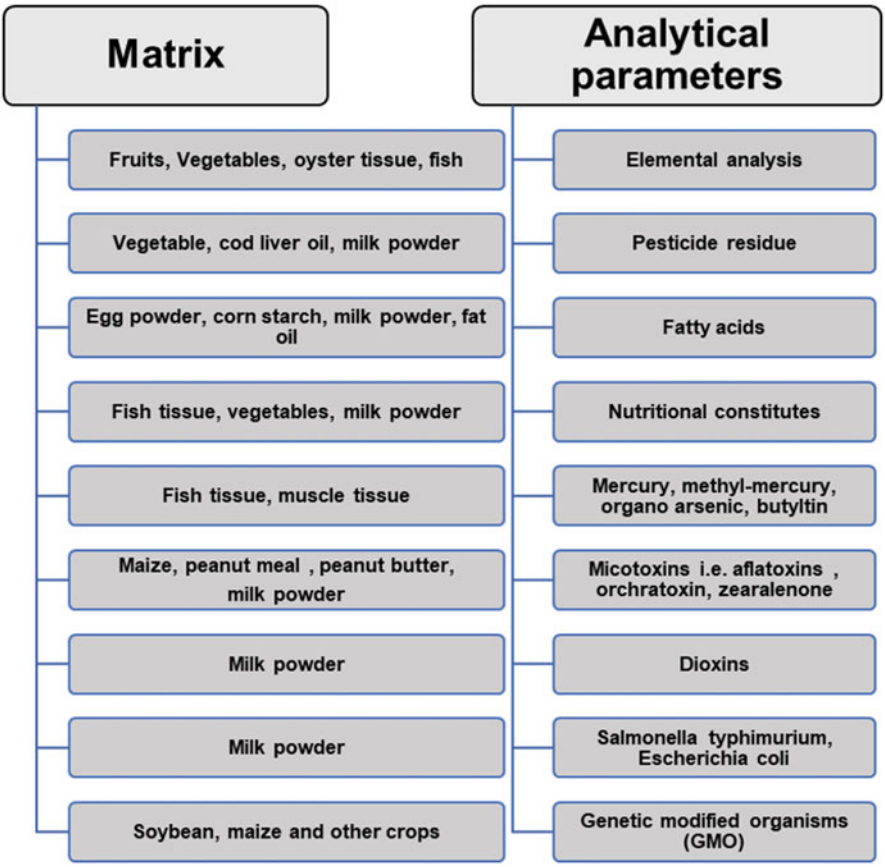

Fig. 3 Matrix and analytical parameters

along with the process blank. Figure 3 depicts some matrixes of food items along with important respective parameters.

(b) Types of Antibiotics

An antibiotic is an antibacterial material which fights against bacterial infections. The antibiotics are utilized as precautionary measure or treatment against bacterial and some protozoan infections. Antibiotics may kill or inhibits the growth of bacteria; however, they are not effective against viruses. The selection of antibiotics to patents is based on empiric or definitive therapy. So, on the basis of mechanism of action, the antibiotics can broadly be divided into two groups, the first one which kills bacterial infection and the second one which inhibits bacterial growth. Antibiotics can also be divided into several categories based on their chemical structure

spectrum of activity. For example, the antibiotics have main groups including β-lactams (penicillins, cephalosporin etc.), macrolides (azithromycin, erythromycin etc.), fluoroquinolones (ciprofloxacin, levofloxacin, etc.), tetracyclines (oxytetracycline, doxytetracyclin, etc.), and aminoglycosides (streptomycin, gentamycin, etc.). These are the subclasses of β-lactams, macrolides, fluoroquinolones, tetracyclines, and aminoglycosides, respectively.

Pesticides and Antibiotics in Our Path

Pesticides are usually released into the environment by several means in order to abolish these pests, but residues from these toxic chemicals also turn out in the air, water, and even in food stuffs (Carvalho 2017). Generally, pesticide is any substance used to kill, repel, or control certain forms of plant or animal life that are considered to be pests. Pesticides may be biological, chemical substances, or a mixture of substances in nature (Saravi and Shokrzadeh 2011).

Some targeted pests include insects, gnawers, weed, plant pathogens, mollusks, nematodes (roundworms), molds, fungus, and microbes that destroy assets, cause nuisance, spread disease, or are major cause of vectors for diseases. Pesticides and antibiotics are both continuously released in three essential commodities, i.e., foods, water, and soil. As mentioned in Fig. 4, the residual toxic chemicals are transmitted to raw material and finally go in to consumer products, causing so many diseases and

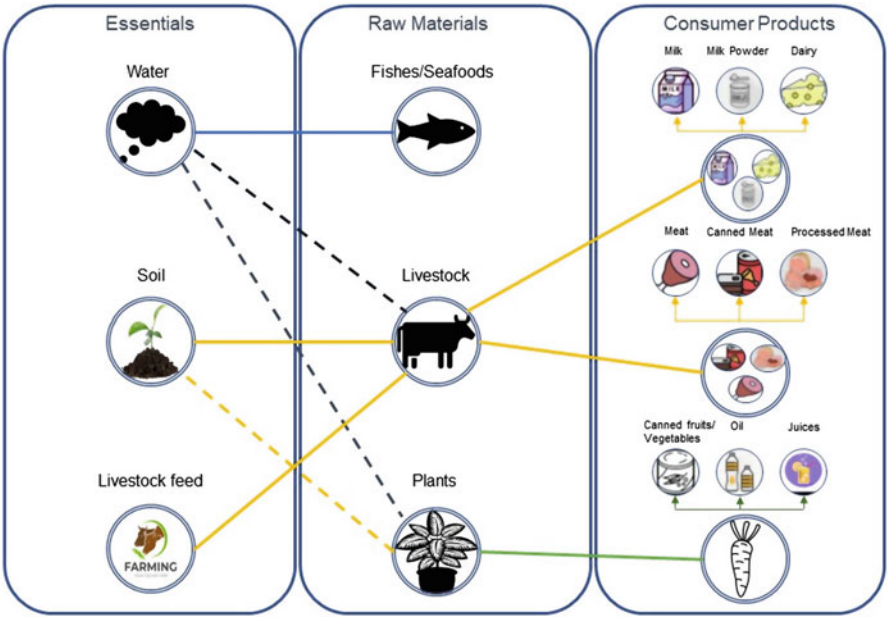

Fig. 4 Pesticides and antibiotics and their path in living things

drug resistances. Pesticides and antibiotics standards help us to precisely screen soil, water, and food quality in agreement with national and international regulations.

Pesticides and Antibiotics CRMs and Their Importance

The global population is growing very fast and expected to be reached ≈ 9.8 bn by 2050, which will lead greatly to increase in food demands. Therefore, combining of growing global demand and India's strong legacy points will come out as an opportunity for intensifying both commodity and value-added exports (Hertel 2011). To fulfill the demand of the growing population, it is important to enhance the production capacity. The enhancement in production yield can be achieved by using a precautionary measure like using appropriate pesticides to control pest. The literature revealed that thousands of varieties of insects, pathogen, and weed reduces more than 30% crop production worldwide (Reddy 2015). The major reduction has been observed in the production of cereals (32%), vegetables (54%), and fruits (78%) without using pesticides. So it is evident from the literature that pesticides play a crucial role in the enhancement of crop production, which is also important for future food security (Hashemi et al. 2014).

In the same way, standard reference materials for antibiotics, namely, International Standards for Antibiotics (ISA), are very much necessary for establishment of standardization and quality control of antibiotic and pharmaceutical products. It is an urgent need of the country to protect not only from counterfeit products but also provide quality assurance in pharmaceutical and food sectors. There are a huge market of the antibiotics and pesticides CRMs as we have more than 10,000 pharmaceuticals and about 150 industrial units manufacturing pesticides and about 500 industrial units engaged in formulations of pesticides. The effective evaluation of the quality of analytical results is very essential and can be achieved by matrix certified reference materials (CRMs) and proficiency testing (PTs). The CRMs come with documentation that mentioning metrological traceability, property values, and related their uncertainty, batch number, lot number with expiring date, etc.

Certified Reference Materials (CRM) and Quality Control

To support measurement laboratories, CSIR-NPL has mandate to produce BNDs for pesticides and antibiotics for residue analysis in crops, vegetables, or fruits with a high water content. The identification of certified pesticides is carefully selected based on different criteria such as their general use (insecticide, fungicide, and nematicide), being typical of different chemical classes (neonicotinoid, organochlorine, organophosphorus, azole, benzimidazole, dicarboximide, strobin, pyrethroid, and N-methyl carbamate), or having an authorized or banned use in India. Consideration is also given to different degrees of difficulty for their analysis when present in a food stuff. The mass fractions of the following pesticides with their associated uncertainties need to be analyzed by using the certified reference materials:

chlorpyrifos, carbendazim, acetamiprid, cypermethrin, diazinon, alpha-endosulfan, fenitrothion, azoxystrobin, imazalil, etc. (Fantke et al. 2014). Certified reference materials (CRMs) are very essential and play a key role in quality control by establishing the metrological traceability for measurements; they are also very important to confirm measurement results reliability (De Bièvre et al. 2011). In total, CRMs are very much essential to support international trade and national legal metrological control of the country. Highlighting the main purposes of CRMs is extensively used in calibration of equipment and assessment of measurement methods/procedure. In accredited laboratories, it is mandatory to use the CRMs for various purposes like internal measurement activities, in proficiency testing (PT) activities, and in legal metrological activities (Kaarls 2018).

It is observed that a country needs consistent and trusted measurement system and establishment of quality infrastructure for easy certification of food items for import, food product registration, market observation, export rejection, etc. Various examples are reported in newspapers regarding the rejection of consignment for foods, tea, and other essential commodity due to high level of residues of pesticides and antibiotics in agro-products. There is need to bridge the gap between measurement and calibration and standard reference materials. It is reported that majority of CRM (10,000 crores) are generally imported from abroad every year. To check the MRL of pesticide and antibiotic residues, mycotoxins and other toxic contaminants with indigenous CRMs need to be developed to make country self-sustain in this broad area (Kovač et al. 2021). To align with national mission, the number of RMPs (in association with NMI) and testing laboratories (related to quality assurance) is continuously increasing in the country. To justify the needs of CRMs, countries like the USA, the UK, Japan, and China have stringent legal and regulatory control and regulatory policies on food products. Therefore before exporting the foods and other agro-products it is need be monitoring the all the parameter later may cause for the rejection. All we can say, CRMs are much needed for the calibration of measuring instrument and regulatory control (imposed by legal entity) of measurement results when it is subjected to establish metrological traceability. The precise and exact measurement in food is imperious to minimize pointless disagreements (De Bievre 2008).

Pesticide Metabolite Standards

It so happened that active compounds of some pesticides may be either converted by the target insects and plants or may be degraded in the environment. In short, the monitoring of pesticide metabolites is required. A wide range of pesticide metabolite neat standards and solutions in various solvents are available in the market. Testing laboratories and food industries can use metabolites standards for the validation of certain analytical methods and can take effect the control of their measuring system. To demonstrate the metrological traceability of the certified values of the CRMs,

NMI needs to establish the degree of equivalence for the analytical methodology which is used with other NMIs through the participation of inter-comparison programs organized by CCQM. For the effective metrological control of the quality of food stuffs, the government has taken the initiatives for production of these CRMs in compliance with the relevant international standards such as ISO Guide 34 and ISO/IEC 17025.

Pesticides and Antibiotics Reference Material (RM)

Reference materials are sufficiently homogeneous material and stable in terms of specified properties; these properties have been established to be fit for its intended use in measurement of nominal properties. Although RM do not provide the same level of accuracy as certified reference materials, their advantage is that RMs are significantly easier to produce. RM is also compliant with ISO requirements and for less exacting requirements on traceability; RM can offer an excellent cost-effective alternative to CRMs. It stated that reference materials are:

- High purified.
- Qualitative and quantitative analysis.
- Detailed description about its properties.
- Certified through National Standardization Technical Committee.

Certified Reference Material (CRM)

The reference material when, represented by its documentation issued by an authoritative body and demonstrating one or more specified property values with associated uncertainties and traceabilities, using valid procedures called certified reference material. Certified Reference Materials (CRMs) occupy the second highest rank in the hierarchy of reference materials. In other terms, Certified Reference Materials are considered to enables the highest level of accuracy, uncertainty and traceability to an SI unit of measurement.

Metrological Traceability

Traceability refers to the value of a standard where it can be related to stated references (national or international standards) through an unbroken chain of comparisons, all having stated uncertainties (ISO). The term “metrological traceability” is described as “Property of a measurement result whereby the result can be linked to a reference through a documented unbroken chain of calibrations, each contributing to its measurement uncertainty.” It is well known that the measurement uncertainty of the property value of a reference material employed in a measurement process will contribute to the uncertainty of the final measurement but should contribute less than

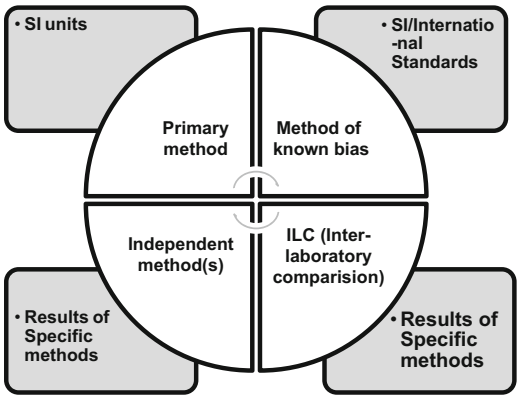

Fig. 5 Measurement methods and associated traceability

one third of the overall measurement uncertainty. In universal hierarchical system, usually, used for assigning property values to product/materials and even if not stated, their traceability can be described in Fig. 5.

Legal Metrological Control

The Central Government of India has enforced Legal Metrology Act 2009 to maintain the units for measurement. The act fully implemented on first April, 2011, in India. The main objective of Legal Metrology is to ensure public guarantee from the point of view of security and accuracy of the weighments and measurements. Figure 5 describing the overall legal metrology flowchart with associated activities which directly contribute to metrological assurance (Fig. 6). The legal metrological control includes:

(i) Measuring instruments and their legal control.
(ii) Metrological management.
(iii) Metrological proficiency.

Selection of CRMs

The ISO accreditation of a CRM guarantees accuracy, identity, and quality the material without additional contamination or error. A certified reference material provides not only the instruction to maintain homogeneity and stability but also provides traceability required under ISO guidelines. Laboratories have many choices for reference and calibration standards but the selection of the correct reference material can be difficult in some cases. However, some of them may be bestowed priority over others; the other parameters are as follows:

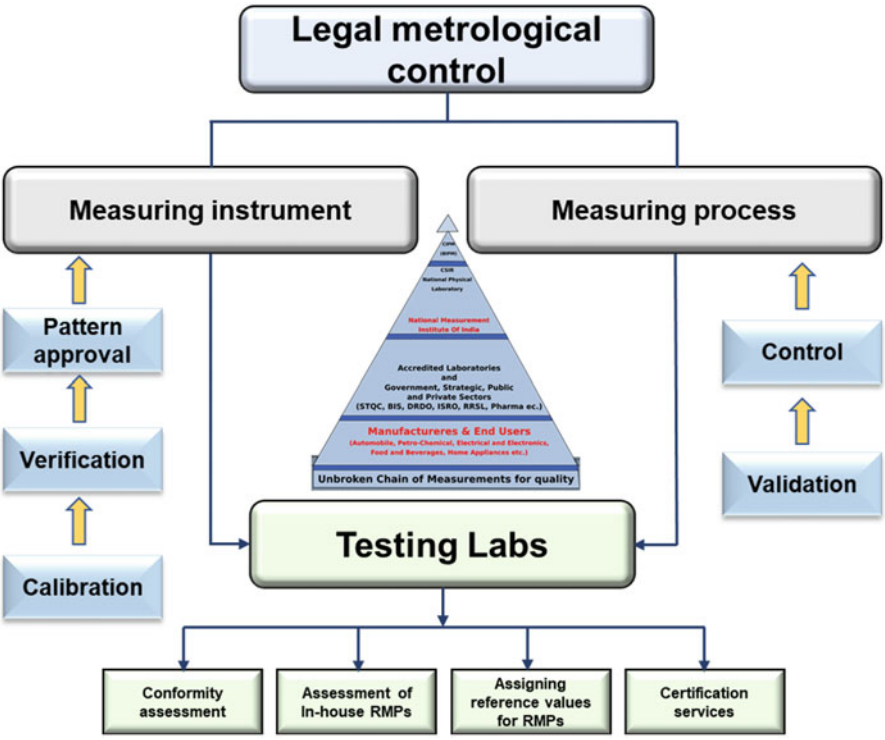

Fig. 6 Legal metrological control that requires the use of pesticides and antibiotics CRMs

Fit for Purposes

The CRMs have a matrix in a physical state and form that is as close as possible to those of the material subjected to the measurement process. Fit for purpose decisions in selection of reference materials can depend on several factors ranging from regulatory requirements, level of accuracy, availability, and type of testing applications. Apart from this, it is also important to consider the other factors like what types of tests, i.e., equipment calibration, method validation, identity, stability assessment, and internal quality control. Certified reference material should have properties at the appropriate level so that it can fulfill the purpose for specific requirement.

Characteristics

A fundamental term in metrological traceability is the measurement of SI units. The CRM needs to be meaningfully compared, across difference places, at different times, by different people, using different equipment. The measurement result must be related to a reference through a documented and unbroken chain of

calibrations, tracing back to the SI unit of measurement. The main important factor is the uncertainty associated with the certified value which is stated as quality parameter and reliability. The uncertainty budgets are an additional aid for specifying the extended measurement uncertainty. For example, the certification data should state accuracy, consistency, homogeneity, purity, and stability along with the expanded uncertainty (U) using a coverage factor $k = 2$ which specify the level of confidence nearly 95%. The precision and trueness requirements must be well matched with associated uncertainty of the certified value (Fig. 7).

Legal Requirements

The CRM should be able to fulfill the legal requirements on the precision and trueness for some special analyses. In some of the countries, there may be required special requirements on the packaging and label specially to mitigate the climatic conditions for CRMs to be imported from aboard.

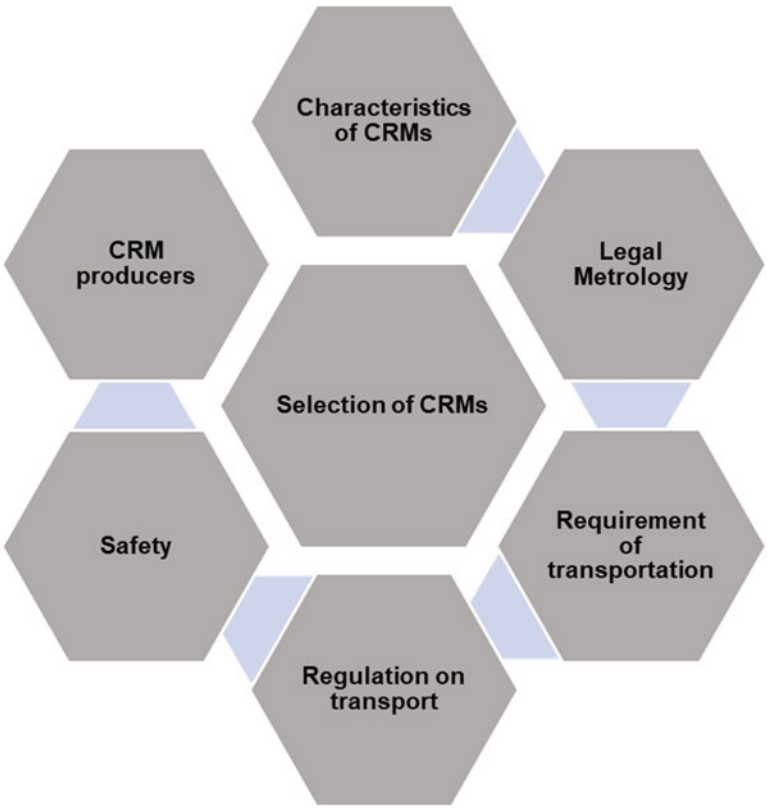

Fig. 7 Aspects considered in selecting CRMs

Regulation on Transportation

International regulation implies for the transportation of CRM which falls under stringent legal policies and norms. Several restrictions have been imposed on importing of certified reference material as they may be biological materials. For import of the CRMs, it is requiring a legal permit as they belong to restricted class categories.

Safety of CRMs

Certified reference material of pesticides and antibiotics requires a lot of attention in terms of safety and stability. Utmost care should be taken to ensure the safety and stability of materials especially for CRMs which are biological in nature, e.g., the materials need to be properly irradiated before packaging.

CRMs Producer

The curiosity attracts the attention of the users who can make the certified reference material. The answer is majority of the certified reference material are developed by the national metrological institutes (NMI) and thereby offered in the market. CSIR-NPL as an NMI of India and as per the mandate has taken the lead role for the developed in-house CRMs as well in association with reference material produces. The RMPs must have the ISO:34 accreditation is the general requirement for the competence to produce the reference material. For any National Measurement Institute (NMI), the CMC (calibration and measurement capability) the most important recognition among other NMI and can be recorded on Key Comparison Database (KCDB) set up by BIPM (http://kcdb.bipm.org) (Bock 2014). All we can say, the essential requirement for the CRM producer is ISO 17025 and 17,034. The accreditation criteria are set out in ISO 17034. The core competence of an RMP in producing reference materials includes the following:

- Functioning of a management system.
- Technical competence of staff.
- Suitability of the production plan.
- The RMs produced are sufficiently uniform and stable.
- The certification values are metrologically traceable to a reference.
- Fitness of the RM distribution process.

It is always advisable to CRM users that they should get the overall information of the CMC through KCBD. It will be help in preferring the which institute's products should be chosen.

Development of Pesticide and Antibiotics Reference Material

CSIR-NPL has started Bharatiya Nirdeshak Dravya (BND®) program for the development of various Indian reference material with trade name BNDs at NPLI. CSIR-NPL developed in-house BNDs as well as in association with reference material producers. The process of developing reference material is very cumbersome and it includes preparation of samples to analysis, which are the most common processes with PTs. The major process and steps involved are as follows:

Homogeneity Testing

As per the ISO Guide 35, homogeneity needs to be assessed by quantifying target pesticides and antibiotics prepared and chosen for CRMs and/or PTs. Homogeneity includes both within and between bottles. By using one-way analysis of variance (ANOVA), well-known statistical approach is applied to evaluate within-bottle and between-bottle differences (Kim et al. 2018). The basic method for evaluation of homogeneity is F-test. Any sample is considered to be homogeneous if the F-test values are smaller than those of the critical values at the 95% confidence interval. Standard deviations between bottles (S_{bb}) and within bottles (S_{wb}) are calculated using Eqs. (1) and (2) in accordance with ISO Guide 35 (Ellison and Botha 2018) as follows:

$$S_{bb} = \sqrt{\frac{MS_{among} - MS_{within}}{n}} \tag{1}$$

$$S_{wb} = \sqrt{MS_{within}} \tag{2}$$

where MS_{among} = squares between groups.
MS_{within} = within a group.
n = the number of measurements per bottle.

According to ISO Guide 13,528 by using Eqs. (3)–(5), the values of S_w and S_s are determined as follows:

$$S_x = \sqrt{\sum \left(X_{t\ldots} - \overline{X}\right)^2/(g-1)} \tag{3}$$

$$S_w = \sqrt{\sum w_t^2/(2g)} \tag{4}$$

$$S_b = \sqrt{S_x^2 - \left(S_w^2/2g\right)} \tag{5}$$

where S_x = the standard deviation of the average sample analyzed.
t = sample (t = 1, 2, 3, g),
X = data analyzed.
$\bar{X}$= average data.
S_w within-samples standard deviation.
S_b between-samples standard deviation.

An agreement between value of S_b less than 0.3r indicates acceptable homogeneity, where r is the target standard deviation representing a relative standard deviation (RSD) of 25% multiplied by the analytical values.

Finally, EURL-PT suggests using Eqs. (6) and (7) to determine and the constant c as follows S_b^2 (Ellison and Botha 2018):

$$S_b^2 = S_x^2 - \left(\frac{S_w^2}{2}\right) \tag{6}$$

$$c = F_1(0.3\sigma)^2 + F_2 S_w^2 \tag{7}$$

Determination of Assigned Value and Uncertainty

The assigned value can be gotten from the average value calculated from numbers of samples. The uncertainty caused by possible inhomogeneity can be evaluated as per ISO Guide 35 (Ellison and Botha 2018) that indicates by using Eq. (8) we can determine the value of uncertainty (u_{bb}) as follows:

$$u_{bb} = \sqrt{\frac{MS_{within}}{n}} 4 \sqrt{\frac{2}{\nu MS_{within}}} \tag{8}$$

where n = the number of measurements per bottle.
νMS_{within} = the number of degrees of freedom of MS_{within}.

If MS_{among} is > MS_{within}, the S_{bb} of Eq. (1) and u_{bb} of Eq. (8) will be employed; in addition Eqs. (1) and (8) can be applied. The uncertainty arises because inhomogeneity may be treated using the larger of the values for either S_{bb} or u_{bb} to prevent overestimation. If the $MS_{among} < MS_{within}$, only Eq. (8) can be applied.

Stability Testing

The result obtained from stability testing specifies the shelf life or expiry date of the CRMs. It is reported in the literature that there are two types of stabilities, i.e.,

degradation at elevated temperature for short duration, and second stability test must be performed at storage temperature to obtain information about the stability during storage called long-term stability.

The samples preparation and other environmental conditions like temperature and humidity for analysis is very important for stability testing. The samples are periodically withdrawn for the testing in stipulated time and the statistical data obtained for the evaluation for the stability.

In the pharma sector, generally two types of stability testing are practiced: (i) real-time stability testing and (ii) accelerated stability testing. Pharmaceutical products are kept under accelerated conditions. The changes under extreme conditions like temperature, light intensity, and humidity are monitored. The test results are compared with the specified standards. After assessing the result, the shelf life of the product is established. Stability testing tests the drug stability and monitors changes in physical, chemical, and microbial characteristics. If changes are detected in the physical conditions of target pesticides and antibiotics, the uncertainties for long-term stability is encompassed in the uncertainties of certified values in accordance with ISO Guide 35 (Ellison 2015). As per ISO guidelines, the stability is assessed on the basis of the analysis of variance (ANOVA) results of the linear regression of respective residual in the stability data (Grimalt et al. 2015). Temperature is an important factor and need to be monitored and evaluated in accordance with ISO Guide 35. There are two approaches for ANOVA: fixed batch effects model and random effect model. According ISO Guide 35, an analyte is considered to be stable provided absolute value of the slope, |b|, is smaller than the product of student's t factor ($t0.95, n-2$) by the uncertainty associated with the slope, $s(b)$, as presented in Eqs. (9), (10), (11), and (12). The slope (b_1) and intercept (b_0) of the linear regression is calculated using Eqs. (9) and (10) as follows (Monteiro et al. 2013):

$$b_1 = \frac{\sum_{i=1}^{n}\left(X_i - \overline{X}\right)\left(Y_i - \overline{Y}\right)}{\sum_{i=1}^{n}\left(X_i - \overline{X}\right)^2} \tag{9}$$

$$b_0 = \overline{Y} - b_1\overline{X} \tag{10}$$

where X_i and Y_i denote the time and the concentration at time I, whereas $\overline{X}$ $\overline{Y}$ denotes the average of X_i and Y_i, respectively. The $s(b_1)$ value can be calculated by using Eq. (11) and s value can be calculated using Eq. (12):

$$s(b_1) = \frac{s}{\sqrt{\sum_{i=2}^{n}\left(X_i - \overline{X}\right)}} \tag{11}$$

$$s^2 = \frac{\sum_{i=1}^{n}\left(Y_i - b_0 - b_1X^i\right)^2}{n-2} \tag{12}$$

Moisture Content

Advanced techniques such as Karl Fischer titrator, dynamic vapor sorption (DVS), and thermal gravimetry analysis also play an important role in the determination of moisture content. As per standard guides, all the samples must be sealed in bottles at 25 °C and 50% relative humidity and must be placed in electronic desiccators. At the time of bottling, the mean % weight difference between before and after the experiment should be around 5.0% (RSD of 0.85%). The moisture content can be estimated by taking 1−g sample from 10 random bottles ($n = 10$) and put the samples in a desiccator (anhydrous calcium sulfate or silica gel) at room temperature for 7 days (Wong et al. 2008). After 7 days, the samples were weighed to get the weight difference. Moisture content can also be calculated by advance techniques DSC-TGA and KFT techniques for structural water present in the samples.

Process of Assigning the Certified Values

The process of getting certified values for CRM is quite comprehensive. As per ISO 35 guidelines to obtained reliable analytical data, it is highly recommended to participate in CCQM a Consultative Committee on the Quantity of Material. The CCQM is a committee whose primary function is to document, develop, and improve the equipollence of national standards (CRMs/RMs). Apart from that, CCQM is held responsible for international benchmarking and comparison to evaluate analytical capabilities of national metrology institutions (Sturgeon et al. 2003). There are so many technically valid procedures available and can be used for the characterization of material to get the property values. To achieve the certified values, a collaborative study needs to be conducted with a PT provider. Consequently, results obtained from above studies showed the accuracy of analytical data and establish global comparability of measurement results, where traceability to the SI units is not yet feasible. PT is necessary for the analysis of various pesticides and antibiotics to confirmed international conformity. The analysis performed are based on a modified method for providing certified values (for CRMs) and reference values (for PT samples) (Raposo et al. 2008). For example, to avoid any predisposition associated with certain analytical methods like various extraction and clean-up procedures, LCMS and GS injection techniques and and LCMS and GC columns are applied to provide the certified values (for CRMs) and reference values (for PT samples) (Hajšlová and Zrostlıkova 2003). Pesticide and antibiotic quantification can be performed by using LCMS with tandem, Q-NMR, GC-MS, HPLC, TG-DTA, Karl Fischer, and other latest techniques (Yarita et al. 2015). In cases if reference values are available by an official method, the validation is conducted by some of the methods mentioned in the IS standards.

Certification of CRMs

All reference material certificates specify its associated uncertainty and a statement of metrological traceability characterized by a metrologically valid procedure. It is clearly distinguished between non-certified and certified values that can be used for calibration, performance checks, and trueness control. All CRMs must be accompanied by detailed certification report including material processing, homogeneity, stability and characterization studies, and value assignment. The certified values can be achieved through comparison of the analytical results obtained by two or more analytical methods used for each pesticide and antibiotics. Uncertainty analysis is not envisioned and should not be considered to account for accidents, mistakes, improper use, improper transport, etc. of the CRM (Ellison 2015; Otake and Yarita 2021). The uncertainty calculated from the mathematical operation and the mathematical representation of this model is a collective sum of property value obtained from the characterization, correction of property value due to the between bottled homogeneity, and correction of the property value of the batch due to long-term and short-term stability (Iso and Oiml 1995) (Fig. 8).

For example, NPLI certified values of the uncertainties are estimated from standard uncertainty due to analytical results (as mentioned above) (Fig. 9).

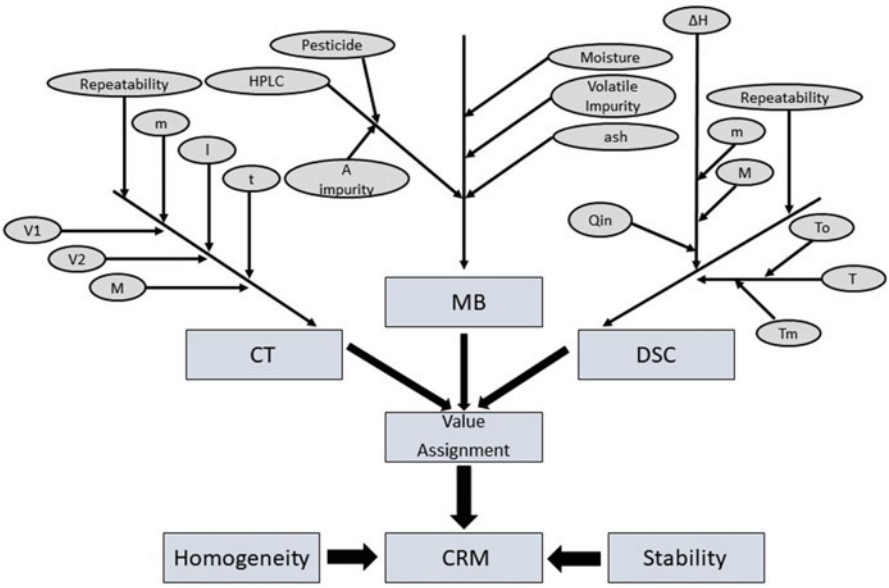

Fig. 8 Alternative model for pesticides and antibiotics CRMs

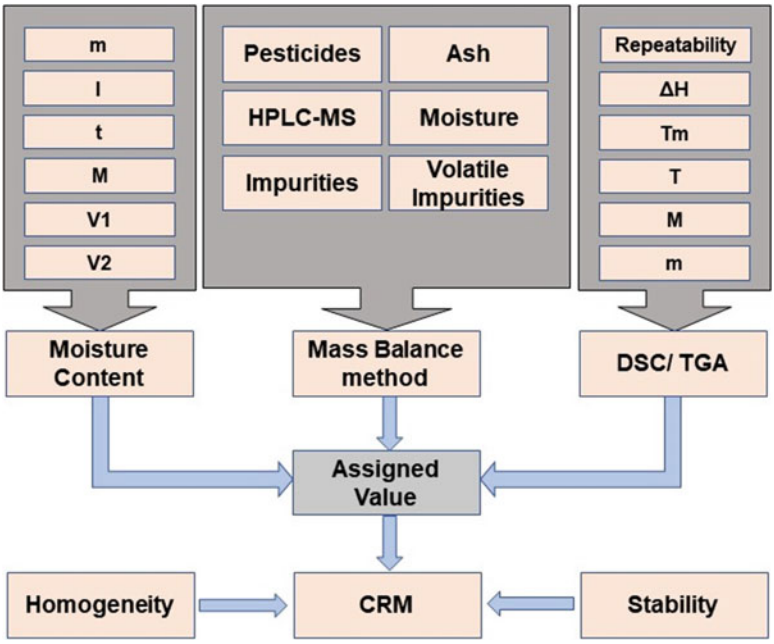

Fig. 9 Process of making pesticides and antibiotics CRMs

Assessment of Participant's Analytical Results

The performance can be assessed and the median value and normalized interquartile range (NIQR) evaluated instead of arithmetic average or standard deviation. PT scheme statistical analysis is applied to each population of analyte results to calculate robust z-scores which are used to fairly assess the testing performances of participants. Robust z-scores are calculated by replacing the mean and standard deviation (SD) in the "classical" z-score equation with the median and normalized interquartile range (NIQR), respectively. The NIQR is determined from the trimmed population of results by first calculating the interquartile range (IQR) of distribution across the middle 50% of results when arranged in ascending order. Z-scores may be two types as its standard deviation from proficiency testing can be calculated from the analytical results reported by participants (z) and another can be calculated from assigned values reported by NMI-NPLI (Z_{NPLI}). The z-scores (z) can be calculated using Eq. (13) (Shiffler 1988):

$$z = \frac{x_i - X}{\text{NIQR}} \tag{13}$$

where x_i denotes the results by each participating member, X denotes the agreement value calculated from the participant's labs results, and NIQR denotes a normalized interquartile range.

$$(\text{IQ} = \text{UPPER QUARTILE} - \text{LOWER QUARTILE})$$

The normalized IQ range is 0.7413× (quartile 3–quartile 1) (Otake et al. 2016).

The z-score is a numerical measurement that describes a value's relationship to the mean of a group of values and can be calculated by using Eq. (14):

$$z_{\text{NPLI}} = \frac{x^i - X_{\text{NPLI}}}{\text{SD}_R} \tag{14}$$

where X_{NPLI} denotes the NPLI reference value and SD_R represents the precision repeatability measure between-laboratory. SD_R can be calculated by using modified Horwitz equation used for quality benchmark and X_{NPLI}. The Horwitz equation is suitable for exponential relationship of the variability of chemical measurements in the interlaboratory trials. Horwitz equation is one of the first empirical parameters applied in the evaluation of the laboratories quality control and proficiency testing (PT) by using reference values. Each z-score interpretation is as follows:

$z \leq |2|$: it is being satisfactory
$|2| < z < |3|$: It is being questionable
$|3| \leq z$: it is being outlier.

Conclusion

Pesticides have been gaining importance since the last 60 years, as they marked fast, easy to use, cheaper substitute for eradicating weeds and pests (Nayak and Solanki 2021). Similarly, antibiotics also play a key role in the management of various diseases and improving human health and life expectancy significantly. However, human health risk is associated with antibiotic residue in the environment. To fulfill the requirement of analysts, industries, and academia, CSIR-National Physical Laboratory New Delhi has started the BND program for developing most promising pesticides and antibiotics standard reference material with trade name Bharatiya Nirdeshak Dravya (BNDs) which will be used in the quantification of pesticides and antibiotics residues. BNDs are high-quality analytical standards for many different application areas and market segments at par with international standards (Pant et al. 2020). These standards are raging from the food and beverage industry to environmental analysis and also to those used in the cosmetic, petrochemistry, and pharmaceutical industries. This chapter covers all the aspects related to the pesticides and antibiotics standards, their needs, and development and more stretches upon glimpse of the overall solutions for quality assurance. Country like India in terms of pesticides and antibiotics is more export-oriented in nature and overwhelming economy of India. Pesticide use has generally been implemented in terms of risk avoidance approach, but sometimes the

possibilities of pest incidence/critical pest inhabitants are regularly perceived in a wrong way to be on the higher side. Therefore, the main concerns on the negative outwardness of chemical pesticides across the globe have led to increasing awareness on the pesticide use, especially in the socioeconomically advanced humanities. The analysis has pointed out to the need for a detailed look on the pesticide certified reference material development indigenously and policy for the legal enforcement for quality assurance and regulatory mechanism at a micro level. It is well established that pesticides have a crucial role to play by increasing production of crops and subsequently raising the farmers' earning also. India has become self-sufficient in production of pesticides and also an important exporter of pesticides. The big challenge for India is to maintain a balance between production and quality. Although India is one of the largest producers of a number of agriculture commodities, on the other hand, EU is one of the largest export markets for India but faces several severe issues like microorganisms exposed to this increasing load of antibiotics in soil and water which can develop resistance (Gruère and Rao 2007). There is a possibility that traces of antibiotics and pesticides remain in edible parts of the plant longer after they are sprayed, affecting human health or making them resistant to antibiotics. As we know, safe food and health are linked together and unsafe foods caused more than 200 diseases. Pesticides use and its management are highly unregulated in India. India registered excellent growth in agriculture, and in 2022, India's export of agricultural commodities crossed $50 bn which is much higher than EU's export to India (Mukherjee et al. 2019). Despite this surge in production, existing literature reported that India faces trade issues as developed nation imposed legal policies and regulatory which in turn affect the export adversely. India's stated aspiration of doubling farmer income by 2022–2023 requires a commensurate increase in the output of the agriculture sector (Rodrik 2001). To mark a "paradigm shift" from residual export after meeting the national demand to targeted export in accordance to the preferences of foreign market and to realize this vision, the governments will have major role to play in strengthening the quality assurance of pesticides and antibiotics in agriculture, as also in attracting the private sector that has the capacity to build demand-driven CRMs and value-added exports. Globally India marked 12th position and in Asia stands on third position in pesticide use. Approximately 292 pesticides are registered in India and more than 50% of the pesticides used are of insecticides. The total of pesticide consumption in India was somewhere around 69,282 tons during 2017–2018. Maharashtra alone consumed the most chemical pesticides followed by Uttar Pradesh, and both the states cumulatively used 40% of total pesticides in India. Biopescticides is an alternative of synthetic pesticides and can helps farmer by replacing it by biopesticides which can minimize the environmental issues. The sustainable goal can be achieved through judicious and minimal uses of pesticides, using alternative chemical pesticides, legal framework, and by awareness to farmers. There is an urgent need to joining hands with all the government institutions, RMPs and public sectors to tackle these issues by anticipating BNDs development.

Abstract

Materials for making engineering goods must have the appropriate mechanical strength to work under various loads. These properties of materials characterize the resistance to deformation in the presence of external forces. In this chapter, strength, hardness, toughness, hardenability, fatigue, etc. of the materials are described in detail. CSIR-National Physical Laboratory, in collaboration with Global PT Provider, has developed hardness blocks BND 2201, BND 2202, and BND 2204 for measuring Rockwell and Vickers hardness. These BNDs are useful to test and verify the HRC/HRV indentation hardness Testing Machine. Also, other mechanical properties for which BNDs are under development are discussed. This chapter will be useful for beginners to understand the mechanical properties and certified reference materials.

Introduction

The mechanical properties of material influence the materials' strength and service life. The mechanical properties of materials characterize the resistance to deformation in the presence of external forces (Pelleg 2012; Soboyejo 2002). Materials for making engineering goods must have the appropriate mechanical strength to work under various loads. Strength, hardness, toughness, hardenability, fatigue, etc. are some significant mechanical properties that decide the quality of materials (Wiederhorn et al. 2006). These different mechanical properties of materials are generally evaluated as per IS standards (Forster 2015). Standards are documents published to ensure the credibility of the materials, products, processes, and services. These establish material requirements, specifications, guidelines, characteristics, and procedures designed (Aswal 2020a). Organizations can promote their products and service consistency, security, and efficiency by adhering to these standards. In today's scenario, where products are assembled from parts manufactured in different countries and sold worldwide, proper standards have become more critical than ever. Measures are very much crucial for the preparation of certified reference material (CRMs) (Aswal 2020a).

CRMs are essential for generating accurate, precise, and reliable measurement data of major and minor constituents of different materials (Aswal 2020b). These have to be used to calibrate analytical instruments and validate test methods to successfully implement the quality assurance program of several governments and nongovernment agencies such as pollution control boards, public health laboratories, industries, R&D organizations, etc. The data generated using CRMs must be traceable to the national/international measurement system for global acceptability. International Organization for Standardization defines the reference material (RM) and CRM and is universally accepted (Aswal 2020a).

As the National Metrology Institute (NMI) of India, National Physical Laboratory (NPL), collaborates with public and private industries to prepare and disseminate CRMs (Aswal 2020a). These are launched as Bharatiya Nirdeshak Dravya (BND) or

Indian reference materials. Several BNDs are developed at NPL, including cement, petroleum, mineral oil, gasoline, diesel, water, pH, and hardness block (Yadav et al. 2021). The availability of BNDs will enhance the capability of Indian laboratories and help the automobile, material testing lab, railways, defense, and aerospace industries in a significant way and thereby enhance the export in these sectors.

CSIR-NPL has developed hardness blocks BND 2201, BND 2202, and BND 2204, respectively, in partnership with Global PT Provider Pvt. Ltd., for measuring Rockwell and Vickers hardness (Pant et al. 2020). Hardness is the most common parameter in the acceptance criteria of the steel industry (Senuma 2002). It provides significant info and insight into the toughness, strength, flexibility, and competence of materials. It is a commonly used test method in industries to validate the quality of components. Hardness block BNDs are produced for the standardization of hardness measurement. Presently, the Rockwell and Vickers hardness BNDs are in practice. Customers of these BNDs include the industries that currently require traceability to an NMI, reference material producers, instrument manufacturers, and end users. BND development for measuring other mechanical properties, such as strength, fatigue, hardenability, etc., is also in progress as per IS standards. In this chapter, the present hardness block BNDs available in India and other future BNDs for measuring mechanical properties are discussed in detail.

Hardness Tests

Hardness is the ability of the material to resist permanent deformation. The main types of hardness measurements are (1) scratch, (2) indentation, and (3) rebound, respectively (B. TEST n.d.). The most widely used in the engineering sector is indentation hardness, mainly for measuring metals. Indentation hardness testing is the most suitable method to investigate lesser volume materials. In this technique, indentations are made on the surface of the materials by indenting a rigid indenter of specific geometry (Khodabakhshi and Gerlich 2020). It is a nondestructive technique compared to other techniques which involve destructive action such as compression, extension, or bending of bulk samples (Broitman 2017). Indentation hardness testing is also crucial to other areas such as microelectronics, micromachines, and the magnetic recording industry (Sangwal et al. 2003). Indentation hardness is measured in different testing methods, including the Brinell, Rockwell, Vickers, and micro-hardness test, based on the type of sample materials (Broitman 2017; Walley 2012).

Brinell Hardness Test Method as per ASTM E10 and ISO 6506

The Brinell hardness test is the most widely accepted test method for coarse or rough surfaces, e.g., castings and forgings, and it is tested as per ASTM E10 and ISO 6506 (Gabauer 2000). In this testing method, the metal surface is indented for a standard time of about 30 sec with a 10 mm diameter steel or carbide ball with a high load of a maximum of 3000 kgf. The resulting indent impression is measured with a specially

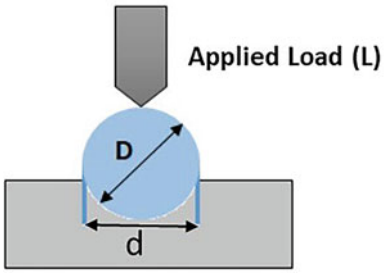

Fig. 1 Schematic representation of Brinell hardness test method (Kim et al. 2005)

designed Brinell microscope system across two diameters. Figure 1 shows the Brinell hardness test method (Kim et al. 2005).

The Brinell hardness (BHN) is calculated as a load (L) by the surface area of indentation (Barua et al. 2021; Muangma 2018) and can be expressed as follows:

$$\mathrm{BHN} = \mathrm{L}/(\pi \mathrm{D}/2)\left(\mathrm{D} - \sqrt{(\mathrm{D}_2 - \mathrm{d}_2)}\right)$$

where: L = applied load in kilogram,
D = diameter of the ball in mm.
d = indentation diameter in mm.

Rockwell Test as per ASTM E18 and ISO 6508

The hardness is obtained by setting the diamond point of the indenter on the material surface and recording the penetration depth under arbitrarily fixed conditions (Asgharzadeh et al. 2020). It is tested as per ASTM E18 and ISO 6508 (Kumar 2019).

Initially, a minor load is first applied to set the indenter on the material, which causes an initial penetration and holds it in position. Then, depending upon the scale being used, a major load is applied to increase the indentation depth. Firstly, the major load is removed, leaving a minor load still acting on the surface. The difference in penetration between the major and minor loads gives the Rockwell number, as shown in Fig. 2 (Chandler 1999).

Vickers Hardness Test as per ASTM 92 and ISO 6507

Vickers hardness test is generally used for harder metal surfaces, including heat-treated steel. The metal surface is exposed to a normal pressure for a standard time using a pyramidal-shaped diamond indenter with a vertex angle of 136° and a load that ranges from 1 kg to 120 kg. It is frequently used to determine thin film hardness and identify specific phases in metallography. Vicker hardness test is carried out as

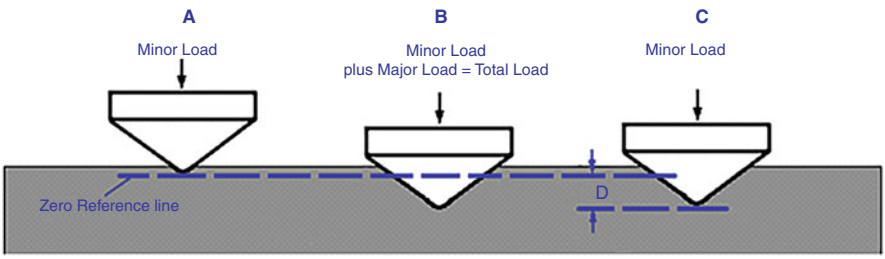

Fig. 2 Schematic representation of Rockwell hardness test method (Chandler 1999)

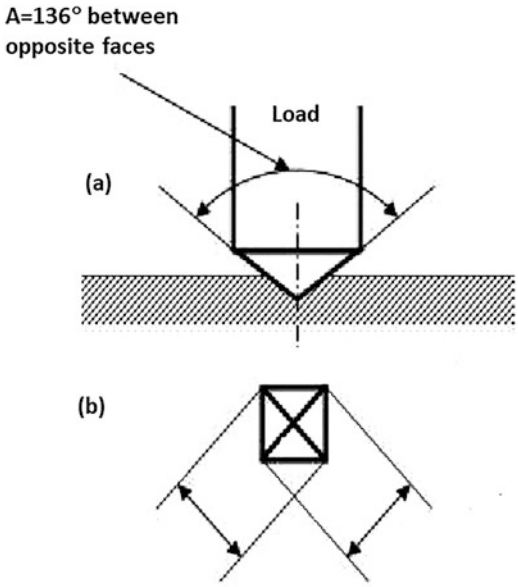

Fig. 3 Shape of Vickers indenter: (**a**) side view and (**b**) top view (Lim and Chaudhri 2006; Gall et al. 2001)

per ASTM 92 and ISO 6507 (Ellis 2003). In the Vickers hardness test, hardness is independent of the applied load since indentations with different loads are geometrically identical (Petrík and Palfy 2014). The shape of the Vickers indenter is shown in Fig. 3 (Lim and Chaudhri 2006; Gall et al. 2001).

The Vickers hardness is calculated from the following expression:

$$HV = 1.854P/L^2$$

Knoop Hardness Test

The Knoop hardness test is performed to measure the microhardness using the universal or microhardness testing machine (Clinton and Morrell 1987). Tests are

carried out as per ASTM E384 (Hetzner 2003). Generally, microhardness testing is done on thin films and brittle materials to avoid cracking. The Knoop indenter is a pyramidal diamond indenter with long and short diagonals at approximately 7:1. The indentation depth is about one-thirteenth of the length of the longer diagonal indenter. The Knoop hardness number (KHN) is obtained from the measurement. It is the number obtained by dividing the load applied (L in Kg) to a pyramidal diamond indenter of the specific size to the projected area of the impression (A in mm^2) (Revilla-León et al. 2021):

$$KHN = L/A$$

Knoop hardness is derived from the following formula:

$$HK = 14.229\ (F/D^2)$$

F is the applied load (kgf), and D^2 is the indentation area (mm^2).

Metallographic polishing is usually required to obtain a smooth surface. In the Knoop hardness test, the long diagonal impression is not affected for about 300 g load. In contrast, a small indentation is formed for lighter loads, resulting in a small elastic recovery. These factors generally give a high hardness reading. Therefore usually Knoop hardness number increases as the load is decreased below about 300 g. Schematic representation of the Knoop hardness test is shown in Fig. 4 (Ben Ghorbal et al. 2017; Sumiya and Ishida 2019).

Scope of Hardness BNDs

Rockwell and Vickers hardness BNDs, developed at CSIR-National Physical Laboratory, help the Indian industry suffering from traceability issues. All measurements have been carried out to establish traceability through an unbroken measurement chain with a stated uncertainty. Calibrated test blocks are used to confirm the instrument's

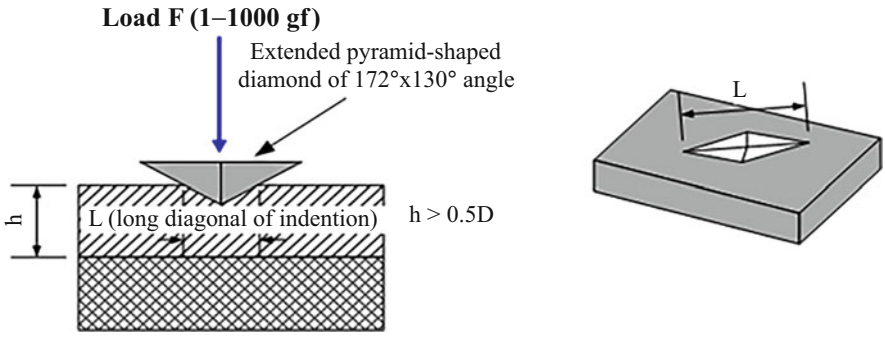

Fig. 4 Schematic representation of Knoop hardness test (Ben Ghorbal et al. 2017; Sumiya and Ishida 2019)

performance and calibration, ensuring the accuracy and traceability of hardness measurements. The hardness BND number and certified values are given in Table 1.

The Rockwell hardness block BND was prepared from steel and calibrated using Rockwell hardness tester ZHR4045/4150 according to IS 1586 (P-1), ISO 6508, and ASTM E18. A cone-shaped indenter was used for hardness measurement. The preload of about 10 kilograms and test load of about 150 kilograms were applied. Rockwell harness blocks (two sets) exhibited the certified value with the expanded uncertainty which was 44.33 ± 0.83 (HRC) and 61.04 ± 0.77 (HRC), respectively. For Vickers hardness for the load of 5 kg/49.03 N, the obtained value is around 735.6 ± 13.9 HV. The coverage factor for the reported values is $k = 1.96$, which agrees to a coverage probability of about 95% for a normal distribution (Fig. 5).

Table 1 Hardness block BND number and the certified values

Hardness BND number	Certified value
BND no. 2201	44.33 ± 0.83 HRC
BND no. 2202	61.04 ± 0.77 HRC
BND no:2204	735.6 ± 13.9 HV-5

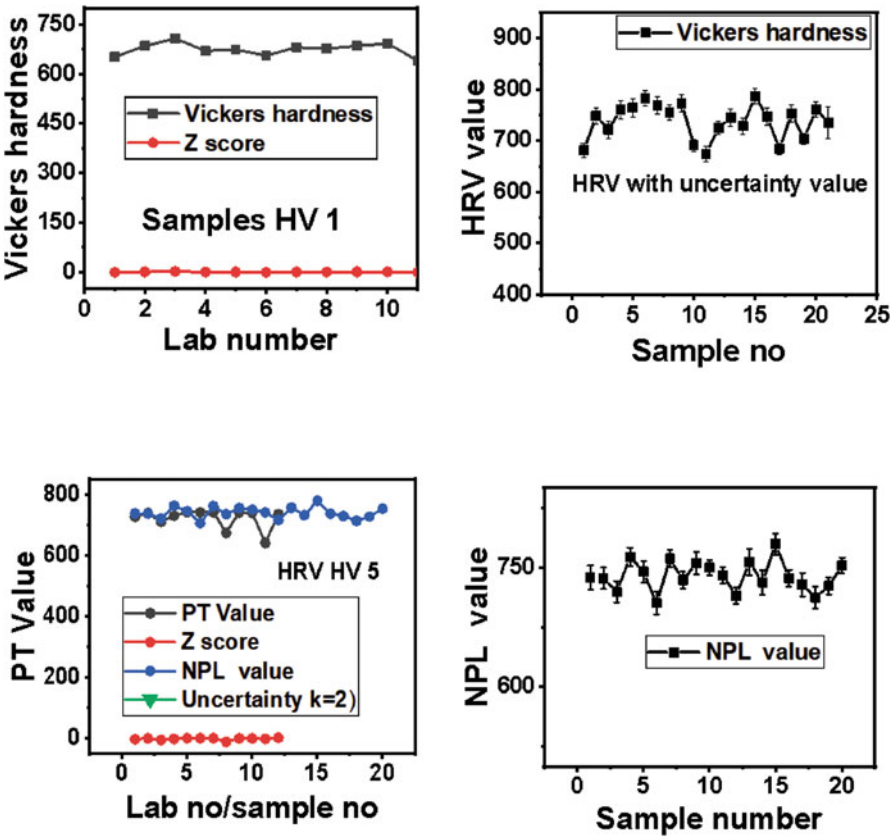

Fig. 5 PT results for Vickers hardness

During the hardness measurement, the selection of test location on the specimen is most important and must follow several precautions: If the indenter is placed closer to the edge of the specimen, the edge will bulge, and the hardness value will decrease accordingly (Kongkavitool et al. 2007). Distance from the edge of the material to the center of indentation should be at least a minimum of 21/2 times the indentation diameter. It ensures that any new indentation is not influenced by the work hardening of the material around a previous indentation.

Experimental Procedures Followed for the Development of Hardness Block BNDs at CSIR-NPL

Procedure for Rockwell Hardness Measurement

Rockwell hardness was tested using Model ZHR4045/4150 (Fig. 6), and the measurements were made as per ISO 6508 and ASTM E18 with preload of 10 kg and test loads of 60, 100, and 150 kg, respectively. The instrument's resolution was 0.1 digits, and the preload was used to cancel out errors. The use of a minor load significantly increases the accuracy of the test since it removes the effects of backlash in the measuring system that causes the indenter to break due to slight surface roughness. It is a rapid and nondestructive technique. The entire procedure

Fig. 6 Rockwell hardness tester

needs 5 to 10 seconds. The block used as a test sample is shown in Fig. 7. The Rockwell number represents the difference in depth from zero datum position due to the application of major load.

Procedure for Vickers Hardness Test

Figure 8 shows the Vickers hardness test equipment used for measuring the Vickers hardness as per IS 1501 (P-1)/ISO 6507-1/ASTM E92. Generally, indention is done

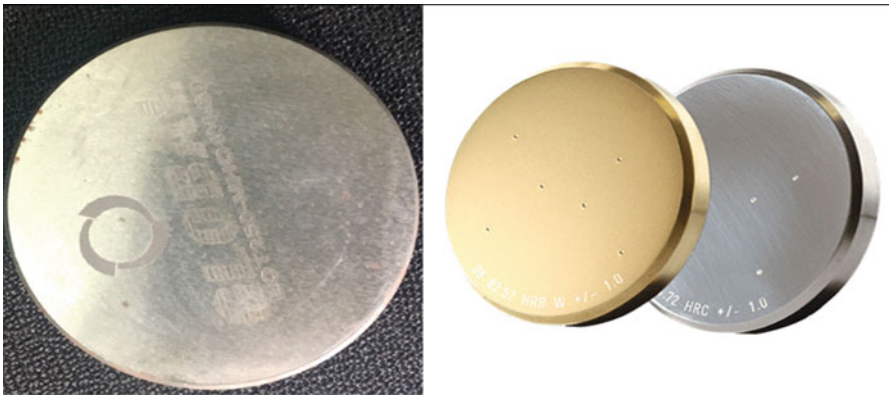

Fig. 7 Test piece used for hardness testing

Fig. 8 Vickers hardness tester

with the help of a pyramid-shaped diamond indenter with a square base. The angles between opposite faces are 136 degrees (see Fig. 2). A test force of 100 kgf is applied for 10 to 15 s. The mark is measured using a microscope.

Instructions for Storage, Commutability, Precautions, and Use for Handling

The BND should be stored in the box supplied with the reference material at a temperature range of 25 ± 10 °C with a relative humidity of 60% or less and should be protected from scratches, cavities, and other mechanical damage, mainly on the bottom surfaces. It is prone to corrosion due to moisture and skin oils. The user should wear protective gloves such as lint-free cotton or powder-free latex gloves while handling the BND. After using, the gloves should be placed back in a container and stored under defined storage conditions (25 ± 10 °C with a relative humidity of 60% or less) to minimize deterioration.

The sample's surface should be cleaned gently, and the top and bottom surfaces should be washed entirely with lint-free paper wetted with ethyl alcohol. The surface should be immediately dried using a soft lint-free paper before the alcohol evaporates, and the surface(s) should be blow-dried using filtered air.

Tensile Test

The tensile test is the standard test used to evaluate the strength of materials and is also considered an acceptance test for the specification of materials. The tensile test is carried out as per ASTM D638 and ISO 527 (Bergonzi et al. 2018). In this test, a specimen is deformed to fracture, with constantly increasing uniaxial tensile load, and simultaneously, elongation of the specimen is observed (Hart 1967). A test sample is steadily pulled or stretched to its breaking point to find the material's ultimate tensile strength. The standard tensile test specimens are shown in Fig. 9.

Fig. 9 Tensile test specimens

Generally, circular-shaped samples are used as the tensile test specimen, but sometimes rectangular-shaped specimens can also be used. For the tensile test, the "dog bone"-shaped specimen is used because during the stretching of the sample, deformation is restricted to the narrow center region to reduce the likelihood of fracture at the ends of the sample. The end of the sample is mounted into the holding grip of the testing apparatus. The tensile machine is designed in such a way to continuously and simultaneously measure the instantaneous load applied and resulting elongations during the testing process. The output result of the tensile test is recorded as a force vs. elongation plot (Sharifishourabi et al. 2014).

The tensile test result is displayed as force (F) applied to the sample vs. elongation (ΔL). The strength of the material is expressed in stress (σ) and strain (**ε**). Stress is defined as the force F divided by the sample cross-sectional area A ($\sigma = F/A$). Strain is the change in length, ΔL, by the initial length of the sample (L) ($\boldsymbol{\varepsilon} = \Delta L/L$). These values are then presented on an X and Y plot called a stress-strain curve. The parameters like modulus of elasticity, yield strength, ultimate tensile strength, strain hardening characteristics, ductility, Young modulus, and the Poisson ratio of material can be calculated from the stress-strain curve (Park et al. 2017). Several parameters such as the composition of metal or alloy, heat treatment condition, plastic deformation, temperature, strain rate, and state of stress applied during the test determine the curve's shape and magnitude. Figure 10 shows a classical stress-strain curve for engineering materials (Tu et al. 2020).

The slope region of the stress-strain curve is referred to as the modulus of elasticity (Young's modulus). The modulus of elasticity measures the stiffness of the materials. It is a factor used to calculate how materials resist deflection under

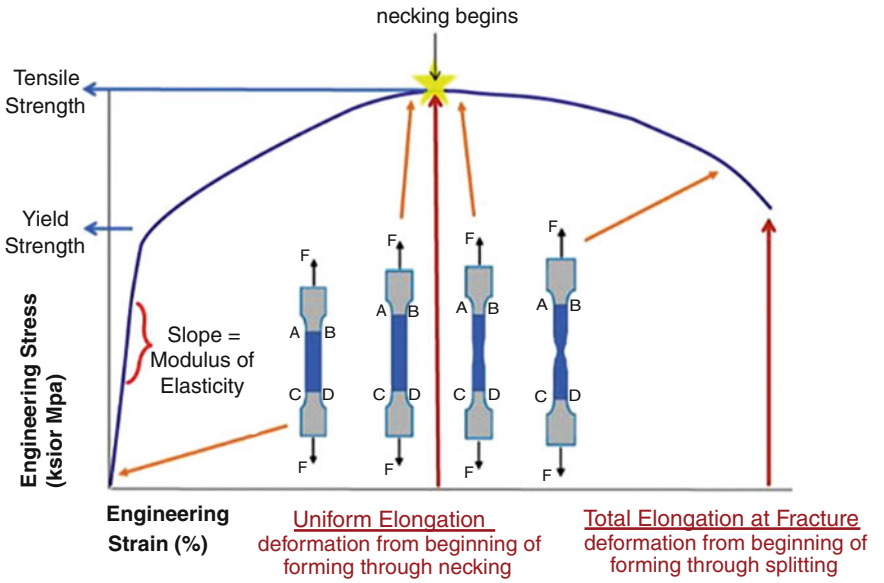

Fig. 10 Stress-strain curves of engineering materials (Tu et al. 2020)

applied load. This property reflects the elastic behavior of the materials. The maximum limit of the elastic behavior is noted as yield strength. It is the point where maximum stress can be developed on the material without causing plastic deformation.

Metals become stronger due to strain hardening as the plastic deformation increases. The load required increases with further straining until it reaches the maximum tensile strength. It is also known as the ultimate tensile strength (UTS) (Zhao and Takeda 2000). UTS is the maximum applied load at failure (P max) divided by the original area (A_0):

$$\text{Ultimate tensile strength (UTS)}\ \sigma\ \text{max}\ = \text{P}\ \text{max}\ /\text{A}_0$$

The diameter of the sample reduces rapidly beyond maximum load due to necking. The load needed for continuing the deformation is stopped as the diameter of the specimen decreases with maximum load until the specimen fractures. The tensile testing unit is shown in Fig.11.

Fig. 11 Tensile testing unit (Sharifishourabi et al. 2014)

Impact of Tensile BND

CSIR-NPL is in the process of developing tensile BND standards for metals and alloys. Steel and aluminum alloy standards are proposed to develop as the tensile sample. It is intended to be used to directly verify tensile testing machines, which can conduct tests following the ASTM A370/ASTM E8/IS 1608–1/ISO 6892-1. Thousand tensile specimens in a year were catered for automobile, aerospace industry, commercial metallurgical laboratories, etc. Presently only indirect verification is being done in India, and direct verification is not available. So these reference materials will effectively help the Indian market with minimum cost.

Fatigue

Fatigue is an essential criterion in the design of engineering materials. Fatigue is a failure in structures such as bridges, machine components, and aircraft subjected to dynamic and fluctuating stresses (Suresh 1998; Sharpe and Wilks 2002). It is determined by the endurance limit or the S-N curve. S-N curve is the plot of cyclic stress amplitude S on the *y* axis and the number of cycles for failure N on the *x*-axis (Lotsberg and Sigurdsson 2006; Ünal et al. 2016).

Fatigue life can be determined as the number of stress cycles that the materials can resist before the failure. Based on the properties of materials, the failure occurs in a few cycles, or sometimes it takes many cycles. The fatigue life cycle is divided into different types such as (1) low cycle fatigue (LCF), in which the cycles range from ~10^4 to 10^5, (2) high cycle fatigue (HCF) (~10^5 to 10^7 cycles), and very high cycle fatigue (VHCF) where the cycle number is greater than 10^7 (Wang et al. 2002a). Fatigue failure generally happens in three different stages and includes (1) crack initiation, (2) crack propagation, and (3) crack failure, respectively (Schütz 1979; Abd Allah et al. 1997).

Fatigue cracking initiates due to the materials being subjected to many cyclic stresses below the ultimate tensile stress or yield stress. Fatigue causes localized damage to the structure due to cyclic loading. The material experiences continuous and repeated loads at various points. When loads are high enough, they cause crack initiation, crack growth, and fracture.

Crack initiation is also known as a crack formation. A microcrack that grows to 0.5 or 1 mm in length for the defined cycles causes fatigue crack propagation. The sum of fatigue crack initiation and propagation is fatigue life. Fatigue failures frequently cause catastrophic failure in engineering materials. For most metals, polymers, and ceramics, the crack propagation takes place slowly, and in the later stages, they are also susceptible to sudden fatigue failures. Fatigue failure depends on cyclic loads, temperature, strain rate, oxidizing environment, structural deformation, embrittlement, structural deformation, frequency of the applied load, etc.

Figure 12 (Zalnezhad et al. 2014) shows the schematic representation of an apparatus used for fatigue testing. Applied stresses may be axial, flexural, or tensional. For simultaneous bend and rotation, the tension-compression stresses are applied on the specimen, and these are frequently conducted by using uniaxial

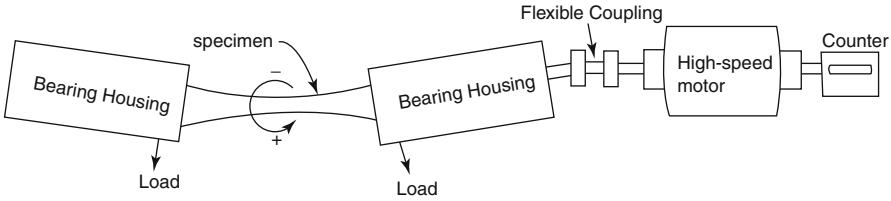

Fig. 12 Schematic representation of a rotating-bending test apparatus used for fatigue testing (Zalnezhad et al. 2014)

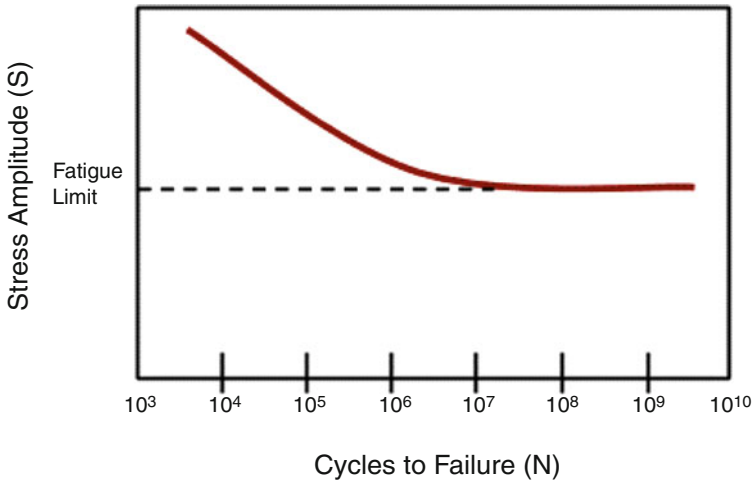

Fig. 13 S-N curve (Callister and Rethwisch 2018)

tension and compression stress cycle alternatively. The test sequences are started by exposing the sample to a stress cycle with relatively large maximum voltage amplitude, usually in sequence 2/3 of the static tensile strength and the number of cycles required for failure. The obtained data are plotted as stress S vs. the log. of the number N of cycles to failure, and it is generally called as S-N diagram (Fig. 13) (Govindaraju et al. 2021; Callister and Rethwisch 2018). It provides the relation between applied stress amplitude, S, to a material specimen and the number of loading cycles, N, the specimen can withstand before eventually failing. The S-N curve becomes horizontal for some materials at low stresses, indicating that the material will not fail at stresses below this limit (Wang et al. 2002b). The fatigue or endurance limit is the stress level below which there is no fatigue failure. The endurance limit is the stress below which a material can withstand an infinite number of repeated load cycles without exhibiting failure (Shen and Carpenter 1929).

Metals such as Fe and Ti alloys have a specific limit, as seen in Fig. 14 (Campbell 2008). In contrast, other materials such as Al and Cu do not have any specific limit, and they finally fail even if small stress amplitudes are applied. The fatigue strength test unit is shown in Fig. 15 (Il Seo et al. 2005).

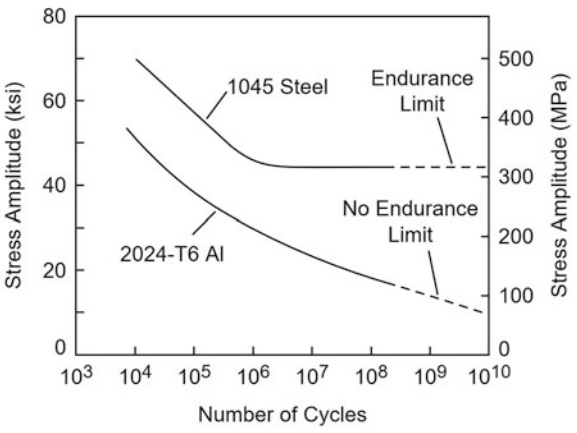

Fig. 14 S-N curve of aluminum and low carbon steel (Campbell 2008)

Fig. 15 Fatigue strength test unit (Il Seo et al. 2005)

Toughness

Toughness is the capacity of materials to absorb energy and withstand shock up to fracturing (Hahn et al. 1972). It is also defined as the amount of energy per unit volume that a material can absorb before fracture. The stress vs. strain curve representing the area of toughness measurement is shown in Fig. 16 (Nataraja et al. 1999).

Toughness can be measured by integrating the area under the stress-strain curve. Tensile toughness is measured in units of Jm^3 in the SI system. In general, tough

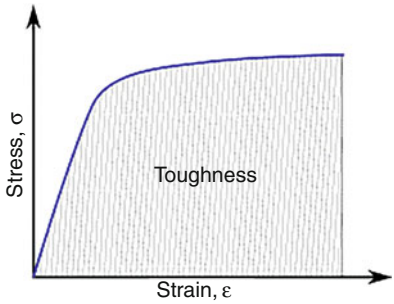

Fig. 16 Stress vs. strain curve representing the area of toughness (Nataraja et al. 1999)

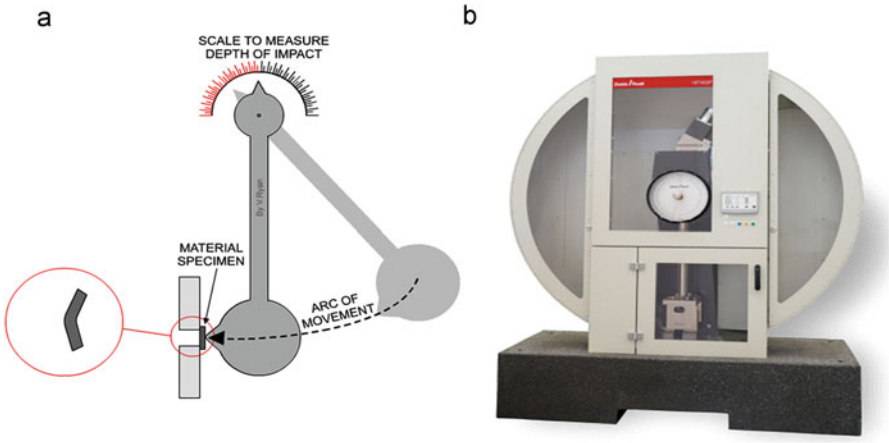

Fig. 17 (**a**). Schematic representation of pendulum Charpy test (Hayden et al. 1967), (**b**) Pendulum impact tester HIT450P (Brezinová et al. 2020)

material must be strong and ductile, and also it should have the capacity to withstand both high stresses and strains.

Ceramics are strong, brittle, and not tough. These also have less degree of ductility. However, very ductile materials with low strengths, such as aluminum, are also not tough. Strength specifies how much force a material can withstand, while toughness represents how much energy a material can absorb before the rapture. The Charpy impact test measures the toughness of the materials (Toth et al. 2002). The schematic representation of the pendulum Charpy test and modern pendulum impact tester HIT450P is shown in Fig. 17a and b (Hayden et al. 1967; Brezinová et al. 2020).

Impact BND standards for metals and alloys are also among the BNDs developed at NPL. To develop a sample, low, mid, and high (CVN) standards are proposed. This reference material is intended to verify the Charpy V-notch machines as per ASTM E23. The Charpy impact test standard is shown in Fig. 18 (Leis 2013; Bokuchava and Petrov 2020). One thousand sets, each of low-, middle-, and high-impact (CVN) RMs, in a year catering to automobile, forging, aerospace industry,

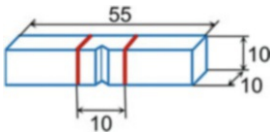

Fig. 18 Charpy impact standard (Bokuchava and Petrov 2020)

commercial metallurgical laboratories, forging, defense, and aerospace industry. NPL is committed to helping the whole Indian industry, which has suffered from traceability issues for a long time, and launching more Indian reference materials, effectively reducing the cost of Indian laboratories.

Hardenability

Hardenability is the alloy's ability to be hardened by the heat treatment process (Grange 1973). It is a measure of depth to which ferrous materials are hardened after quenching. It is also referred to as the depth of hardening. It is one of the essential parameters for the welding process and is inversely proportional to weldability, i.e., joinability of materials (Andersson 2011).

The Jominy end quench test (Newkirk and MacKenzie 2000) measures the hardenability of the ferrous alloys as per ASTM A255. When a hot steel workpiece is quenched in cool water, the area of the steel in touch with the water cools immediately. The workpiece temperature attains equilibrium with the quenching medium like water, oil, or air. However, the inner depths of the workpiece do not cool so rapidly. In larger steel workpieces, the cooling rate is slow enough to fully transform austenite into a structure other than martensite or bainite phases. Therefore, the workpiece is prevented from having the same crystal structure throughout its entire depth, creating a softer core and more rigid outer shell. The inner soft core is the combination of ferrite and cementite.

The hardening property of steel materials depends on the amount of carbon, alloying elements, and grain size of the austenite phases. The relative amount of the different elements present in the steel is calculated by determining the material's carbon equivalent (CE) (Kang 2011).

The cooling rate of the quenching medium depends upon the thermal conductivity and specific heat capacity. Generally, brine solution and water cool the steel faster than air or oil. Cooling occurs more rapidly if the fluid is agitated. The specimen's geometry also influences the cooling rate. For example, considering the two samples of the same volume, the higher surface area sample will cool faster than the lesser one.

Figure 19a represents Jominy end quench test. In this test, the cylinder-shaped sample is used with a diameter of 25.4 mm and a length of 102 mm, respectively (Peng et al. 2020). Generally, the steel sample is normalized to remove the differences in microstructure due to forging and austenitizing at 800 to 925 °C to transform the steel microstructure into austenite. The test steel sample is transferred

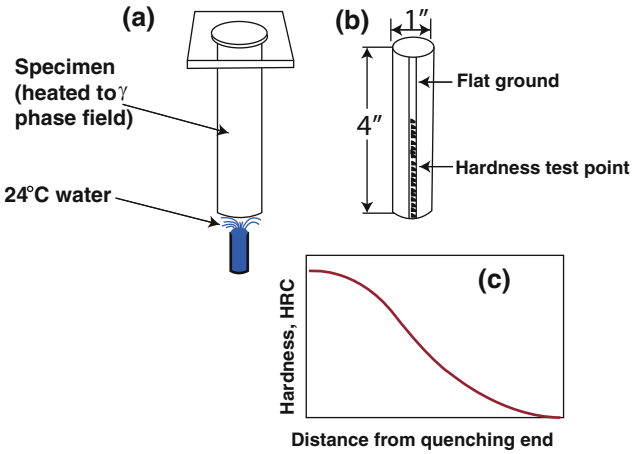

Fig. 19 (**a**) Jominy end quench test to check the hardenability, (**b**) specimen after test, and (**c**) hardness vs. distance from quench end (Callister and Rethwisch 2018)

rapidly to the test fixture, where one steel end is quenched with the controlled water flow. The cooling rate differs from one quenched end to another end of the sample. The cooling rate is very fast at the quenched end and slower cooling rates at the other end, similar to air cooling. The round sample is made flat by grinding along its length on opposite sides to a depth of at least 0.38 mm to eliminate decarburized materials formed during the forging process (Fig. 19b). The sample should not heat up during grinding as it can cause tempering and softening of the microstructure. The hardness is measured at regular intervals away from the quenched end of the specimen. The hardness is typically measured at about 1.5 mm intervals for alloy steels and 0.75 mm for carbon steels as close to the quenched end. The hardness decreases as the distance increases from the quenched end (Peng et al. 2020). High hardness was observed in the region with high-volume martensite fractions (Kandpal et al. 2021). Lower hardness occurs in the region where bainite or ferrite transforms into pearlite microstructures. Hardness measurement is commonly done using a Rockwell or Vickers method. A hardness curve describes the hardenability of the steel (Fig. 19c). It refers to the plot of hardness value measured at a certain length away from the quenched end of the sample. From the plot, the hardness decreases with an increase in quenching distance.

Conclusions

Strength, hardness, hardenability, toughness, and fatigue are some of the material's most important mechanical properties, which decide their suitability for engineering applications. In laboratories/industries, the mechanical properties are tested as per IS/ASTM standards for selecting materials as per the requirements. Several CRMs are developed to calibrate the instruments for accurate measurements. In India, these

CRMs are sold under the trade name BND. Recently CSIR-NPL has developed hardness blocks BND 2201, BND 2202, and BND 2204, respectively, in partnership with Global PT Provider Pvt. Ltd., for measuring Rockwell and Vickers hardness. Several BNDs are under development to cater to the nation's future needs.

Abstract

In the globally connected world, measurement unit and metrological traceability are the two essential requirements for reporting measurement results. While use of System International (SI) ensures international parity in reporting calibration and testing results in similar unit of measurements, laboratories must ensure metrological traceability also. Without traceability and knowledge of uncertainty of measurements and generated data, at each stage of calibrations, technical validity of results remains questionable. Further, wherever direct calibrations of the equipment are not possible, reference materials (RMs) and certified reference materials (CRMs) must be used. Thus CRMs – reference materials with certified values – accompanied with measurement uncertainty play an important role in confidence building in measurements conducted by the laboratories. Use of RMs and CRMs is mandated in respective product standards and ISO/IEC 17025:2017/ ISO17043:2010/ISO 9001:2015 system standards, for quality control (QC) and quality assurance (QA). Decisions on acceptance of production lots, based on associated measurement results, are critical to the survival of businesses, and, therefore, it is essential for the manufacturers and the laboratories to ensure that reported measurement data and results are technically valid. It is needless to mention that today it is all about data, analytics, artificial intelligence (AI) robotics, and automation – the hallmark of Industry 4.0. Data are the basis of all decisions.

This chapter discusses the role played by RMs and CRMs in standardization, QC, and QA and their application for various purposes by the respective bodies – in manufacturing and services sector – and international trade. Discussion reveals that ISO/IEC 17025:2017 embodies the spirit of plan-do-check-act (PDCA) cycle. Taking the case of Indian cement industry, the requirement of calibrations and RMs at various stages of production and quality control is also discussed.

Introduction

Data and information management play a vital role in the world economy. The world economy is expanding. World GDP is expected to be of $100 trillion size, even before 2024 (Centre for Economics and Business Research (CEBR) 2021). In the globally connected world of today, quality of products and services determines a nation's competitiveness. All measurements have to be technically valid and acceptable across the world. Thus, quality infrastructure, system of accreditation, generation of results by competent laboratories, and traceable measurements and calibrations – using standard equipment and/or reference materials (RMs) – play an important part in equipment standardization, quality control (QC), and quality assurance (QA) in the industry.

RMs with certified values are required for equipment calibration and maintaining metrological traceability. RMs with certified values, called certified reference materials (CRMs), are measurement standards. These are essential for quality control and quality assurance in the industry. CRMs ensure traceability and accuracy of measurements with associated value of uncertainty – at the stated confidence level – and accuracy, or inaccuracy for that matter, decides the fate of a production lot or export consignment. Thus, RMs or CRMs are needed primarily for making accurate and technically valid measurements and a variety of purposes, like standardization, calibration, method validation, quality control and quality assurance, etc. The world today exchanges goods and services at an unprecedented speed and scale. We have global supply chains, and slightest disruption – least of all of technical nature – in any part of the chain has cascading effect. Data accuracy and precision help break technical barriers to trade and assure better quality of life (Kumari et al. 2022). In the global economy, world CRM market, valued US$1190.32 million in 2019, is expected to grow at a CAGR of 6.8% (Global CRM market growth (2020(2027) 2021).

Measurement Units and International System

Reference materials play an important role in a nation's economy. Competitive countries have technical capabilities to produce and use RMs and CRMs across industry sectors. In the industrial world, product quality and acceptability decisions require making measurements. Decisions have to be made on the basis of data and facts. One can't imagine working without data, large data, analytics and automation in Industry 4.0 – characterised by artificial intelligence, machine learning, Internet of Things (IOT), cloud computing and analytics – which is changing the ways of manufacturing and distribution of products and services. Manufacturers are integrating the new technologies into their production facilities and throughout their operations, and using the embedded software for data collection, analysis and better decision making (What is Industry 4.0? 2022)

Scientific, R&D, and engineering organizations have to make measurements and express results in universally used units. In this context, standard unit system helps us understand the measurements in one set of unit system, and this facilitates global trade (Understand the International System of Units and its seven basic SI Units n.d.). System of units is the set of base units and derived units, together with their multiples and submultiples, for a given system of quantities, and the **International System of Units** (SI) is the system of units which is based on the International System of Quantities, adopted by the 11th General Conference on Weights and Measures (CGPM) in 1960 (ISO/IEC Guide 99 2007).

Global Trade relies heavily on monetary standard (gold or currency) and internationally accepted product, process, system and measurement standards. Here lies the importance of international institutions, like, International Bureau of Weights and Measures (BIPM), General Conference on Weights and Measures (CGPM), International Organisation for Standardisation (ISO), **ISO/REMCO** Committee on Reference Materials, Eurachem- A network of organisations in Europe, EUROMET- The European Association of National Metrology Institutes, National Metrology Institutes (NMIs) of various countries, International Laboratory Accreditation Cooperation (ILAC), International Accreditation Forum (IAF), National accreditation bodies of various countries, quality infrastructure in the countries world over, which have together contributed to the development of knowledge on reference standards and materials. In India, we have authoritative organisations, like, CSIR-NPL, i.e. National Physical Laboratory, India (NPLI), Bureau of Indian Standards (BIS), Quality Council of India (QCI) which – apart from National Accreditation Board for Testing and Calibration Laboratories (NABL) – has other boards also under it, and various other R&D organisations in different sectors (Aswal 2020)

Measurement Standards and Reference Materials

Reference material is basically a measurement standard. Measurement standard is defined as "realization of the definition of a given quantity with stated quantity value and associated measurement uncertainty, used as a reference" and, national measurement standard – standard for a country – is a measurement standard which is recognized by a national authority for assignment of quantity values to other measurement standards, with the purpose to serve in a particular state/economy (ISO/IEC Guide 99 2007). Cross-country use of national measurement standards also is often made for comparison or whenever needed, as traceability through these standards can be disseminated worldwide. Definitions of these standards are given in ISO/IEC Guide 99:2007 (ISO/IEC Guide 99 2007). Hierarchy of measurement standards can be depicted as in Fig. 1. The figure gives a brief description also of these standards.

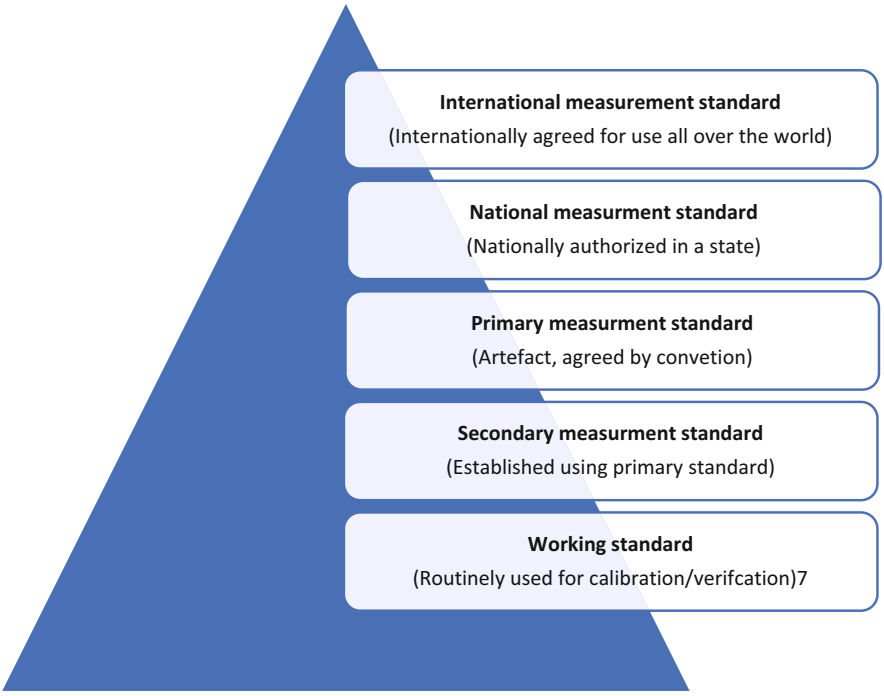

Fig. 1 Hierarchy of measurement standards (ISO/IEC Guide 99:2007)

Classification, Selection, and Use of Reference Materials

Reference materials are classified into three classes: primary, secondary and in-house or working standards (ILAC-G9 2005; EA-4/14 INF 2003; EEE/RM/062rev3 2002), with uncertainty increasing down the level from primary to working standard. ISO/IEC Guide 99:2007 (ISO/IEC Guide 99 2007) mentions two classes: Certified Reference Materials (CRMs) and Reference Materials (RMs)

RMs are materials whose property values are well established. These can be used for instrument/equipment calibration, assessment of a measurement method, and assigning value. CRMs are accompanied with additional documented information and have greater utility in the industry. Measurands of CRMs are traceable to SI units, and uncertainty – at a stated level of confidence – is reported in the certificate.

A measurement operation may serve more than one quality purpose, and there may be functional overlap also (EEE/RM/062rev3 2002). Thus, we need different types of RMs for different functions or levels of control. For example, a CRM, also called standard sample, is desirable for equipment standardization and calibration (standardization of Blaine apparatus for determining cement fineness), but a working-level reference material is adequate for checking hourly samples (for

Table 1 Reference materials – types (ILAC-G9:2005)

Type	Description
Pure substances	These are characterized for chemical purity and/or impurities present in minor/trace quantity
Standard solutions and gas mixtures	These are prepared using gravimetric procedures, mainly from pure substances, and are used for calibration
Matrix reference materials	These are prepared from matrices which contain components of select nature
Physicochemical reference materials	These are characterized for a variety of properties, like melting point, viscosity, etc.
Reference objects or artefacts	These are characterized for a variety of functional properties, like flash point, hardness, etc. microscopy specimens and microbiological specimens are also included in this category

determining fineness) and quality control in cement industry, as per STI/269/7, 2016 (STI/269/7 2016), and IS3535:1986 (IS 3535 1986).

According to ILAC-G9:2005 (ILAC-G9 2005), international guidelines for selecting and using reference materials, and EA-4/14 INF:2003 (EA-4/14 INF 2003), guidelines for selecting reference materials, the RMs (presented in Table 1) are of five types.

Reference materials play an important role in method validation, equipment calibration, estimation of measurement uncertainty, internal quality control (QC), external quality assurance (QA), training of personnel, and proficiency testing (ILAC-G9 2005)

Further, as per ILAC-G9:2005 (ILAC-G9 2005), validity of measurements can be assured through use of validated methods and appropriate equipment, deployment of competent personnel, establishing metrological traceability and estimating measurement uncertainty, participating in interlaboratory comparisons (ILC) and proficiency testing (PT), and laboratory accreditation.

ISO Documents (Guides and Standards) on Reference Materials and Important Definitions

ISO Guides and Standards

ISO has published a series of guidance documents on reference materials. The list of these documents is presented in Table 2.

RM and CRM Definition

ISO Guide 30:2015 (ISO Guide 30 2015) defines reference material (RM) as "Material, sufficiently homogeneous and stable with respect to one or more specified properties, which has been established to be fit for its intended use in a measurement

Table 2 ISO documents on reference materials

Document type and number	Document name
ISO Guide 30:2015	Guidance document for terms and definitions (ISO Guide 30 2015)
ISO Guide 31:2015	Guidance document for certificate contents, labels and related documentation (ISO Guide 31 2015)
ISO Guide 32:1997[a]	Guidance document for calibration in analytical chemistry and use of CRMs (ISO Guide 32 1997)
ISO Guide 33:2015	Guidance document for good practice in using RMs (ISO GUIDE 33 2015)
ISO Guide 34:2009[b]	General requirements for the competence of RMPs (ISO Guide 34 2009)
ISO 17034:2016	Standard for general requirements for the competence of producers of RMs (ISO/IEC 17034 2016)
ISO Guide 35:2017	Guidance document for checking homogeneity and stability (ISO Guide 35 2017)

[a]Withdrawn and revised by ISO Guide 33:2015
[b]Published as standard

process." CRM is an RM with certified property (SI traceable) results, with associated measurement uncertainty reported in the certificate. The standard defines CRM as "Reference Material characterized by a metrologically valid procedure for one or more specified properties, accompanied by a certificate that provides the value of the specified property, its associated uncertainty, and a statement of metrological traceability" (ISO Guide 30 2015).

Role of Reference Materials in Standardization, QC, and QA (ISO Requirements)

ISO/IEC 17025:2017 Requirements: PDCA Approach

ISO/IEC 17025:2017 (ISO/IEC 17025 2017) deals with the subject of reference materials in Sect. 6 (resources) and Sect. 7 (process requirements) under three aspects: metrological traceability (Subsect. 6.5); selection, verification, and validation of methods (Clause 7.2.2); and ensuring the validity of results (Subsect. 7.7). Subsection 8.6 deals with management system improvement.

Metrological Traceability and Measurement Uncertainty

Metrological traceability in ISO/IEC 17025:2017 (ISO/IEC 17025 2017) is considered a "resource." Clause 6.5.1 of the standard requires the laboratories to establish and maintain metrological traceability of measurement results. Traceability can be assured by direct realization of the SI units, calibrations, or RMs. Traceability has to

be documented through unbroken chain of calibrations and linked to an appropriate reference.

Measurement uncertainty. Measurement uncertainty is defined as follows: *Uncertainty of measurement is a non-negative parameter; it characterizes the dispersion of the quantity values which are attributed to a parameter*, according to ISO/IEC Guide 99:2007 (ISO/IEC Guide 99 2007), referred in ISO/IEC 17025:2017 (ISO/IEC 17025 2017).

According to Clause 6.5.2, the laboratories are required to ensure that measurement results are traceable to the International System of Units (SI) through using the services of competent (ISO/IEC 17025 accredited) agency – for calibration or procuring CRMs – which ensures traceability to SI.

Clearly, reference materials with certified values, reporting measurement uncertainty, and assured traceability play all important role in QC and QA by providing evidence of technical validity and thereby building customer confidence. For claiming competence, reference material producers have to fulfil the requirements of ISO 17034:2016 (ISO/IEC 17034 2016).

Method Selection, Verification, and Validation

Sect. 7 is about process requirements in the ISO/IEC 17025:2017 (ISO/IEC 17025 2017) Scheme. A note in Subclause 7.2.2.1 of Clause 7.2.2 (validation of methods) under Subsect. 7.2 (selection, verification, and validation of methods) in the standard recommends for calibration or bias evaluation using RMs, systematic assessment of influencing factors, testing robustness of method, comparison with other methods, interlaboratory comparison (ILC), and evaluation of measurement uncertainty. All these techniques need the application of reference materials for method validation.

Validity of Results

Clause 7.7.1 of Subsect. 7.7 (ensuring the validity of results) under process requirements (Sect. 7) of ISO/IEC 17025:2017 (ISO/IEC 17025 2017) requires planned monitoring of the laboratory quality control activities and, as a minimum, recommends to:

(a) Use RMs or QC material.
(b) Use calibrated alternative instruments.
(c) Conduct functional check(s) on laboratory equipment;
(d) Use working standards for routine calibration.
(e) Conduct intermediate checks on equipment.
(f) Conduct replicate tests or calibrations on test/calibration items.
(g) Retest or recalibrate samples/items retained by the laboratory.
(h) Correlate results for different characteristics of a sample.
(i) Review test/calibration results.

(j) Participate in interlaboratory comparisons (ILC).
(k) Test blind samples, the samples whose parameter values are not known to the analyst.

Monitoring and Review

Further, Clause 7.7.2 of Subsect. 7.7 of the standard requires monitoring laboratory performance by participating in proficiency testing (PT) conducted by ISO/IEC 17043 (ISO/IEC 17043 2010)-accredited competent PT providers and/or interlaboratory comparisons. Thus, the issue of nonavailability of accredited PT providers is addressed through allowing participation in ILC schemes.

Finally, Clause 7.7.3 of Subsect. 7.7 is about review and action for improvement. It requires that data from monitoring activities should be analyzed, and used, for control and improvement of the laboratory's activities; appropriate action is required to be taken in case of deviations (ISO/IEC 17025 2017). Statistical techniques should be used for defining and analyzing problems and planning actions for improvement.

The requirements of reference materials, prescribed in ISO/IEC 17025:2017 (ISO/IEC 17025 2017) and discussed above, are summarized in Table 3.

It is very clear from the above that the technical validity of results cannot be assured without discussion on metrological traceability and implementing the recommended measures in all quality control activities: method selection, verification and validation, and monitoring and review, i.e., the activities spanning planning, implementation, checking, and action, all stages of plan-do-check-act (PDCA) cycle, which is also called PDSA (plan-do-study-act) cycle, quality control cycle, or management cycle or Deming cycle, and is the basis for continual improvement.

Japanese organizations, after the Second World War, learnt from the teachings of Dr. Juran and Dr. Deming and implemented PDCA and quality circle approach and total quality control (TQC), now known as total quality management (TQM), and established international competitiveness of the Japanese industry. The main requirements of ISO/IEC 17025:2017 (ISO/IEC 17025 2017) regarding ruse of reference

Table 3 Important sections of ISO/IEC 17025:2017 on reference materials

Section number	Section name	Statement
6.5.1	Metrological traceability	Laboratories have to establish and maintain metrological traceability of their measurement results, linking them to an appropriate reference
6.5.2	Metrological traceability	Measurement results have to be traceable to the SI units through certified values of CRMs
7.2.2	Method validation	The techniques mentioned for method validation, particularly evaluation of measurement uncertainty, need application of CRMs
7.7.1	Validity of results	Laboratories need to use reference materials as one of the most important tool for ensuring technical validity of results

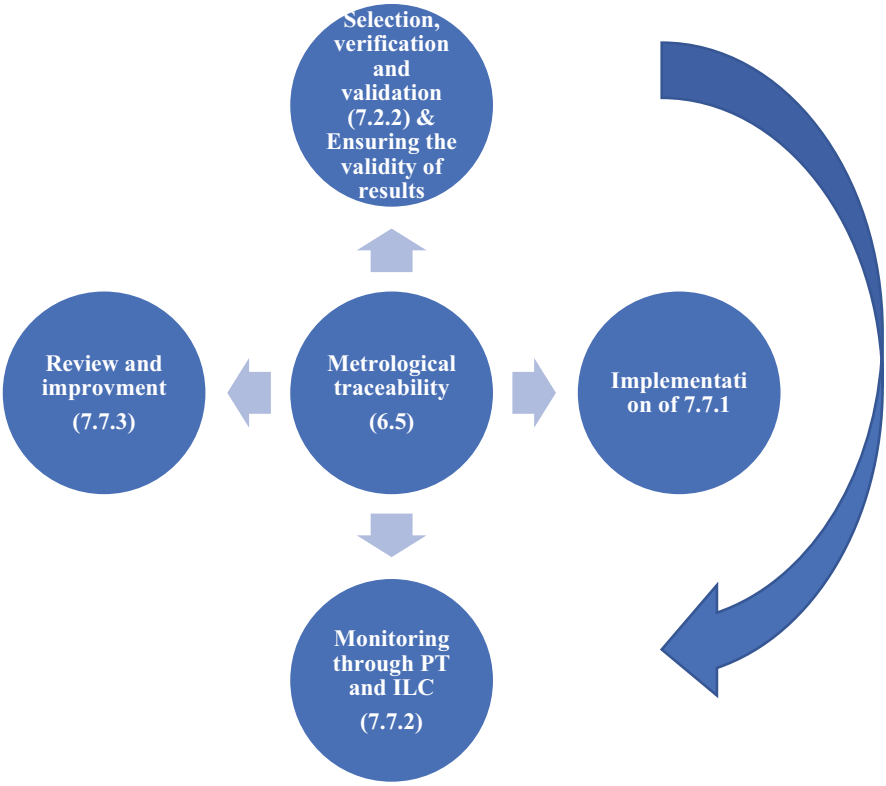

Fig. 2 QC and QA with application of ISO/IEC 17025:2017 requirements

materials in quality control (QC) and quality assurance (QA) are presented in Fig. 2. In the context of the laboratory competence, these measures help control the quality of measurements and also give assurance about quality, internally and externally, to interested parties.

System Improvement

Along with monitoring of process elements, monitoring and review of the management system are also required. Laboratories are required to improve the activities and results in a system's framework. Improvement is facilitated by adopting plan-do-check-act (PDCA) model for problem-solving and conducting periodic internal audits and management review. ISO/IEC 17025:2017 (ISO/IEC 17025 2017) in Subsect. 8.6 stresses on these aspects, along with risk management, use of policies and procedures, data analysis, and PT results. The structure of the management and technical systems, in fact, is based on PDCA framework (Fig. 3) in all 17,000 series

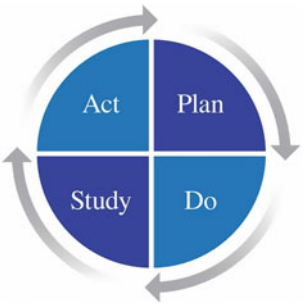

Fig. 3 PDCA cycle of continual improvement

standards, like ISO/IEC 17025 (ISO/IEC 17025 2017), ISO 17034 (ISO/IEC 17034 2016), ISO/IEC 17043 (ISO/IEC 17043 2010), and ISO 9001 (ISO 9001 2015).

ISO 17034:2016 on Production of Reference Materials

About ISO 17034:2016

ILAC-G12:2000 (ILAC-G12 2000) guidelines for RMPs contained 13 management system requirements and 19 technical requirements. ISO Guide 34: 2009 (ISO Guide 34 2009) which laid down requirements for the competence of RMPs contained 15 management requirements and 18 technical requirements.

ISO 17034:2016 (ISO/IEC 17034 2016), earlier Guide 34 (ISO Guide 34 2009), lays down general requirements for the competence of reference material producers (RMPs). Like ISO 17025:2017 (ISO/IEC 17025 2017), ISO 17034:2016 (ISO/IEC 17034 2016) includes structural, resource, and management system requirements. To address unique production aspects of reference materials, process requirements are detailed as technical and production requirements in the standard. ISO 17034:2016 (ISO/IEC 17034 2016) has been harmonized with the recent editions of ISO Guides on reference materials. The term quality manager has been removed in the standard and clause on risk management included. The production of multiple batches has been addressed explicitly, and homogeneity must be assessed for each property of interest (Trapmann et al. 2017). Figure 4 presents the family of reference material guides which support ISO 17034:2016 (ISO/IEC 17034 2016).

ISO 17034:2016 (ISO/IEC 17034 2016) shows the following major changes when it is read with ISO Guide 34:2009 (ISO Guide 34 2009):

- The standard is restructured as are the other ISO 17000 standards on conformity assessment.
- The standard includes requirements for all types of RMs and specifies additional requirements for CRMs.
- The standard is harmonized with revised versions of ISO Guide 31 (ISO Guide 31 2015) and ISO Guide 35 (ISO Guide 35 2017).

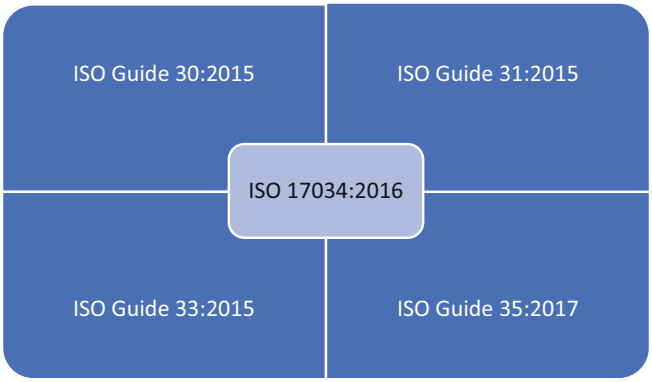

Fig. 4 Family of ISO Guides on reference materials supporting ISO 17034:2016

- The standard, like other 17,000 documents, requires addressing risks and opportunities.

ISO 17034:2016 Criteria for Competence of RMPs

ISO 17034:2016 (ISO/IEC 17034 2016) lists the following principal requirements for RMPs: general requirements, structural requirements, resource requirements, production and technical requirements, and management system requirements.

Sect. 7 on production and technical requirements in ISO 17034:2016 (ISO/IEC 17034 2016) contains the following subsections: 7.1 general requirements, 7.2 production planning, 7.3 production control, 7.4 material handling and storage, 7.5 material processing, 7.6 measurement procedures, 7.7 measuring equipment, 7.8 data integrity and evaluation, 7.9 metrological traceability and certified values, 7.10 assessment of homogeneity, 7.11 assessment and monitoring of stability, 7.12 characterization, 7.13 assignment of property values and their uncertainties, 7.14 RM documents and labels, 7.15 distribution service, 7.16 control of quality and technical records, 7.17 management of nonconforming work, and 7.18 complaints.

The process of production of RMs begins with need identification. Basically, production and delivery have to be planned for the following activities:

- Customer need identification.
- Material selection.
- Measurement method selection and verification.
- Material processing.
- Material testing and evaluation.
- Labeling and packaging.
- Homogeneity assessment.
- Stability checking.
- Value assignment.

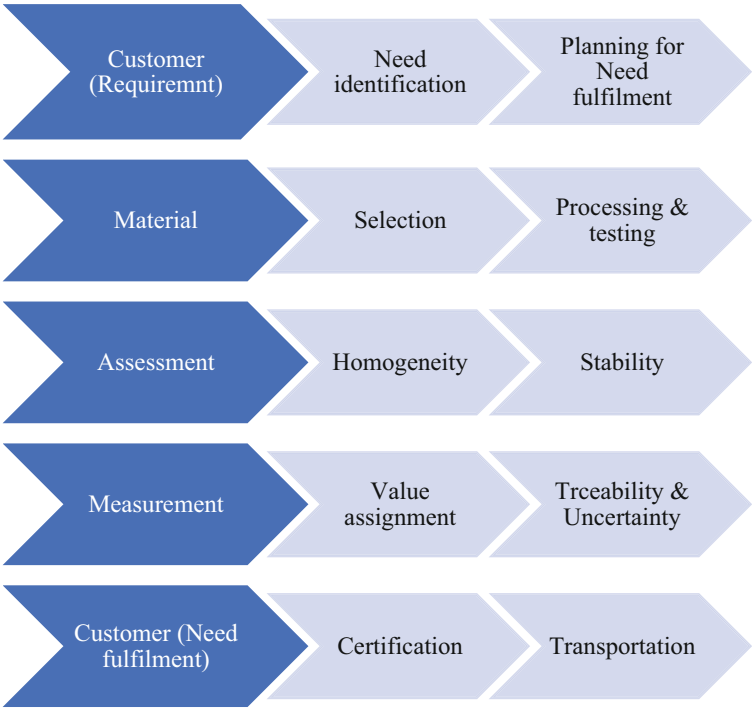

Fig. 5 Five-stage CMAMC approach to reference material production and delivery

- Certification.
- Transportation and delivery.
- Customer feedback and complaints analysis.

The steps of the process are presented as five stage process (CMAMC) relating to customer (requirement), material, assessment, measurement, and customer (need fulfilment), in Fig. 5. Establishment of metrological traceability and statement of measurement uncertainty is mandatory. The process begins with customer and ends with customer.

To avoid risk of technical invalidity of results, due care has to be taken for maintenance of storage and environmental conditions. This needs discussion on storage requirements for RMs as also their homogeneity and stability.

Facilities, Storage, and Environmental Conditions for Production and Distribution of RMs

Provision of facilities and environmental conditions and control of material handling and storage are important requirements for maintaining the technical validity of

reference materials. ISO 17034:2016 (ISO/IEC 17034 2016), firstly in Subsect. 6.4, requires that all facilities for production and distribution of RMs: laboratory facilities, calibration areas, testing areas, material handling, and processing and packaging areas, including energy sources, temperature and humidity conditions, lighting, and ventilation, should be such which ensure proper material handling, processing and packaging, and performance of various activities. Monitoring and strict control of these facilities are required. Further, ISO 17034:2016 (ISO/IEC 17034 2016) in Subsect. 7.4 lays down the requirements for material handling and storage. Personnel handling the materials should have undergone training on material handling. Adequate safety measures for environmental protection need to be taken. Precautions have to be taken to protect against adverse environmental conditions and any unforeseen or unintended contamination. Candidate RMs and RMs have to be identified and preserved, and integrity of these materials has to be ensured throughout the production process. Packaging and labeling process also have to be controlled and condition (stability) of RMs assessed at appropriate intervals.

Homogeneity, Stability, and Value Assignment

Homogeneity of RM candidates and stability of RMs are important requirements, a prerequisite, during their production and use. ISO 17034:2016 (ISO/IEC 17034 2016) requires establishing documented procedures for assessing homogeneity and stability on packed items. Homogeneity assessment is done by performing repeatability (within sample/bottle standard deviation) and reproducibility (between sample/bottle standard deviation). For stability check (checking condition of the materials during their utilization period) – which is conducted at periodic intervals, same laboratory – same test method and same parameters are checked. ISO Guide 35:2017 (ISO Guide 35 2017) provides approaches for assessment of homogeneity and stability, management of the risks associated with possible stability issues, characterization and value assignment of properties, evaluation of uncertainty for certified values, and establishment of the metrological traceability of certified property values. ISO 13528:2015 (ISO 13528 2015) also is a useful standard for the purpose.

Indian Reference Materials

Gross domestic product (GDP) in India is expected "to grow at 12-12.5 per cent (8 per cent real GDP and 4-4.5 per cent inflation) in the current financial year, and the economy will attain a size of USD 3,350-3,400 billion in 2022-23 and touch USD 5 trillion by 2026-27" (PhD Chamber 2022). In this environment, there is a growing market for RMs and CRMs. The reference materials produced in India by the premier organizations are of the highest quality and meet traceability requirements. Certificates issued for CRMs contain uncertainty statement as required. Due care is taken in homogeneity assessment, stability checking, storing, stocking, and

transporting. Indian organizations are getting ISO 17034:2016 (ISO/IEC 17034 2016) accreditation also.

Bharatiya Nirdeshak Dravyas (BNDs)

National Physical Laboratory of India (NPLI) has established a scheme of producing Bharatiya Nirdeshak Dravyas (BNDs). Now RMs produced by competent organizations are elaborately checked in coordination with reference material producer (RMP) by CSIR-NPL and certified for traceability. These RMs are then marked as BND by CSIR-NPL. BND is the trademark, and this marking allows dissemination of traceability throughout the world for test measurement of certified parameters; BNDs in different sectors are uploaded on the international COMAR database (Pant 2018).

Collaboration between CSIR-NPL and the National Council for Cement and Building Materials (NCCBM)

Apart from CSIR laboratories, the National Council for Cement and Building Materials (NCCBM), a premier governmental autonomous organization, has been making RMs for over four decades and delivering to cement and construction material organizations, R&D bodies, and third-party laboratories in the country and abroad (Breja et al. 2000). The CRMs produced by NCCBM are cost-effective, and quite a few were listed in ISO/REMCO directory (ISO/REMCO Document N 330 List of producers of certified reference materials, Information by Task Group 3 n.d.) and COMAR (Code d'Indexation des Matériaux de Reference) database also since early times. Over the years, it made 78 types of CRMs, including the ones for meeting quality control needs of cement industry, like CRMs of Blaine fineness and chemical composition for cement of different types and pozzolanic materials and CRM of pure phases of cement clinker, coal, etc., and the efforts support government of India's "Make in India" campaign (Breja et al. 2017).

Indian cement industry and overseas cement manufacturing plants routinely use CRMs produced by NCCBM, for equipment standardization and calibration and product quality control and quality assurance. Some of these CRMs, like the one for Blaine fineness, have been explicitly mandated by Indian standard codes (IS standards on various types of cement) and Bureau of Indian Standards Scheme of Testing and Inspection (BIS-STI), for use in quality control, maintaining traceability of measurements, and ensuring parity in results produced by different cement testing laboratories. These CRMs are used for ensuring technical validity of measurements also and meeting the requirements of Clause 7.7 of ISO/IEC 17025:2017 (ISO/IEC 17025 2017).

Now going one step further, NCCBM has collaborated with CSIR-NPL and developed Bharatiya Nirdeshak Dravyas (BNDs). "The National Measurement Institute (NMI) of respective country is to maintain the measurement standard

which is metrologically traceable to the international standards at International Bureau of Weights and Measures (BIPM) through unbroken chain of measurements with stated uncertainties. NPLI is developing IRMs (Indian Reference Materials) in association with National Council for Cement and Building Materials" (Kumari et al. 2022). NCCBM is the first organization, outside CSIR, to collaborate and jointly develop and issue these CRMs. The first five BNDs of cement and pozzolanas, produced by NCCBM in collaboration with NPLI, were released by Dr. Harsha Vardhan, the then minister of science and technology, Govt. of India, on 16 August 2018. Among these, the BND 5001 of Ordinary Portland Cement (OPC) for Blaine fineness and BND 5051 for chemical parameters of OPC, BND 5004 for fly ash for Blaine fineness are most sought for by the cement industry. More BNDs of NCCBM were dedicated to the nation by Prime Minster Mr. Narendra Modi on 4 January 2021, foundation day of NPLI (Yadav 2021). NCCBM has received ISO 17034:2016 (ISO/IEC 17034 2016) accreditation also from the National Accreditation Board for Testing and Calibration Laboratories, New Delhi.

Honourable Minister of Science and Technology, Govt. of India (fourth from right), releasing the BNDs at CSIR-NPL. Also present are Director CSIR-NPL (third from right) and the author (second from right)

Role of Reference Materials in Production, Quality Control, and Quality Assurance in Manufacturing Industry

Manufacturing processes operate under strict control. The essential equipment and instruments used in controlling input, process, and output quality parameters have to be checked and calibrated wherever measurements impact process and product

quality requirements. Quality control and quality assurance laboratories of the manufacturing units must be competent and use calibrated equipment and instruments. Third-party testing and calibration laboratories also must use calibrated equipment. RMs and CRMs wherever required have to be used. Case of quality control and quality assurance and the role of reference materials in cement industry are discussed in this section.

Quality Control in Cement Industry

India is the second-largest producer of cement in the world with 210 large cement plants and around 350 mini cement plants. Indian cement industry produced 334.48 million tons of cement in 2019–2020 and 232.57 million tons in 2020–2021 up to January 2021 (Cement Units, Lok Sabha Unstarred Question No. 4617 2021). Cement manufacturing is under mandatory licensing, and the Bureau of Indian Standards (BIS) is the standards publishing and licensing organization in the country.

Cement manufacturing is a complex process, involving mining of raw materials – mainly limestone and clay – crushing to −80 mm size, grinding to a fine −90 micron size, sintering at a temperature of 1450 °C, cooling the output clinker, and grinding with gypsum in a cement mill. In India, 90% of cement is packaged in bags and distributed. Clinker and cement quality are governed by raw material composition and control of process parameters. Indian cement industry has world-class cement plants and testing laboratories. Quite a few laboratories have received ISO/IEC 17025:2017 (ISO/IEC 17025 2017) accreditation also.

Sampling and Inspection (IS 3535:1986 Requirements) in Cement Manufacture

IS 3535:1986 (IS 3535 1986) prescribes the methods for sampling and the criteria for conformity of hydraulic cements. The manufacturer is required to draw representative samples in accordance with the standard requirements (presented in Table 4) for various cement types. This standard was first issued in 1966 and then revised in 1986. It lays down the requirements for sampling and inspection to meet the quality control and quality assurance needs of the cement plants at all stages of cement production: clinker manufacturing, clinker grinding to make cement, and final inspection of cement.

BIS Scheme of Testing and Inspection (BIS-STI): Requirement of Calibration and RMs

All mechanical and chemical test equipment, including balance, sieves, Blaine apparatus, vibrating machine, humidity chamber, compression testing machine, thermometer, data logger, sophisticated chemical testing instruments, glassware, etc., in the laboratory must be calibrated. Casting molds and other appliances are

Table 4 Frequency of inspection and tests for production of hydraulic cement (IS 3535:1986)

Sl. no.	Test	Clinker/pozzolana	Cement grinding	Cement packing
1	Chemical composition	Every day: one composite sample for clinker Every week: one composite sample for pozzolana	Every week: one composite sample	Every week: one composite sample
2	Fineness	Every day: one composite sample (prepared from clinker sample taken hourly)	Every alternate hour: one sample Every day: one composite sample	Every day: one composite sample
3	Setting time	-do-	a. Every hour: one sample b. Every day: one composite sample	-do- –
4	Soundness	-do-	-do-	-do-
5	Compressive strength	-do-	-do-	-do-

Table 5 BIS scheme of testing and inspection for certification of ordinary Portland cement according to IS 269: 2015 (sixth revision)

Sl. no.	Test equipment	Frequency of calibration
1	Blaine apparatus for fineness determination	Every day: with producer's own standard cement sample (working standard) Every month: using NCCBM-supplied standard cement sample (CRM)
2	Compressive strength testing machine for compressive strength determination	Every month: with producer's own proving ring and the ring from ISO/IEC 17025-accredited laboratory or NPL or NPL-accredited proving ring manufacturer (once in 2 years)
3	Autoclave pressure gauge used for volume expansion test	Every month: with producer's own dead weight pressure gauge tester or Every 6 months: from ISO/IEC 17025-accredited laboratory or NPL/NABL-accredited manufacturer of such gauges
4	Vibration machine used for cube casting	Every month: with producer's own tachometer. The tachometer has to be calibrated from ISO 17025-accredited laboratory (once in a year)

required to be periodically checked. As a minimum, BIS Scheme of Testing and Inspection (STI/269/7 2016) for ordinary Portland cement (IS 269 2015) lays down the requirements (Table 5) for equipment calibration. Similar guidelines have been issued for other varieties of cement also. Use of NCCBM standard cement sample is explicitly mentioned for calibration of Blaine air permeability apparatus.

CTM Calibration in Cement Plant Lab

Blaine Apparatus Calibration in Plant Lab

National Council for Cement and Building Materials (NCCBM) was the first organization outside CSIR-NPL to sign a memorandum of understanding (MOU) with NPLI for BND marking of its CRMs, for use in cement and construction sector. BNDs are the primary standards; the metrological traceability of BND is linked to SI units (Kumari et al. 2022). The point is that in the area of reference materials, BND – being approved by NMI – is the first link in the traceability chain and occupies the top spot in the traceability pyramid in India.

Conclusion

World of business works on commonly accepted standards and codes. Any deviation or violation of the accepted standards and codes impacts the quality of measurements and leads to problems at consumer's end and return of consignments. This also results in delays/disruptions and shortages in various parts of the world, and disruptions have a huge economic cost. Therefore, it is important for the countries to work toward self-reliance, upgrade their systems to international levels, and compete. Technically, all countries have to raise the standard of measurements, undertake all test and measurements as per standards and guidelines, and maintain accuracy of measurement results. Results of all calibrations must have evidence of metrological traceability and provide statement of measurement uncertainty, and test results should be reported after ascertaining measurement uncertainty at a given value. Here lies the importance of RMs and CRMs. Self-reliance in terms of production of CRMs is a measure of a nation's technical capabilities and reduces dependence on costly imports. India has a sound accreditation system and national standards authority (BIS), national metrology institute (NMI), and a scheme of BNDs to serve the country's needs. NCCBM, a governmental autonomous body, is playing a pivotal role by contributing in the development of BNDs for cement and construction sector and ensuring the traceability of reference material values. Premier organizations in other sectors of the economy also should come forward and support

the mission of BND development for meeting the country's requirements. Such initiatives should be taken by other countries also for meeting the requirements of CRMs for their respective product standards and competence requirements for RMPs.

Abstract

India and China have a demand for lots of gold and silver due to their age-old customs. Also, purchasing gold and silver is considered an investment. There is a very large market for these metals and due to the unavailability of the proper knowledge and regulation, there is a possibility of rigging in this. Therefore, there is a need for government regulations that these precious metals should be sold only after testing. For testing, one needs standard equipment to calibrate the equipment reference materials. Generally, these reference materials are costly in the international market, and therefore for ease, each nation should produce its own reference materials, which should be comparable to international standards. India has taken an initiative in this direction and registered BND (Bharatiya Nirdeshaka Dravya) as Indian reference materials. In the case of Gold, the first BND was released in collaboration with the Mint, Mumbai, and, currently, 7 BNDs have been released in association with Jalan and Company, New Delhi. This chapter describes the methods and procedures in detail.

Introduction

Precious metals are rare and have a high economic value due to various factors, including their scarcity, use in industrial processes, and role throughout history as a store of value. The most popular precious metals with investors are gold, platinum, and silver (Schoenberger 2011; Grimwade 2009; Barefoot and Van Loon 1999). On average, the Earth's crust contains 11 parts per billion of gold, 70 parts per billion of silver, and 1 part per billion of platinum instead of the abundantly found iron (23,000,000 parts per billion) (ter Haar 1949).

India is the largest consumer of gold, silver, and platinum jewelry, as precious metals are ancient Indian culture(Narang and Singh 2012). The business of jewelry in India is nearly a trillion dollars. Precious metals are easy to handle and craft due to their mechanical properties like malleability, which means they can be deformed, pressed, or rolled into sheets. They possess ductility – the property of being bent, because of which they can quickly be drawn into long wires without fracture (Lee et al. 2003; Yu et al. 2022). A gram of gold can be drawn into a wire 2300 m long. These metals have high optical reflectivity, which is responsible for their attractive luster and sheen. Gold reflects 95%, silver 97%, and platinum 73% of the light incident.

They withstand corrosion and tarnishing by not chemically reacting with their surroundings. They can last for years without diminishing quantity or quality, thus retaining their monetary value (Washbourne 2021). However, metals with similar mechanical properties (but are much more abundant), like copper and the alloy brass (mainly copper and zinc), are not used for jewelry manufacturing.

Global Market

The Global precious metal market was valued at USD 182.1 billion in 2019 and is expected to grow at a compound annual growth rate CAGR of 9.0% in revenue from 2020 to 2027 (Size 2020). Asia-pacific is the primary producer as well as consumer of gold. The metal is significantly consumed in China and India as the precious metal value is determined by finance measurement. Countries have established laws regulating the manufacture and sale of precious metal items to protect the market and consumers.

Therefore, through the Board of Indian Standards, the Government of India has a proposition that gold with a certain purity, 9 karats, 14 karats, 18 karats, 20 karats, 22 karats, and 23-karat, will be available with the jewelers. Another gold purity will not be allowed in the market. Regulation authorities have made the rule mandatory to have a Hallmark on Gold items (Goyal et al. n.d.).

Possible Impurities

The purity of gold is measured in karats. Thus, 14 k gold will be 58.5%, and 10-carat gold will be 41.7% pure. In simple terms, the higher the carat, the higher the gold's purity, and the greater its value (Kinneberg et al. 1998). Sometimes, it becomes confusing as gold comes in various colors, like, rose gold, white gold, and green gold. The variation in color of gold is made by mixing some percentage of other metals like copper (rose gold), platinum (white gold), etc. Similarly, silver has antimony and lead in the majority. Physical examinations are insufficient to determine the item's purity; the supplier provides a purity certificate.

Role of CRMs and Need for BNDs

For a typical person, differentiation in a metal can be made by the corresponding color like gold is yellow, silver and platinum is white. It is challenging to identify the mixing of other low-cost metals/alloys by physical examination. It led to cheating and forgeries in the market, and the customer ended up having a low purity item even paid for higher.

Many standard test procedures were used to define the purity of the specific metals, including sophisticated instruments like X-ray fluorescence (XRF) calibrated with certified reference materials (CRM) (Stankiewicz et al. 1998). India is currently procuring CRMs for various metals at a considerable cost due to additional load freight charges. Suppose the low-cost CRMs at par with the international level can be produced locally. In that case, CRMs can be made available to all the jewelers and mandatory to calibrate their equipment for certification. Therefore, there is a need to make different grades of CRMs for metals like gold, silver, platinum, etc.

Methods/Techniques of Testing Purity and Concentration of Metal

BAM Federal Institute for Materials Research and Testing certified three gold-based reference materials (CRMs) suitable for X-ray fluorescence spectrometry (rose gold, white gold, and yellow gold) (Venkateswaran 2013). The alloying elements' mass fractions, gold, silver, partially copper, nickel, and zinc, were certified. Characterization of the CRMs was performed using wet chemical methods and fire assay.

Gold Purity Testing

There are two methods to determine the purity of gold: destructive and non-destructive. The destructive techniques are fire assays and inductively coupled plasma mass spectrometer (ICP MS). Other methods are not destructive. Among the nondestructive techniques, touchstone and energy dispersive X-ray analysis can only determine the purity of the top surface. The nondestructive method like weighing balance, density meter, or ultrasound can measure bulk properties but cannot tell about the element present as an impurity.

Fire Assay Method

Initially, sampling is done. If the sample is in the ingot or dore bar, then sampling is done by drilling diagonally from the upper and lower side of the sample.

The fire assay method (Singh and Rugged 2012; Hoffman et al. 1998) is carried out per the BIS standard IS 1418:2009. It is a destructive method used for purity determination in gold samples, jewelry, etc. This method has been used for a long time. The cupellation process is used in this method. In the cupellation process, the ore of precious metal, pure silver, and copper are treated at high temperatures in an oxygen environment. At high temperatures, precious metal does not get oxidized. Still, other base metals present in the ore and lead are used for wrapping the precious metal from their metal oxides. These metal oxides, especially lead oxide, are absorbed by the cupel of magnesium oxide/calcium phosphate.

In this method, the known amount of the sample is weighed in triplicate/duplicate. A known amount of pure silver is inquarted in the gold sample to facilitate the parting of the gold by nitric acid. A known amount of pure copper is added to the gold sample to stop spurting during cupellation. To minimize possible systematic errors in the procedure, assaying of standard proof sample is also carried out parallelly.

After weighing all these materials, these are wrapped in known weighted lead foil, and a small ball-type shape is made mechanically with the help of balling pliers. This ball is carefully kept in the cupels and held in a preheated cupellation furnace at 850 °C. The temperature of the cupellation furnace is increased to 1100 °C, and the cupellation

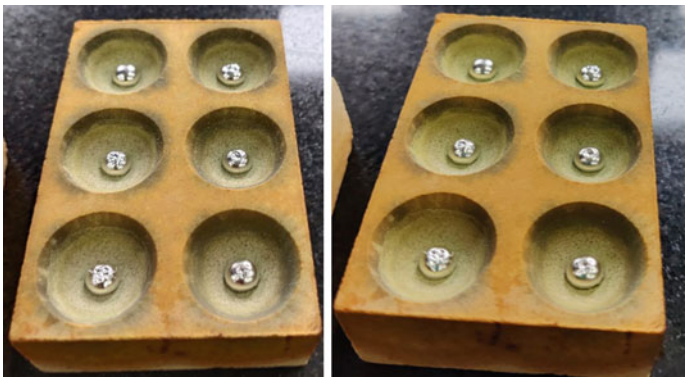

Fig. 1 Gold-silver alloy button in cupel after cupellation process

Fig. 2 Elongated gold-silver alloy fillets after annealing at 800 °C in an annealing tray

at 1100 °C for 30 min is done. In the cupellation process, all the lead gets absorbed by the cupel. After it gets cooled down, a button type shape of a gold-silver alloy is obtained (as shown in Fig. 1).

That button-shaped alloy is cleaned with a soft brush and flattened with the help of a polished hammer. This flattened button is annealed at 700 °C for 5 min in an annealing tray to facilitate the softening of the flattened button. These flattened buttons are again flattened with the help of a rolling mill and made in elongated fillets of approximately 0.2 mm thickness (Fig. 2).

Then this fillet is annealed at 800 °C to facilitate the softening of the fillet. A cornet is made from that soft elongated fillet, and the cornet is kept in the parting tray (Fig. 3). The parting tray is immersed in.

1.2 sp. gr. nitric acid for separating silver from gold by selectively dissolving the silver in nitric acid at 90–95 °C for approximately 30 min or until no more nitrous

Fig. 3 Cornet in small thimbles, which are kept in a parting tray

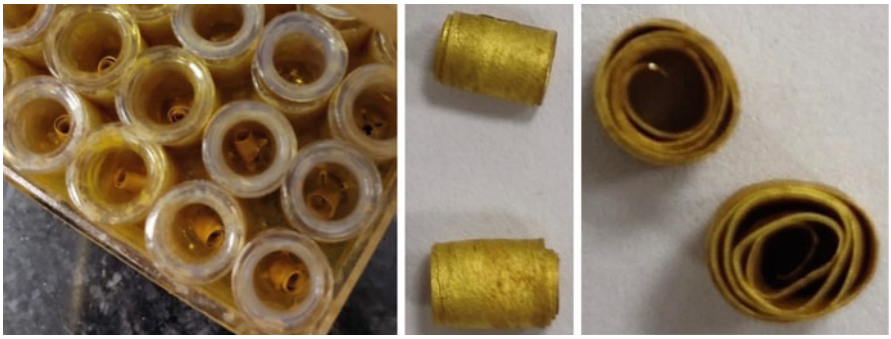

Fig. 4 Cornet in the thimbles after the parting and annealing process

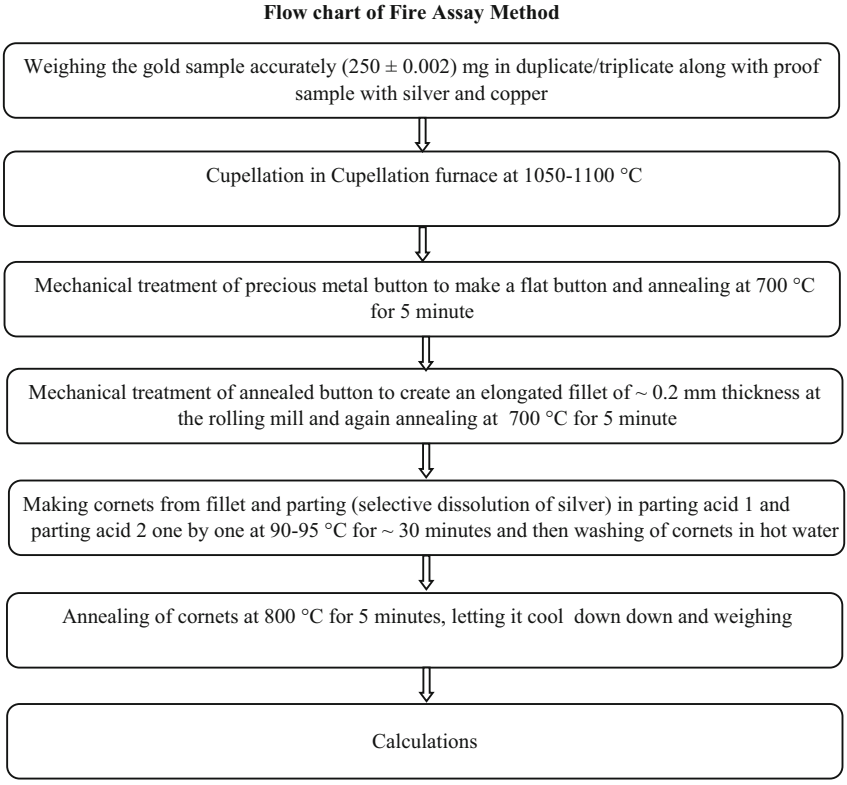
fumes are observed. Then it is washed by immersing the parting tray in hot distilled water. It is dipped in 1.3 specific gravity nitric acid at 90–95 °C for approximately 30 min to refine gold further. Furthermore, it is washed thoroughly to remove all the nitrates. Then the cornet is dried by heating and annealed at 800 °C for 5 min (Fig. 4). Finally, the weight of the cornet is taken.

$$\mathrm{w} = \frac{m_2 + \Delta}{m_1} * 1000 \tag{1}$$

w is the purity of the precious metal in part per thousand (PPT). m_1 and m_2 are the initial and final weights of the test sample

$$\Delta = \frac{\Delta_1 + \Delta_2}{2} \tag{2}$$

Δ_1 = Initial weight of first proof sample – Final weight of the first proof sample
Δ_2 = Initial weight of second proof sample – Final weight of the second proof sample



Gravimetric Method

As described in method (Gee 1877), the gold metal's surface is initially cleaned. Five replicates are taken in separate beakers after washing and drying the known amount of gold (0.2 g). These samples are dissolved in 20 ml aqua regia (3:1 ratio of hydrochloric acid and nitric acid) in 10 ml of de-ionized water. Then these samples are heated on a hot plate to digest samples to make them in syrup-like conditions. Then 5 ml of hydrochloric acid and 50 mL of de-ionized water are added and heated up to boiling. Approximately 10–12 g of hydroxylamine hydrochloride/hydroxyl ammonium chloride was added to digested samples under hot conditions and boiled once again. The golden yellow/ brown color precipitate is formed. After cooling down the precipitate at room temperature, it is filtered through a cleaned, dried, and pre-weighed G-4 crucible. Then the precipitate is dried at 105 °C for 1 h. It is allowed to cool down and be weighed. The weighing of G-4 crucibles before and

after precipitate filtration is carried out at room temperature. The initial and final weight difference of the G-4 crucible gives total gold.

Silver Purity Testing

Gravimetric Method

The method used for silver assaying/testing in silver and silver alloys is carried out per the BIS standard IS 2113:2014 (Nadin et al. 2001). In this method, precious metal or ore of the precious metal is dissolved in nitric acid (Tripathy et al. 2018). Nitrate salt of silver is formed. Silver nitrate remains soluble in acid, and silver is precipitated in silver chloride using hydrochloric acid. Silver chloride precipitate is filtered in a previously weighed sintered glass crucible. Then it is dried at 140 °C for 1 h. Weight of crucible along with AgCl ppt is taken. Then Ag is estimated in the form of AgCl.

Briefly, in this method, a 1.00 g ± 0.01 mg silver alloy sample is weighed in triplicate. These are transferred to a 250 ml beaker. Then 15 ml of nitric acid in a 1:1 ratio is added. The beakers are kept on a hot plate at approximately 100 °C till the samples are completely dissolved. The nitrous fumes are expelled (Fig. 5). Then the beaker is removed from the hot plate, and the solution is diluted with 100 ml of distilled water. Now 20 ml of hydrochloric acid is added with the help of a glass rod continuously stirring to facilitate the precipitation of silver as silver chloride. Again, the beaker is covered with a watch glass, kept on a hot plate, and heated. After 1 h, a few drops of dilute hydrochloric acid (1:9) are added to check the completeness of the precipitation process of silver. Then the beaker is kept on a hot plate for at least 2 h.

The beakers are removed from the hot plate and allowed to cool down (Fig. 6). Then all the content in the beaker is carefully filtered through a previously dried and weighed sintered glass crucible. All the walls of the beaker are washed with distilled water to avoid losses.

Now sintered glass crucible is heated at 140 °C for 1 h in the oven to dry the precipitate. After the crucibles are cooled down, the weight of the crucible is taken.

Fig. 5 Beakers on the hot plate during nitrous fumes expelled

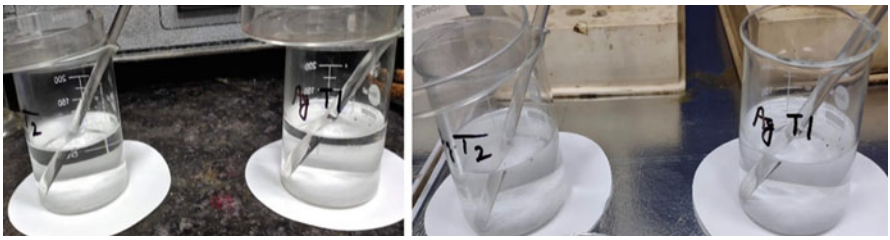


Fig. 6 Precipitation of silver as silver chloride

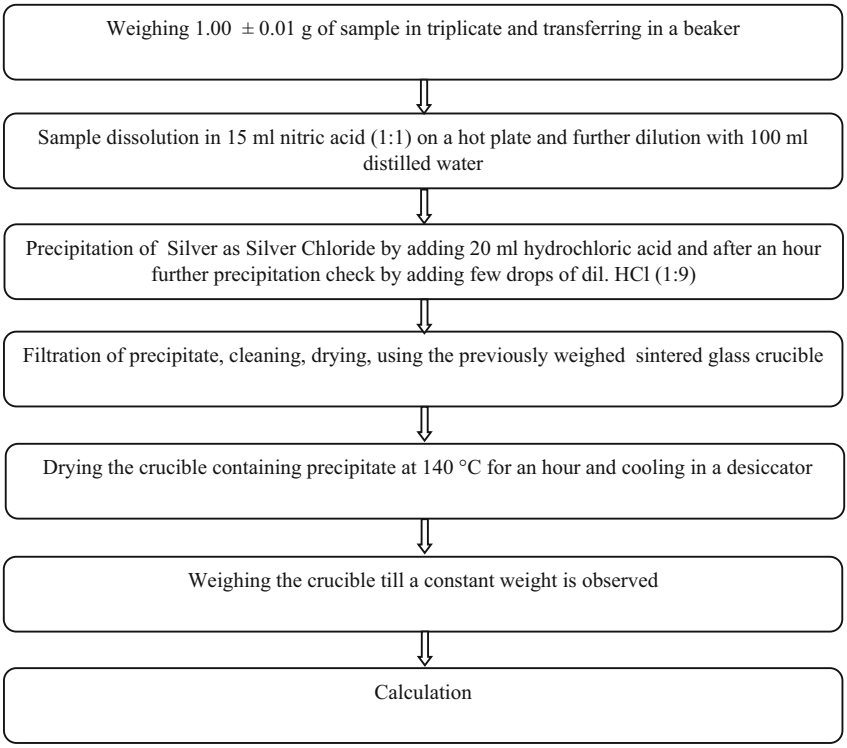
$$\text{Silver (in part per thousand)} = \frac{\text{A} * \text{molar mass of silver} * 1000}{\text{B} * \text{molar mass of silver chloride}} = \frac{\text{A} * 0.7526 * 1000}{\text{B}} \quad (3)$$

A is the weight of silver chloride in g, and B is the weight of the sample in g.

Flow chart of gravimetric method (Silver assay)



Volumetric Method

In this method (Easterbrook 1957), a known amount of the sample is dissolved in nitric acid. This solution is titrated with standard sodium chloride or potassium chloride solution using the potentiometric indication of the endpoint. The silver content is calculated based on consumed standard sodium chloride or standard potassium chloride solution.

Supporting/Secondary Test Methods

X-Ray Fluorescence (XRF)

X-ray is a nondestructive technique for determining the material's qualitative and quantitative composition (Nayak and Singh 2007). X-ray is considered to be the fingerprint of a material. Each element has characteristics of X-ray energy, and depending on the energy, the element can be determined. A quantitative analysis can be done depending on the intensity of the peak. In X-ray fluorescence spectroscopy, a high-energy beam falls on the sample, and X-rays are emitted. X-ray characteristics tell about the element and the intensity of the peak of the concentration of the component. Thus, XRF can give both qualitative and quantitative information about a sample.

Using XRF, samples can be characterized into two modes: wavelength dispersive X-ray fluorescence (WDXRF) and energy dispersive X-ray fluorescence (EDXRF) (Brouwer 2006). There is separate instrumentation for these two. WDXRF has better accuracy than energy-dispersive XRF. However, for practical purposes, EDXRF is considered enough to measure gold purity within the 0.1% range. On the other hand, WDXRF is expensive and requires many operational, installation, and maintenance costs. It also has limitations of chamber volume. Therefore, for general purposes, EDXRF is considered suitable for work related to gold. However, for research purposes, WDXRF can be very good where the purity has to be determined to be very high, like in certified reference material. For certified reference material, the uncertainty in the measurement should be as low as possible; therefore, WDXRF will be more suited.

EDXRF uses a less powerful X-ray source, so the requirement for a water chiller, etc., is not a requirement (Yusoff et al. 2002). Thus, the instrument is cheaper and smaller than the WDXRF, and a reasonable accuracy is achieved. However, the device needs to be calibrated against the known standards.

Recently, using XRF has become common as it is a handheld instrument. It serves several purposes, like (i) checking the concentration of gold, (ii) finding the presence of other elements, and (iii) checking the authenticity of the sample. XRF is used for forensic and pharma purposes also. For the forensic department, it is challenging to know whether a yellow metal is a bar of gold or not! The instrumental technique provides quick and accurate results. The test can be done at several points of a sample. Thus, the composition can be detected in several places. Depending upon the metal and sample, the composition of the top surface of 10–50 micron thickness can be analyzed.

Trace Element Analysis

Platinum group metals in the samples (insoluble in nitric acid) can lead to defects if they are conveniently removed without detection. Other techniques, such as touchstone, partitioning, atomic absorption spectroscopy (AAS), and induction-integrated plasma spectrometry (ICP), are suitable for gold analysis. While some require minute samples, they are destructive techniques, and most require prototyping. Furthermore, except for ICP, these methods do not have sufficient accuracy (Amais et al. 2020).

The most common official method of determining silver is potentiometric titration. It is an extinction technique based on potentiometric monitoring of precipitation of silver chloride (ISO Standard 11,427). Spectroscopic techniques can determine silver, but its solutions are unstable, and the results are not accurate enough.

Flame Atomic Absorption (AA)

The sample is dissolved in aqua regia and absorbed in an acetylene flame. The beam of light travels through the flame at the wavelength of gold. The gold in the sample is the ratio of light to the concentration of the element in the solution. Absorption is compared with standard solutions to determine the concentration of gold in the sample (Tuzen et al. 2008).

Inductively Coupled Plasma-Atomic Emission Spectrometry (ICP-AES)

The aqueous sample is absorbed into the plasma, and the gold in the sample emits light at distinct frequencies (Su et al. 1995). The intensity of light emitted is measured by software with standard gold-bearing solutions. The software then calculates the gold concentration of the sample.

Inductively Coupled Plasma-Mass Spectrometry (ICP-MS)

Gold in aqueous form is ionized. The intensity of the signal at mass 186 is measured, and the signals of any potentially interfering isotopes are measured. Intensity is measured in 186 μ to determine the concentration of gold in the sample and compared to solutions containing standard gold by software (Zhao et al. 2011).

Instrumental Neutron Activation Analysis (INAA)

The residue is extracted from the filter paper and radiated into the center of the nuclear reactor (Miransky et al. 1993). Most elements are radioactive and emit gamma-ray radiation of specific wavelengths. Gold wavelengths are measured and compared to gold standards to determine the concentration of gold in the sample.

Indian Reference Material (Bharatiya Nirdeshak Dravya-BND®)

Various countries are wearing standards and regulations governing gold jewelry manufacture and sale. The difference in the marking system's allowable tolerances and Standards of Finance, among other things with so much variation, makes it easy

to see why international trade in gold jewelry can be hampered by the standards and regulations of individual countries.

India's First 4N pure Gold BND: BND registered 4201 is India's first high purity 99.99% gold reference standard manufactured by CSIR and government mint Mumbai in collaboration with Bhabha Atomic Research Centre BARC Mumbai (Fig. 7a). BND 4201 standard gold bars are 25% cheaper than the imported version. Further, recently high purity gold and gold-alloys BNDs have also been produced by Jalan and company (Fig. 7b). India's high purity silver and silver alloys BNDs have been produced by Jalan and Company in collaboration with CSIR-NPL.

Fig. 7 (**a**) BND 4201: India's first high purity gold reference standard, (**b**)

Gold is very highly respected in Indian and Chinese culture. It is considered very auspicious and an excellent investment for the future. Therefore, it is rare to find how to know the purity of the material necessary.

Future Plans for High Purity Gold and Silver Standard

BND of other purity gold will be prepared in collaboration with the Government of India MINT and Jalan & company. Figure 8 shows a photograph of the new development in this direction. Gold and silver BNDs made in collaboration with Jalan was launched on 4 January 2022 and 20th May 2022.

Certification of Reference Materials and Testing is done based on the relevant ISO guidelines ISO-Guide 34 and ISO-Guide 35 [7.8] and the Guidelines for the Production of BAM Reference Materials (Venelinov and Sahuquillo 2006).

Uncertainty in the measurement was evaluated per the GUM guide, a guide to the expression of uncertainty measurement – JCGM 100: 2008. Uncertainty is a non-negative parameter characterizing the dispersion of the quantity values being attributed to a measurand based on the information used. Measurement uncertainty includes components from the systematic effect, such as components associated with corrections and assigned quantity values.

In general, measurement uncertainty comprises many components. Some of these may be evaluated by Type-A evaluation of measurement uncertainty. It is evaluated

Fig. 8 Photograph depicting the release of gold and silver BNDs made in collaboration with Jalan and Company

based on a statistical analysis of a series of measurements of the quantity value and based on standard deviation. At the same time, Type B evaluation of measurement uncertainty can also be characterized by standard deviations, evaluated from probability density functions based on experience or other information.

Traceability: Property of the result of a measurement or the value of a standard whereby it can be related to stated references, usually national or international standards, through an unbroken chain of comparisons, all having stated uncertainties.

In collaboration with the Jalan and company, CSIR-NPL has produced the following BNDs.

BND 4201A: pure gold 9999 (high purity gold)
BND 4202: gold-alloy 916 (22 karats)
BND 4203: gold-alloy 833 (20 karats)
BND 4204: gold-alloy 750 (18 karats)
BND 4101: pure silver 999
BND 4102: silver-alloy 925

These BNDs will soon be available in the market, allowing jewelers to use instrumental methods rather than the conventional fire essay to ensure the purity of previous precious metal at a low cost compared to the imported.

Conclusions

This chapter described the need for reference materials, and initiatives taken by India. Till now a total of six BNDs have been made in collaboration with the reference material producer, Jalan and company and many more are in the pipeline. These BNDs shall help in reducing the cost of the imported reference materials for calibration of the XRF instrument used for checking the purity of gold and silver.

Acknowledgment PK thanks DST-SERB for the Ramanujan Fellowship grant (SB/S2/RJN-091/2017).

Abstract

Reference materials play a significant role in the calibration of sophisticated instruments. The rapid advancement in science and technology and globalization of economies poses a strong need for more stringent metrological regulations in trade and commerce. For achieving greater heights in application-oriented science, accurate measurements of the requisite quantities are the basic essentials nowadays. It can only be possible by the calibration of corresponding instrument with suitable reference materials. Large numbers of reference materials are produced by various National Metrology Institutes (NMIs) throughout the world. CSIR – National Physical Laboratory (NPL) (NMI of India) is also making Indian reference materials (Bharatiya Nirdeshak Dravyas: BND®) for calibration of numerous sophisticated instruments. The present chapter focuses on the principle and applications of sophisticated instruments like powder X-ray diffraction (PXRD), FTIR, and UV-Vis spectroscopy. We have briefly mentioned about its role for measuring various physical quantities and the importance of calibration by using the Indian Reference Materials (BNDs).

Introduction

Accurate and precise measurement plays an important role in the development of science and technology. The measurement system has always stood as the backbone of a country, which is unnoticed by most of its population. Starting from daily shop to international trading and from laboratories to industries, everywhere proper measurement is one of the key factors for human beings to get better life. The branch of science that deals with the study of measurement is known as metrology. The major work of this branch is to reduce the error or uncertainty of measurements from the true values (BIPM 2017). Measurements are carried out by various scientific instruments to obtain appropriate results for which calibration of those specific instruments are most desirable. Calibration is a process of comparison between true or standard value and measured value obtained by the instrument. In order to acquire accurate measured value, calibration of an instrument with reference

materials is a basic and integral objective for most of the measurements (Koeber et al. 2010; Fanton 2019; de Medeiros Albano and ten Caten 2016; Pradhan and Tarafder 2016). The materials which fulfill the required criterion for calibration of various instruments are known as reference materials (RMs). In simple language RMs can be defined by specific types of materials whose property values are sufficiently homogeneous, stable, and can be used for establishing property value of material. When those reference materials are characterized by a metrological valid procedure for one or more specified properties, accompanied by a certificate that provides the value of the specified property, its associated uncertainty, and a statement of metrological traceability, then they are known as certified reference material (CRM) (de Albano and ten Caten 2014; Rutkowska et al. 2020). Several countries are producing various RMs and CRMs by their National Measurement Institutes (NMIs) for calibration of different instruments. Among them, NIST, USA, is one of the lead producers of RMs whose products are known as standard reference materials (SRMs). The production of RMs and CRMs boosts a countries' economic growth in many ways. Firstly, uses of RMs and CRMs will increase the confidence level of measurements whereas their production will create jobs for the future generations. As the preparation and production of RMs and CRMs are related to the branch of metrology, it will also introduce a new chapter to the education system. It will also helps in boosting the exporting capabilities of a country. From the last few decades, India stood amongst the top countries while importing but fails as one of the top exporter. The main reason of less export is rejection of our products by the other countries due to their quality. The use of RMs and CRMs will increase the quality of products and help in improving exports as well as getting good products while importing. This will lead to exponential growth of the countries' economy and automatically the socioeconomic life of the people will get better (Pauwels et al. 1998; Ihnat and Stoeppler 1990; Linsinger et al. 2001; Kumari et al. 2022). Now India is also producing Indian reference materials (IRMs) for sophisticated instruments calibration and various products by its NMI known as National Physical Laboratory, India (NPLI). These RMs produced by NPLI are known as Indian Reference Materials (IRMs) or Bharatiya Nirdeshak Dravya (*BND*®). The major purpose of producing BND® is to calibrate and increase the quality of products in the country. It will also help in developing the socioeconomic level of India. The information regarding the IRMs for calibration of various sophisticated instruments like PXRD, FTIR, and UV-Visible spectroscopy are discussed in details in forthcoming sections.

Why Calibration?

We are surrounded by measurements at every step of our life. But it is difficult to answer whether the measurements we performed are accurate and precise. In order to overcome such a situation, calibration of instruments is a basic requirement. Calibration helps to reveal the accuracy and confirm the reliability of equipment (Menditto et al. 2007; Stallings and Gillmore 1971; Shehata et al. 2014). There are measurement errors or large deviation of outcomes, so that it is no longer within a specific range. These types of errors in measurements display that there is no assurance of quality. By calibrating the equipment, the deviation in results can be

identified and documented. If the outcomes are out of permissible range, the instrument requires to be regulated. In this procedure, measuring device is calibrated, so that errors of results are reduced and deviations are within the equipment specifications. Hence calibration computes and regulates errors and uncertainties within measurement procedure to a tolerable level. In short, calibration of instruments is equally essential as measurements. It allows customers and trades to have self-assurance in outcomes and quality control of products. It enhances the self-reliance of accurate and precise measurements essential in technology, scientific research, invention, development, manufacture of millions of products and facilities worldwide. This can be understood by taking the following example. In case of any medicinal product, testing results may be wrong if measured through non-calibrated instruments. Consumers taking those medicines may feel sick or get into risk. These types of problems can be avoided by using calibrated instruments with CRMs or RMs. It assures the user and ultimately the consumers that the outcomes are accurate and precise if the instruments are calibrated and hence develops confidence in the consumer or person operating the instruments in getting the correct measurements.

Calibration is very significant in our daily life starting from trade, pharmaceutical, medical, transportation, aerospace, scientific laboratory to academia, etc. One can think what would happen in the trade if measurements are not accurate and precise. Both the buyer and seller will be in confusion regarding the quality of a product and their reasonable share in market. Similarly in the field of pharmaceutical how comfortably will one take medicine if equipment for measurements is not often calibrated. Calibration permits billions of individuals on the earth to take medicine with assertions of safety and effectiveness. The advantages of calibration involve enhanced profitability, revenue, innovation, safety, and cutting cost by decreasing production errors. Calibration of instrument helps to conserve money by avoiding untruthful acceptance and refusal of goods and by extending the lifetime of fabricating devices. Calibration is imperative as it supports to keep the world proficiently running, progressive, and secure.

Role of Reference Materials

The science of measurements plays a key character for growth engine and constant evolution of industries. The correctness of measurements during performance of analysis and control laboratories is crucial for operation of current society. Now academia, research laboratories, and industries are focusing on quality assurance, quality control, and traceability of outcomes. Reference materials (RMs) play a significant role in these consequences. RMs can be defined as those substances that are key factors in maintaining a healthy measurement system and to get very precise value (White 2011; Shehata et al. 2019). These stable substances with steady homogeneous property value, which can be used for calibration of an instrument, are known as reference materials (RMs). RMs can be in pure form or a mixture of gas, solid, or liquid. RMs are useful to validate and control the analytical procedure. Recently, RMs have become more crucial as quality desires have been turned sterner with customer requirements for suitably verified and controlled the outcomes.

In our daily life, we deal with measurements, which are also essential for modern science and technology. Precise measurements are the most important to have business with foreign countries. The comparable measurements are tested, measured, internationally accepted, and inevitable to improve the quality life of users and the social-economic growth of society through unobstructed trade. If the observed measurements are inaccurate, it will lead to critical consequences. So it is important to develop reference standards for satisfactory quality in research and development activities for various instruments. In order to calibrate these high-tech instruments, the certified reference materials (CRMs) are required. CRMs are commonly used for calibration of measuring instruments and validation of outcomes from these calibrated instruments. It also helps to evaluate measurement procedure and finally provide a quantity value with a corresponding uncertainty value of measurement results. The use of CRMs in measurements is an essential need for worldwide approval of products and test statements in the current situation of globalization of economy (Rutkowska et al. 2020). Now assurance of high quality in measurements and traceability to the analytical measurements with international measurement system (SI unit) can be confirmed using these CRMs.

Why Need of Indian Reference Materials?

There are some trade barriers due to differences attached with measurement data. These mismatches arise due to instruments without calibration. As mentioned above, the calibration of the instrument is done by some reference materials. If a nation does not have reference materials, it will be difficult to assure the quality of products for import/export. Then it will import these standards. It will affect the socioeconomic fiber of the nation. In this regard, NPLI is producing Indian reference materials (IRMs) with association of some specified reference materials producers (RMPs) by following the stern guidelines of ISO17025 and ISO 17034 & 35. Indian Reference Material or Bharatiya Nirdeshak Dravya (BND®) is the trademark of certified reference material (CRM) developed by NPLI. IRMs play crucial role in the industrial and scientific development by providing consistency and comparability of the measurements for the quality assurance (Trapmann et al. 2017; Ashwal 2020; Aswal 2020; Velichko 2010). IRMs are employed for calibration of equipment, allocation of property value of other CRMs, and validation of analytical procedure.

The production of IRMs will support the government for making India a developed country. The aim of the BND® program is upgradation of the socioeconomic growth of the nation through quality assurance of products for import, export, and by providing resourceful job opportunity. BNDs/IRMs are the core of scientific, academia, research, and industrial development by ascertaining quality assurance and controls in measurements.

National Physical Laboratory, India (NPLI) is devotedly involved in preparation of BNDs/IRMs with association of medium and large industries. NPLI has already worked on BNDs for drinking water, petroleum products, building materials, gold, powder X-ray diffractometer, etc. As every field is associated with complex

instruments, calibration of instrument is possible using RMs. So now the most important task is to develop IRMs. If IRMs are not available for any imported goods for long time then we will not be able to check the quality of goods or it may expire. So keeping in mind the significant role and requirement of IRMs for the nation, NPLI has initiated its mission mode program on development of IRMs in numerous fields. Now importance of BND® activity at national level will definitely bring a vast change in the socio-economic status through assurance and quality control for import/export and domestic costumer products in all the fields.

Powder X-Ray Diffractometer (PXRD) and Its Applications

There are numerous instruments available for various material characterizations. Most of the instruments need to be calibrated before being used in order to get a precise result. Among all the available characterization technique, a very well-known technique, i.e., powder X-ray diffraction technique is vastly used in research laboratories, academia, and industries across the world. In the following section, the importance of powder X-ray diffractometer (PXRD) and the effect of calibration on this instrument are explained in detail (Das et al. 2014; Mo and Zhang 1995; Polizzi et al. 1991). Also the various RMs used in PXRD for calibration of different parameters is discussed in the forthcoming section.

PXRD is one of the oldest and powerful techniques for characterizing various materials. The identification of phase, quantitative analysis, lattice dimensions, structural imperfections, and particle size of sample from various disciplines like polymeric, environmental, geology, pharmaceutical, and forensic sciences are measured using this tool (Upadhyayula et al. 2009; Sharma et al. 2012; Das et al. 2014). It is employed for identification and characterization of unknown minerals, inorganic compound, etc. The basic assumption of powder diffraction is that for every set of planes, there are statistically relevant numbers of crystallites that are properly oriented to diffract the incident beam. The recorded diffraction pattern is the characteristic of any crystalline phase. The intensity, position, shapes, and width of diffraction lines provide information about the specimen. Powder diffraction data comprises a record of photon intensity versus detector angle 2θ. The following information can be determined using XRD patterns as given in Table 1:

Working Principal of PXRD Instrument

The basic principle on which a PXRD instrument works is Bragg's law. This law suggests that atoms present in the crystal structure form an imaginary plane. When X-ray falls on the atoms, it diffracts, but from Bragg's law it is interpreted as "When X-ray is diffracted from atoms, it appears such as reflecting from an imaginary plane." The constructive interference between two X-ray beams occurs if

Table 1 Information about different parameters by PXRD

Information from PXRD	Detailed parameters
Unit cell lattice dimensions and Bravais lattice symmetry	1. Index peak positions 2. Lattice parameters may vary and so giving information about alloying, strains, solid solutions, doping, etc.
Phase composition of a specimen	1. Quantitative phase analysis can govern the relative quantity of phases in a mixture by referencing relative peak intensities
Residual strain (macro-strain) and Crystallite size and micro-strain	1. Indicated by peak broadening 2. Other defects (stacking faults, etc.) can be evaluated by investigation of peak shapes and peak width

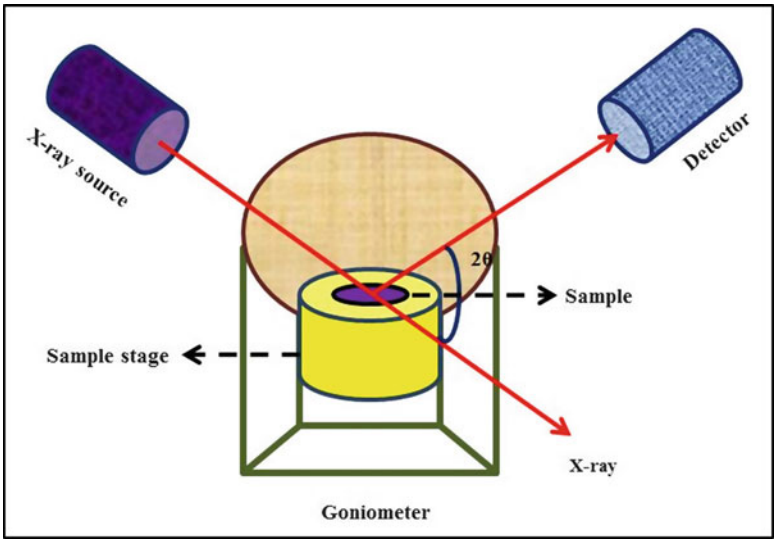

Fig. 1 Schematic diagram of powder X-ray diffractometer

$$2d\sin\theta = n\lambda \tag{1}$$

Where "d" is lattice spacing between two planes, "θ" is angle of incidence of X-ray, "n" is order of diffraction and "λ" is wavelength of X-ray (Mendenhall et al. 2015; Chauhan and Chauhan 2014). This law is valid for most of the X-ray diffraction-based instruments like Single crystal X-ray diffraction, X-ray Fluorescence, etc.

Basically, PXRD consists of three major sections, i.e., source, goniometer, and detector. The schematic diagram for a PXRD is shown in Fig. 1. Mainly a source is an X-ray tube with copper as source material. A goniometer is a sample stage where sample is spun or fixed as per requirement. The detector portion is primarily a scintillation counter detector to detect the diffracted X-ray photons. When the

sample is fixed on sample stage of a goniometer and X-ray is allowed to fall on it with making an angle θ, it gets diffracted from atoms, ions, or molecules present in sample in every possible directions. Now the detector is rotated through an angle "2θ" by Bragg-Brentano geometry and detects the constructive diffracted ray satisfying Bragg's law in Eq. (1). The fingerprint of the material is obtained on a computer screen as a graph between 2θ and Intensity (No. of photons counts) in X and Y axis, respectively.

As we are living in an instrumental world, there might be possibilities of getting error while measurements are carried out. This can be explained by taking a simple demonstration. Let us consider a case, where some instrumental defects in PXRD are giving some random errors in XRD pattern of a sample. It will lead to produce unnecessary confusion in material characterizations. Specifically if we want to detect one specific material say "X," the result might give the sign of other material say "Y" due to that instrumental defect. Similarly there might be several other possible errors caused by the observer while carrying out some experiments. These issues in an instrument can be avoided if the XRD fingerprint of sample is already known. It will allow us to identify whether the XRD is working properly or not. In order to fulfill such requirements, the instrument should be calibrated with some CRMs. As all the property values of CRMs are already known, the instrument should give exactly same known results for proper working condition. There are several advantages of calibrating an instrument. One of the major advantages for research and development department of country is that "the experimental data produced by the instrument will be internationally accepted." This will increase the impact of R and D and scientific research of the country.

Indian Reference Materials (IRMs) for PXRD

X-ray diffractometer has various applications in the field of academia and research, material sciences, pharmaceutical, forensic sciences, microelectronics, polymer glass industries, etc. It is a significant method for material characterization. (Bunaciu et al. 2015; National Institute of Standards and Technology Certificate Standard Reference Material® 640f Line Position and Line Shape Standard for Powder Diffraction (Silicon Powder)). PXRD has seen an enlarged relevance in the area of mineral science and mineral process optimization. With this, powder methods have advantages to determine new polymorphic forms. The XRD technique can be employed to measure lattice dimensions, identify impurities, detect phases, and analyze mixtures of polymorphs. Every single application shows a particular challenge with regard to the development of reference materials. Accuracy is crucial for d spacing (2θ line position), line shape, intensity, and full width half maxima. But it is affected by many instrumental factors like axial divergence, sample-displacement error, step size, deviation in X-ray wavelength, and due to some specimen factors. A conventional method to acquire accurate and precise measurement is calibration of instrument. Calibration can be performed by certified reference materials. In recent decades, enormous numbers of certified reference materials are being developed for

different parameters like line position (2θ), line shape, intensity, quantitative phase analysis, full width half maxima, etc. CSIR-NPL is working on the development of such Indian reference materials, which is described in the following sections.

Reference Materials for Calibration of Various Parameters in PXRD

Line Position Calibration with "Si" Powder

The fingerprint of PXRD pattern of a sample is identified by a graph between 2θ and intensity. Now the line position can be calibrated with the help of SRM "Si (640f)," which is stable cubic structured material (National Institute of Standards and Technology Certificate Standard Reference Material® 640f Line Position and Line Shape Standard for Powder Diffraction (Silicon Powder)). In order to calibrate PXRD instrument, experiment is performed on the CRMs and the certified values are compared. If observed results are not matching with the certified results then experimental conditions will be modified till obtaining the certified one. CSIR-NPL is also working on "Si" to develop it as its own certified IRM, which will be cost effective. This will help in boosting the economy of our country.

Line Shape Calibration with LaB_6 Powder

The peak profile analysis (PPA) in X-ray diffraction is a usual calculation procedure in powder diffraction. The presence of diffraction peaks broadening in a PXRD is primarily due to contribution of instrumental and sample broadening. The instrumental broadening produces unnecessary misinformation about the sample. Thus instrumental broadening in PPA for a PXRD instrument should be identified. This issue can be resolved by the use of SRM 660c, i.e., LaB_6. SRM 660c holds a peculiar property, i.e., absence of size and strain-induced broadening. LaB_6 also preserves regularly spaced, non-overlapping, and high intense diffraction peaks whose FWHM is a quadratic function of 2θ. It shows distinct diffraction peaks in this material. These features make the material prepared for calibration of line shape. Hence, values of lattice parameters are given in the certificate for calibration of instrument (National Institute of Standards and Technology Certificate Standard Reference Material® 660a Lanthanum Hexaboride Powder Line Position and Line Shape Standard for Powder Diffraction; Cline 1994). CSIR-NPL is also working on this material to develop it as a cost effective IRM.

Quantitative Analysis with α-Alumina

Quantitative analysis in PXRD instrument determines the crystalline phase purity in the sample, i.e., the amount of amorphous and crystalline content in the sample can be identified by this analysis. SRMs 676a α-alumina is used as an internal standard for quantitative analysis calibration in PXRD instrument (National Institute of Standards and Technology Certificate Standard Reference Material® 676a Alumina Powder (Quantitative Analysis Powder Diffraction Standard)). NPLI has already developed its own cost-effective certified reference material α-alumina for quantitative analysis.

Calibration of Infrared (FT-IR) Spectrophotometer Using BND®2004

Fourier Transform Infrared (FT-IR) Spectrophotometer and Its Applications

Infrared (IR) spectrophotometer has become an important analytical technique finding applications in each and every area of materials characterization and scientific research. Fourier transform infrared (FT-IR) spectrophotometer provides the analysis of molecules in electromagnetic spectrum falling between visible and microwave regions. The most useful range of analysis falls in the range of 4000–400 cm^{-1}. This technique reveals various fundamental facets of materials in many areas such as chemical, pharmaceutical, analytical, biomedical, food industries, etc. Indeed, FT-IR measurement is very fast, eco-friendly, simple, user-friendly, repeatable, and requires very small number of materials. The molecular FT-IR is based on Michaelson interferometer and also known as interferometric infrared spectroscopy. Except for enantiomers, no two molecules can give the same IR spectrum. The technique offers both qualitative and quantitative measurements of materials by simple inspections and using standards, respectively, and therefore is widely used for quality control and ensuring the quality of the final products. FT-IR spectroscopy is used in various industries to provide quality control, like in pharmaceutical field (for medicines), biomedical area (for protein, vitamin, lipids, starch, uric acid, etc.), and food industry (water, spirit, honey, oil, nut, flours, flakes, meat, rice, drinks, etc.).

The Working Principle

FT-IR spectroscopy measures the interaction between matter and electromagnetic fields in IR region at a molecular and atomic level. IR radiation absorbed by the molecules, especially organic molecules, is converted into energy of molecular vibrations, which itself is accompanied by several rotational energy changes. These vibrational-rotational energy changes occur between 4000 cm^{-1} and 400 cm^{-1} and is captured and presented by FT-IR spectrophotometer. The frequency or wavelength of absorption depends on the relative mass of atoms, force constant of the bonds, and geometry of the atoms. The position of the bands in IR spectrum is presented in wavenumber (ν) with a unit in cm^{-1} while the band intensity can be presented in transmittance (T) or absorbance (A). Only the vibrations that result in rhythmic change of molecule's dipole moment are observed in IR spectrum. The assignments of the bands can be approximated by application of Hook's law mentioned in the equation given below-

$$\nu = \frac{1}{2\pi c}\left[\frac{f}{(M_x M_y)/(M_x + M_y)}\right]^{\frac{1}{2}} \tag{2}$$

FT-IR spectrophotometer can be used for characterization of gases, liquids, and solids. Gases are characterized by expansion in evacuated cells. Liquids may be tested in neat or in solution transparent in region of interest. Solids are characterized as mull, pressed disks, or *as*-deposited glassy films.

Calibration of FT-IR Instrument and Reference Standard

The FT-IR instrument is one of the main tools for characterization, identification, inspection, counterfeit detection, and quality control, and therefore, a reference standard for calibration of FT-IR spectrophotometer is required (Lowry et al. 2000). Indian Pharmacopoeia commission (IPC) and other country's Pharmacopoeia like British Pharmacopoeia and the US Pharmacopoeia, etc., have set standards for all the drugs that are manufactured, sold, and consumed in that particular country. The resolution standards are defined for particular wavenumbers. The validation of FT-IR instrument performance is based on five tests, i.e., power spectrum, resolution, wavenumber accuracy, wavenumber repeatability, and absorbance reproducibility. The reference standard is used for the calibration of FT-IR instrument and validation of its performance. There are different reference standards for calibration of wavenumber accuracy, FT-IR instrument's photometric linearity, diffuse reflectance in NIR, Mid IR and UV regions, reflectance, NIR wavelength standard, ATR reference standard, etc.

For preparation of reference standard, researchers have realized the requirement of stable material with characteristic peaks covering the wide range of IR region. In this direction, a number of molecules, polymers, and materials were tested to be used as reference materials. Among all, polystyrene was the most suitable in terms of stability and suitable peaks position for calibration. Generally, polystyrene and its films are used in different applications such as in rigid food service containers, CD cases, appliance housings, envelope windows, automobile body panels, photoluminescence, and many other products. Polystyrene is the most employed aromatic thermoplastic polymer synthesized from the polymerization of styrene monomer and has been found to be used as reference standard on preparation of standard films as per ISO Guide 35 with high accuracy.

Material Preparation

Polystyrene (PS) films are used as reference standard for calibration of wavenumber/wavelength in IR range. Styrene monomer of high quality is used for polymerization either by thermal or catalyzed reaction to produce amorphous polystyrene polymer (Fig. 2). The produced polystyrene may be of different grades, like rubber modified high impact polystyrene (HIPS), Medium impact polystyrene (MIPS), general purpose polystyrene (GPPS), and expandable polystyrene (EPS). GPPS is highly used due to its clear appearance, rigidity, and multipurpose applications (Wackerly and Dunne 2017). MIPS is used for high flexibility and HIPS is applied where high

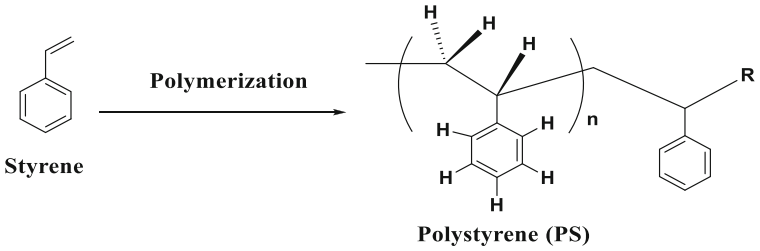

Fig. 2 Polymerization of styrene for the synthesis of polystyrene

impact resistance is required. EPS shows the insulating behavior. The modification of polystyrene is performed by addition of plasticizers, release agents, and stabilizers to achieve the desired properties. For specific applications, other additives like flame retardants, colorants, UV stabilizers, and impact modifiers are added to the formulation. The relative stereochemical relationship of consecutive phenyl groups determines the tacticity, which has an effect on various physical properties of the material.

Polystyrene is transformed into different products. One of the most important applications of polystyrene in science field is the preparation of polystyrene film for calibration of FT-IR spectrophotometer. In this regard, the National Institute of Standards and Technology (NIST), USA developed a reference material for calibration of wavelength/wavenumber scale of spectrophotometer in IR spectral region with the trade name "SRM 1921b." This reference standard and derived certified reference material (CRM) are most widely used across the world and therefore also imported in India for calibrating the wavenumber scale of spectrophotometers on the IR region. There is urgency for India to get self-reliant in calibration reference standards so that dependency on a foreign country is completely removed. CSIR-NPL, which is also the NMI of India maintains the primary standard for the International System (SI) units and provides traceability of many parameters for calibration. CSIR-NPL developed polystyrene-based reference standard for calibration of wavelength values of FT-IR spectrophotometers in the region from 4000 cm^{-1} to 400 cm^{-1} with the trade name BND® 2004. The developed BND® 2004 is comparable to other reference standards being used for peak position, absorption/transmittance, stability, thickness, uncertainty range, etc. The indigenous development of FT-IR standard (BND®2004) saves a huge amount of foreign exchange by replacing the purchase of SRM1921b from NIST and other imported IR standards.

Indian Reference Material BND®2004

FT-IR spectrophotometer operates on different measurement methods, such as diffuse reflection method and attenuated total reflectance. In diffuse reflection method, a sample holder is used to place the sample between IR source and detector. The beam passes through the sample and the transmitted energy of the IR radiation is

measured and presented in the form of either percentage transmittance or absorbance spectrum. For calibration of FT-IR instrument, BND®2004 is used, which is a matte-finished polystyrene film with a thickness of 38 (±2) μm placed in the center of a cardholder. CSIR-NPL has developed the reference standard by a cost-effective in-house method. During the development of the films, special care is taken to avoid any kind of impurity or dust getting added. A batch of ~100 films is prepared and characterized by calibrated FT-IR spectrophotometer by randomly picking 25–30 films. The films should exhibit the clear peaks of standard polystyrene with good resolution. The homogeneity of the films has been checked thoroughly by statistical method measuring at five different positions of a 25 mm diameter to detect any impurity or interferences due to undetected problems during preparation. Ideally there is a difference in peak position, the intensity from one point to other should be negligible, and the film is called highly homogeneous with respect to given characteristics. The stability of the film is also measured as per ISO Guide 35. There are two types of stability to be considered in reference materials, one is long-term stability of the material and the other is short-term stability. Long-term stability is estimated by repeated measurements as time elapses determining the lifetime of reference material. Short-term stability is recorded at different temperatures providing the information for the appropriate storage conditions and transport conditions.

The process developed by CSIR-NPL is simple, fast, and cost-effective as there is no requirement for costly and sophisticated equipment. The precursor materials are required with a specific molecular weight range, polydispersity, and high purity. The process used is hot press method at a specific temperature with pressure using special metal plates to obtain matte-finish roughness. The developed films are of uniform thickness and stable under appropriate storage conditions. This is an eco-friendly process and low capital cost is required to set up the facility. The advantages of the process are requirement of a small amount of precursor, no wastage of materials, no side product formation, and no disposal are required. The product film is a matte finished polystyrene film (38 ± 2) μm thick with a ~ 32 mm diameter and > 80% transmittance (Fig. 3). The thickness of the films is tested by stylus profiler.

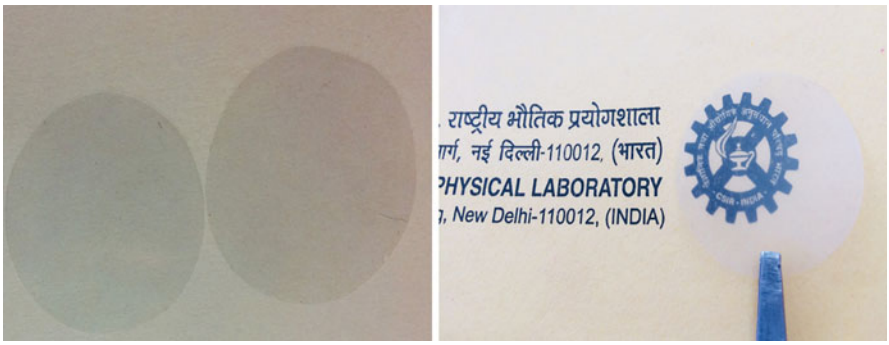

Fig. 3 Photograph of polystyrene films and transparency

The characteristic FT-IR peaks of BND®2004 is shown in percentage transmittance (%T) (Fig. 4) and absorbance (Fig. 5). The specific 14 peaks positions considered for calibration are summarized in Table 2. The peaks cover the full range and peak positions are used for calibration. Pharmacopoeia defines the differences between the absorbance at the absorption minimum of 2870 cm^{-1} and the absorption maximum of 2849.5 cm^{-1} peak is to be >0.33 or > 18 in %T. The difference between the absorbance at the absorption minimum of 1589 cm^{-1} and the absorption maximum at 1583 cm^{-1} is to be >0.08 or > 10 in %T (Figs. 5 and 6). BND®2004 complies with all the requirements and is being sold in India for calibration of FT-IR equipment.

Ultraviolet-Visible (UV-Vis) Spectroscopy and Its Applications

Spectroscopy is a general methodology that can be adapted in many ways to extract the information we need (energies of electronic, vibrational, rotational states; structure and symmetry of molecules; dynamic information) and to understand how light interacts with matter and how one can use this to quantitatively understand the sample.

Ultraviolet-Visible (UV-Vis) spectrophotometry is based on the absorption of the electromagnetic spectrum in the ultraviolet and visible region (Skoog et al.). It measures the amount of discrete UV/visible light wavelengths absorbed/transmitted through a sample and provides potential information about the composition and

concentration of the sample. UV-Vis spectroscopy technique has broad aspects in science, ranging from identification and quantification of organic compounds, bacterial culture, and quality control in the beverage industry, drug identification, and chemical research.

It works on the principle of Beer-Lambert Law, which establishes a relationship between attenuation of light through the sample. It states that "*the quantity of light absorbed by a substance dissolved in a fully transmitting solvent is directly proportional to the concentration of the substance and the path length of the light through the solution*."

Mathematically,

$$A = \log\left(\frac{I_0}{I_t}\right) = \varepsilon cl \tag{3}$$

Also,

$$T = \frac{I_t}{I_0} \tag{4}$$

where,

A = Absorbance
c = Concentration
l = Path length of sample cell
ε = Extinction coefficient
T = Transmittance
I_t = Intensity of transmitted light
I_0 = Intensity of incident light

The instrument comprises light source (deuterium or tungsten lamp), monochromator, sample holder, and detector. There are typically three basic designs for UV-Vis spectrophotometer – single beam, double beam, and simultaneous type instrument. The single-beam instrument (Fig. 7a) analyses one wavelength at a time using a filter or a monochromator between the source and the sample. The double-beam instrument (Fig. 7b) comprises a light source, a monochromator, a splitter, and a series of mirrors. The arrangement of splitter and mirrors split the beam between the reference sample and the sample to be analyzed, allowing more accurate measurements. On the other hand, the simultaneous instrument (Fig. 7c) does not have any monochromator; instead, a diode array detector is used, which allows the instrument to detect the absorbance at all wavelengths simultaneously. The simultaneous instrument is usually much faster and more efficient.

UV-Vis spectroscopy relies on the absorption of UV/Visible light of the electromagnetic spectrum by the analyte. Specific energy is required for electron transition

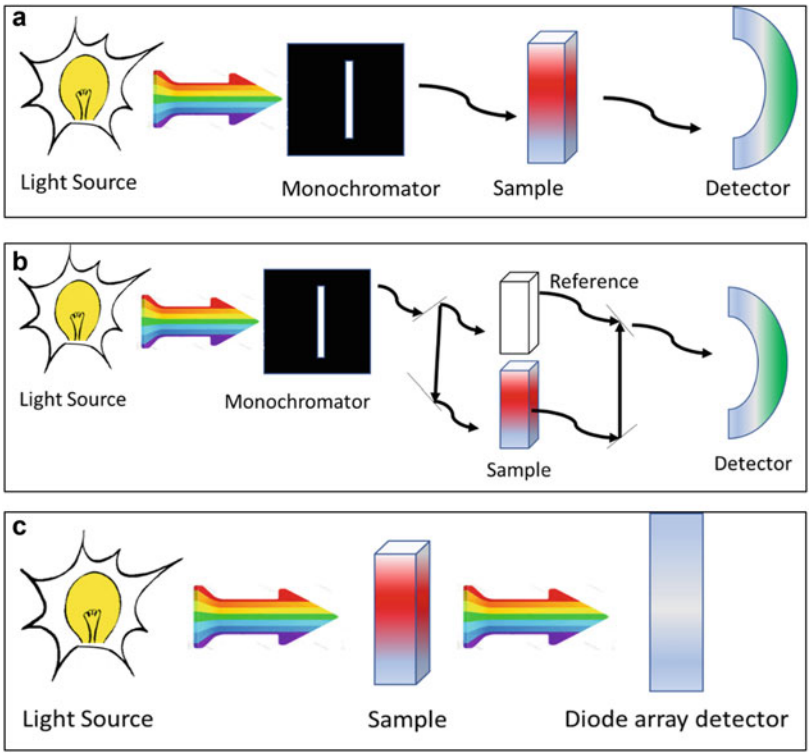

Fig. 7 (**a**) Schematic of single beam UV-Vis instrument. (**b**) Schematic of a double-beam UV-Vis instrument. (**c**) Schematic of a simultaneous UV-Vis instrument

from lower to higher energy levels and results in absorption spectra. Electrons in different bonding environments require different energies for transition to higher states; therefore, absorption occurs at different wavelengths for different materials. The UV-Vis region corresponding to the wavelength range of 800–200 nm of electromagnetic spectrum covers energy in the range of 1.5–6.2 eV.

Electronic transitions resulting from the absorption of electromagnetic radiations in the ultraviolet and visible ranges form the basis for quantitative analysis of compounds. These electronic transitions mainly occur from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO) on radiation absorption with energy equivalent to the energy difference between the excited and the ground states. Valence electrons in most of the molecules can be found in one of the following orbitals listed in ascending order of their energy levels: σ (bonding) orbital $<$ π (bonding) orbital $<$ n (non-bonding) orbitals. The unoccupied high-energy orbitals are π^* (anti-bonding) orbital and σ^* (anti-bonding). The possible transitions (Figs. 8 and 9) that occur in most of the organic molecules are

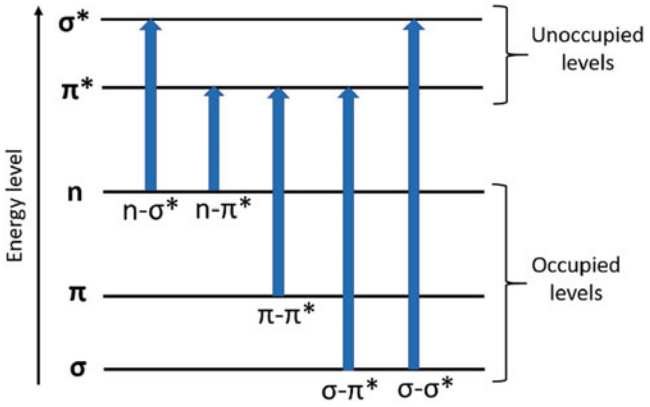

Fig. 8 Electronic transitions and their energy levels

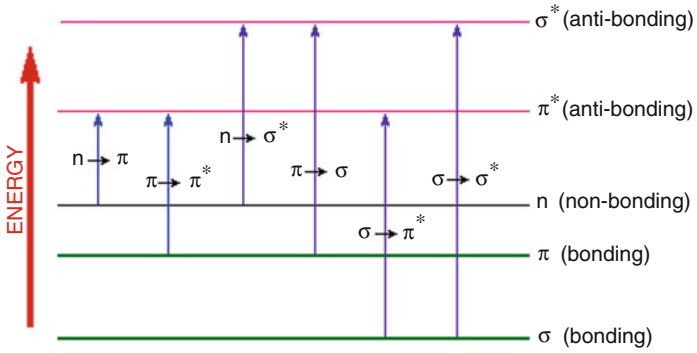

Fig. 9 Schematic of possible transition

σ−σ*, σ−π*, π−π*, n−σ*, n−π*. The σ−σ* transition that occurs only in alkanes requires very high energy, which does not fall in the UV-Vis region. The energy for the rest of the transitions falls in the UV-Vis region and gives rise to a band spectrum due to superimposed vibrational and rotational levels in molecules (Pavia et al. 2001). The electronic transitions that precisely lie in the visible region belong to the d-d transitions or the charge transfer phenomenon occurring in transition metal complexes and are responsible for their characteristic color (Lee 1999).

σ → σ* transition: This type of transition is observed with saturated compounds, e.g., methane (CH_4), which has a C-H bond only, undergoes σ → σ* transition having absorbance maxima at 125 nm.

π → π* transition: Such transitions are observed in compounds containing multiple bonds like alkenes, alkynes, nitriles, carbonyl, aromatic compounds, and show absorbance in the region 170–205 nm.

n → σ* transition: Such transitions are observed in saturated compounds containing atoms with lone pair of electrons like O, N, S, and Halogens and show absorbance in the 150–250 nm region.

n → π* transition: Compounds containing double bonds involving heteroatoms (C=O, C ≡ N, N=O) show that such transitions have absorption at a longer wavelength around 300 nm.

σ → π* transition and π → σ* transition: Such electronic transitions are forbidden transitions and are only theoretically possible.

The UV visible spectrometer different components present in the UV-Vis spectrophotometer are as follows:

Source of Light

UV-Vis spectrophotometer is a light-based technique that essentially requires a steady and wide range of wavelengths source. A high-intensity single Xenon lamp is most commonly used as a light source for both UV and visible ranges. However, such lamps are comparatively costlier and are less stable compared to tungsten and halogen lamps. Some instruments are based on two lamps, tungsten or halogen lamp, commonly used for visible light and a deuterium lamp as a UV light source. For the whole range scan, i.e., UV to the visible region, there is a switchover between the light sources, which typically occurs during the scan between 300 and 350 nm. Here the light emission is similar from both light sources, which results in a smooth transition.

Wavelength Selection

A suitable wavelength of light must be selected from the broad wavelength light source for the sample analysis. There are certain available methods for the selection of wavelength and are discussed below:

- **Monochromator**: The desired wavelength of light is achieved by rotating diffraction grating by tuning the incoming and reflected angles of light. The groove frequency of diffraction grating defines the optical resolution. The higher the groove frequency, the better will be the optical resolution and the narrower the usable wavelength range. Typically, 300–2000 grooves per mm are being used in gratings for UV Vis spectroscopy. On the other hand, a prism disperses the radiation into different wavelengths according to the respective refractive index. It provides the different wavelengths at different angles allowing for the selection of specific wavelengths. The dispersion is linear in the

case of grating, whereas it is nonlinear for prism, making it advantageous to use grating over a prism.

- **Absorption filters**: Absorption filters are generally colored glasses or plastics designed to absorb specific wavelengths of light.
- **Interference filters**: These are also known as dichroic filters, made of many dielectric material layers, which cause light interference between thin layers of materials. Such filters eliminate undesirable wavelengths by destructive interference and act as a wavelength selector.
- **Cut-off filters**: Such filters allow light either below (short pass) or above (long pass) specific wavelength to pass through.
- **Band pass filters**: Band pass filters allow a range of wavelengths to pass through for the analysis of the sample
  The filters are often used with monochromators to narrow down the wavelengths of light for more accurate and precise measurements and improve the signal-to-noise ratio.

Sample Holder

The sample is placed between the light source and the detector. In double-beam spectrophotometers, a reference sample holder is used for baseline correction and considered as the "blank sample." The liquid samples are placed in cuvettes of different path lengths depending on the sample's characteristics. Most plastic and glass cuvettes are inappropriate for UV absorption studies as plastics generally absorb UV light, and glass can act as a filter. Therefore, a quartz sample holder is generally preferred to identify sample signatures in the UV region.

Detectors

In UV-Vis spectrophotometers, photoelectric coatings or semiconductor-based detectors are generally used, which convert the light into a readable electronic signal as light passes through the sample.

On exposure to light, a photoelectric coating ejects negatively charged electrons, which generate electric current proportional to the light intensity. A photomultiplier tube (PMT) is the most commonly used detector in UV-Vis spectroscopy. A PMT can generate a larger electric current by sequential multiplication of the ejected electrons; therefore, it is useful for detecting very low light signal levels (Amelio 1974).

On the other hand, an electric current proportional to the light intensity is generated in semiconductor detectors when exposed to light. Photodiodes and charge-coupled devices (CCDs) (Tauc and Grigorovici 1966) are two of the most common detectors based on semiconductor technology.

Applications

Pharmaceutical Analysis

UV-Vis spectroscopy provides spatially and temporally resolved absorbance measurements, which are highly useful in pharmaceutical analysis. It provides real-time monitoring of drugs and drug release kinetics of sustained-release drug formulations, along with quantitative and qualitative analysis. Many drug molecules contain chromophores that absorb specific wavelengths of ultraviolet or visible light; also, the concentration of constituents in drug molecules can be estimated using the Beer-Lambert law, where the absorption of spectra generated from these samples at given wavelengths can be related directly to the concentration of the sample.

Food Analysis

Food is mainly comprised of water, fat, proteins, and carbohydrates together with numerous other components. The functional properties of such components, governed by their molecular structure and their intra−/intermolecular interactions, define the characteristics of food products. The demand for high quality and safety in food production requires high quality and process control standards, which requires appropriate analytical tools to investigate the food. UV-Vis spectroscopy is an important, flexible, widespread analytical method primarily used in the food industry for quality control of food and beverages. It allows the identification of the origin and the detection of adulteration, among other vital characteristics in food products that plays a crucial role in examining the quality of edible oils.

Identification of Unknown Sample

The absorption spectra of a particular compound are unique. A data bank of UV spectra can be used to determine an unknown compound.

Qualitative and Quantitative Analysis

UV-Vis spectroscopy is commonly used in analytical chemistry for the quantitative and qualitative analysis of various analytes, such as transition metal ions, conjugated organic compounds, and biological macromolecules. Mainly absorption in organic compounds is observed due to chromophores, which usually contain π (unsaturated) bonds. When such chromophores are inserted into a saturated hydrocarbon (which exhibits no UV-visible absorbance spectrum), it produces a compound with absorption between 185 nm and 1000 nm. Some of the most common chromophores and its corresponding maximum absorption are given in Table 3.

Table 3 List of common chromophores and their absorbance maxima

Selected chromophores and their absorbance maxima			
Chromophore	Formula	Example	Imax (nm)
Carbonyl (ketone)	RR'C=O	Acetone	271
Carbonyl (aldehyde)	RHC=O	Acetaldehyde	293
Carboxyl	RCOOH	Acetic acid	204
Amide	RCONH2	Acetamide	208
Nitro	RNO2	Nitromethane	271

Concentration Determination

UV-Vis is a fast and reliable method to determine the concentration of an analyte in a solution. Beer-Lambert law establishes a linear relationship between absorbance, the concentration of absorbing species in the solution, and the path length as given in Eq. (3). UV-Vis spectroscopy is an effective technique for determining the concentration of the absorbing species for a fixed path length.

Bandgap Estimation

The optical band gap estimation in semiconducting materials is crucial for many optoelectronic applications. To this end, UV-Vis spectroscopy offers an easy and appropriate method of estimating the optical band gap as it explores electronic transitions between the valence band and the conduction band.

The optical band gap can be estimated using the following two methods

Method 1:

Bandgap energy,

$$E_g = \frac{hc}{\lambda} \tag{5}$$

where $h = 6.626 \times 10^{-34}$ Js

and $c = 3 \times 10^8$ m/s

$$E = \frac{1.24 \times 10^6}{\lambda} \text{eV}, (\lambda \text{ in m}) \tag{6}$$

Method 2:

The energy band gap of a given material can be more precisely calculated using the Tauc (Amendola 2017) plot method as given below.

$$\alpha = \frac{A\left(h\nu - E_g\right)^n}{h\nu} \tag{7}$$

Rearranging the above equation,

$$(\alpha h\nu)^{1/n} = A^{1/n} h\nu - A^{1/n} E_g \tag{8}$$

where

$$\alpha = \frac{\ln(1/T)}{x}$$

α = Absorption coefficient
T = Transmittance
x = Thickness of the sample
E_g = Bandgap of the material
n = 2, 1/2, for direct allowed and indirect allowed transitions, respectively.

By plotting the graph of $(\alpha\, h\nu)^{1/n}$ vs. $h\nu$, we will get slope as $A^{1/n}$ and y-intercept as $A^{1/n}E_g$. Dividing y-intercept by A^n, the band gap can be estimated.

Size Determination in Metal and Metal Oxide

Among metal nanoparticles, gold nanoparticles (AuNP) have been studied in detail because of their extraordinary optical properties due to surface plasmon resonance (SPR). The size of concentration of AuNP determines the optical, electrical, and chemical properties of AuNPs. UV-Visible spectroscopy has proved to be an excellent tool in identifying the concentration and size of the AuNPs.

Mie (Haiss et al. 2007), in 1908, presented a solution for the calculation of extinction and scattering efficiencies of small metal particles. Later, Heiss et al. (Chauhan and Chauhan 2014), using Mie theory, have developed methods to calculate the particle diameter (d) of gold nanoparticles ranging 3–120 nm using UV-Vis spectra. They derived the analytical relations between the extinction efficiency (Qext) and particle diameter (d), which further determines the particle concentration (c). The particle diameter is given by:

$$d = \frac{\ln\left(\frac{\lambda_{spr} - \lambda_0}{L_1}\right)}{L_2} \tag{9}$$

where d is diameter, λ_{spr} is peak value, L_1 and L_2 are fit parameters, and λ_0 is the experimental value. The average of the absolute error in calculating the experimentally observed particle diameters was observed only 3% for the fit parameters determined from the theoretical values for d $>$ 25 nm ($\lambda_0 = 512$; $L_1 = 6.53$; $L_2 = 0.0216$); therefore, Eq. 9 allows a precise determination of d in the range of 35–110 nm (Brus 1987).

Size Determination in Semiconductor Nanoparticles

Many theoretical models were proposed to give a quantitative agreement of dependencies of energy bandgap (E_g) on the crystal size (R) with the experimental data for a wide range of semiconductors. Brus Model (Bunaciu et al. 2015) (i.e., the effective mass approximation) is the most used theoretical model for the experimental data analysis of energy bandgap E_g (R) dependencies. According to this model, the bandgap of semiconductor nanoparticles (considered as a sphere with radius R) is given by:

$$E_g(R) = E_y(\text{Bulk}) + \frac{h^2}{8m_0R^2}\left(\frac{1}{m_e^*} + \frac{1}{m_h^*}\right) - \frac{1.8e^2}{\varepsilon_0\varepsilon_r R} - 0.248\frac{4\Pi^2 e^2 m_0}{2(4\pi\varepsilon_0\varepsilon_r)\left(\frac{1}{m_e^*} + \frac{1}{m_h^*}\right)} \tag{10}$$

where,

E_g = bulk band gap value
h = plank's constant
m_0 = electron mass
m_e^* and m_h^* = electron and hole relative effective mass, respectively
e = electron charge
ε_0 = permittivity of vacuum
ε_r = relative dielectric constant of the semiconductor

The bandgap shift with respect to the bulk value is given as

$$\Delta E_g = \frac{h^2}{8m_0R^2}\left(\frac{1}{m_e^*} + \frac{1}{m_h^*}\right) - \frac{1.8e^2}{\varepsilon_0\varepsilon_r R} - 0.248\frac{4\Pi^2 e^2 m_0}{2(4\pi\varepsilon_0\varepsilon_r)\left(\frac{1}{m_e^*} + \frac{1}{m_h^*}\right)} \tag{11}$$

The first term is referred to as the quantum localization term or the kinetic energy term, which shifts the $E_g(R)$ to higher energies proportionally to $1/R^2$.

The second term results from the screened Coulomb interaction between the electron and hole, which shifts the $E_g(R)$ to lower energy as $1/R$.

The third is a size-independent term related to the salvation energy loss. This term is usually small and can be ignored.

Instrument Calibration

Ultraviolet-Visible (UV-Vis) spectrophotometry is routinely used in academics and industrial settings like the food and pharmaceutical industry to analyze compounds for quality assurance and testing. Any form of critical evaluation, whether in clinical

Table 4 List of RM and CRM for calibration of UV-Visible spectroscopy (source www.starna.com)

Parameter	Available reference material	Range (nm)

	Benzene vapor	230–270
Resolution (derivative)	Toluene in methanol	265–270

biochemistry, environmental research, food, and beverages, etc., essentially demands the accuracy of results depending on the instrument's performance. A regular performance testing of UV-Vis spectrophotometers under standard operating procedures is a prerequisite to ensure the proper functioning of the equipment and meet the required benchmarks of standardization. The UV-Vis spectrophotometer must be routinely calibrated for absorbance, wavelength accuracy, stray light, and resolution using RMs or CRMs as listed in Table 4.

CSIR-National Physical Laboratory, India (NPLI) has recently started indigenous development certified reference materials (CRMs) under the registered trade name of Bharatiya Nirdeshak Dravya (BND®) for the calibration of UV-Vis spectrophotometer as most of the CRMS are being imported. The absorbance calibration CRM BND®2021 is already available, and wavelength calibration standard BND®2022 is under preparation.

Conclusions

This book chapter explains about the importance of measurements, calibration, RMs and CRMs in metrology. Especially, the vital role of Indian Reference Materials in uplifting the socioeconomic life is elaborately discussed. Further, the chapter highlights the role of CSIR-NPL, India to enrich the economy of the country by

producing IRMs. The calibration and its importance on a few of the sophisticated instruments like PXRD, FTIR, and UV-visible spectrometer by using various RMs, CRMs, and especially IRMs are elaborately discussed. It emphasizes that calibrated instrument can produce more accurate results with minimum uncertainty than non-calibrated one. In case of PXRD there are several measuring parameters, which are calibrated using different RMs. Si, LaB_6, and α-alumina are few of them used to calibrate line position, line shape, and quantitative analyses in PXRD. Similarly, polystyrene is used to calibrate FTIR spectrometer. The details of all absorption peaks of polystyrene present in IR region are also given in this chapter. The process of calibration of FTIR using polystyrene is also described, which suggests calibration increase the confidence level in the measurement results of FTIR. Similarly, the working principle, applications, and its calibration using various RMs and CRMs are explained to demonstrate the significance of reference materials and calibration in sophisticated instruments. Also, the importance of the role of RMs, CRMs, and IRMs for calibration of instruments, the role of IRMs in uplifting India's economy and its effects are deliberated in this chapter. Till date, all the certified reference materials are procured from other countries with very high cost. Not only the cost and they need to procure it again and again after the validity of the reference material is expired. Thus, there is huge recurring loss of natural resource. Also we are procuring so many materials, products, and sophisticated instruments, and many times we get substandard products and we have certified calibration facility to check it. When the developed countries procure products from other countries, they send their representative and check the quality before importing it. Even some of the major existing industries in India are taking the traceability or reference materials from abroad at huge cost. Developed certified reference materials traceable to SI unit (BNDs) at CSIR-NPL and any RMPs will bring a paradigm shift in the socioeconomic fabric of the country through quality control assurance for export, import, and domestic consumer products in every sector.

Abstract

The importance of using certified reference material (CRM) for qualifying materials is identified at various levels in biological evaluations as prescribed by international standards like ISO, ASTM, USP, etc. The initiatives under quality management systems and regulatory controls in employing CRMs increase the reliability and acceptance of biocompatibility evaluations leading to safe clinical

use of medical devices. This chapter explores the possibilities and challenges for the routine use of CRMs in the biocompatibility evaluation of materials and medical devices.

Keywords

Reference material · Negative control · Positive control · Biological evaluation · Cytotoxicity · Implantation · Certified Reference Materials

Introduction

Medical devices can be any instrument, apparatus, machine, appliance, implant, and reagent for in vitro use or in vivo use that are intended to be used, alone or in combination, for addressing medical requirements of humans. When a device or material performs with an appropriate host response in its specific application, it is said to have biocompatibility. In medical device development, a set of appropriate physicochemical and biological evaluations are devised to establish biocompatibility.

Devices with proper design and development phases within a regulatory framework ascertain their success in clinical use. A work platform contained within international standard ISO 13485: Medical devices – Quality management systems – Requirements for regulatory purposes definitely paves guidelines for getting regulatory approvals of a developing device. ISO 14971: Medical devices – Application of risk management to medical devices is applicable in identifying hazards and estimating risk at different device development stages from the design phase onwards. Special care in the selection of raw materials and the use of material additives are having much relevance in medical device development concerning biocompatibility. Impurities in raw material or residues of trace elements from the manufacturing process or residues of disinfection agents, etc. may cause undesirable effects in the clinical performance of the final product.

By definition "any substance or combination of substances, other than drugs, synthetic or natural in origin, which can be used for any period of time, which augments or replaces partially or fully any tissue, organ or function of the body, to maintain or improve the quality of life of the individual" is identified as a biomaterial (Bergmann and S. A. 2013). In biocompatibility evaluations, the performance of the biomaterials including chemical, toxicological, physical, electrical, morphological, and mechanical properties will get characterized and established (ISO10993-1; 2018). The use of qualified biomaterial with proven safety and efficacy is of at most importance with respect to its functionality in the human physiological environment. Although critical performance analysis in preclinical evaluations can control the risk elements of such materials and devices, the databases of regulatory authorities report a considerable number of complications and adverse events annually. The main factors that challenge the process of biomaterial evaluation for qualifying them for medical use are non-uniformity in regulations, the difference in material development, and methods of their evaluation, preconceived post-marketing data, the cost

involved, etc. For clinical acceptance, established biocompatibility characteristics through documented material evaluations matrix within risk-based quality management platform is very essential. The selection of strategies for evaluating biomaterials could be performed wisely to address the regulatory requirements (Masaeli and Tayebi 2019). Qualifying biomaterials to meet regulatory requirements insist traceability to international standards in physicochemical characterization and biological evaluations. The use of appropriate certified reference material (CRM) is identified as one of the key elements to address this requirement.

International Standards for Biological Evaluations: ISO 10993

The international standard ISO 10993 is formulated for the safe use of medical devices or biomaterials considering the potential biological risks arising from their clinical use. These standards can guide in biocompatibility studies or biological evaluations which are meant for assessing the fitness without any harmful physiological effects (Ratner et al. 2013).

In risk-based thinking for medical device development, it is important to conduct appropriate research and experiments on each component material prior to use. According to ISO 10993, a reference material (RM) is defined as material with one or more property values that are sufficiently reproducible and well established to enable the use of the material or substance for the calibration of an apparatus, the assessment of a measurement method, or for the assignment of values to materials (ISO10993-5 2009.). The use of an RM will facilitate the comparability of the response between laboratories and help assess the reproducibility of the test performance within individual laboratories. Properly characterized control materials designated as RMs are recognized as the integral part of any biocompatibility evaluations by optimizing quantity and cost for in vitro tests, in vivo tests, and animal experiments. Materials used as RMs shall be characterized specifically for the biological evaluation for which the use of the material is desired (Joseph et al. 2009) .

Biomaterial Classification and Selection of RMs

Selection of the material is the principal criteria for the proper functioning of any medical device. Any corrections in device design cannot improve device performance if the material is not compatible. Anticipated anatomical position and physiological conditions of in vivo or in vitro use determine what material should be used in the development of a device. Lightweight polymer or ceramic materials may be selected for cochlear and dental prostheses, whereas for total hip replacements and total knee replacements, mechanical properties of metallic devices are considered beneficial. Devices like artificial heart valves used in blood circulation may be composed of different components made of metals, ceramics, and/or polymers to achieve the required functionality (Navarro et al. 2008).

According to the site of application, requirements on material characteristic properties may vary. A smooth surface finish of a metallic heart valve may not be

appropriate for the osseointegration of metallic screws used in orthopedic applications (Vayalappil et al. 2016). In such cases, the engineering design of devices is governed by the compliance of material properties with the end-user requirements. Apart from the physicochemical properties, biological response or reactivity of the material of choice will be the deciding factor in designing medical devices. These properties have to be characterized by evaluating responses to appropriate test methods like cell culture studies, animal implantation studies, etc.

The characterization process should address the identification of hazards in the usage of medical devices, arising from variations with the manufacturing process, or risks caused by various factors like insufficient control of the manufacturing process, variation in concentration of additives, and impurities in raw materials. Such screening evaluations in accordance with ISO 14971 can be performed with test samples of device materials.

The ISO 10993 standard allows the selection of characterization matrix based on end- use of materials. By following the matrix, biomaterials may get qualified through a series of suitable biological evaluations. Cytotoxicity evaluation is the preliminary screening test widely employed in medical device development. The individual biomaterial components are exposed independently to a monolayer of cells and the morphological changes to the cells if any will be microscopically scored (Fig. 1). The results will be compared with positive and negative reference material.

Experimental controls are used in biological evaluations to either validate evaluations or compare the results between materials, thereby qualifying the material for end-use. As per the specifications of evaluation methodology employed, experimental controls negative and/or positive controls shall be used. RMs when used as experimental controls in biomaterial evaluations should be of the same class as that of the test material, i.e., polymer, ceramic, metal, etc.

Metals

Mechanical properties of metals make them preferable biomaterials for load-bearing applications and are used in supporting or replacing strenuous activities that need

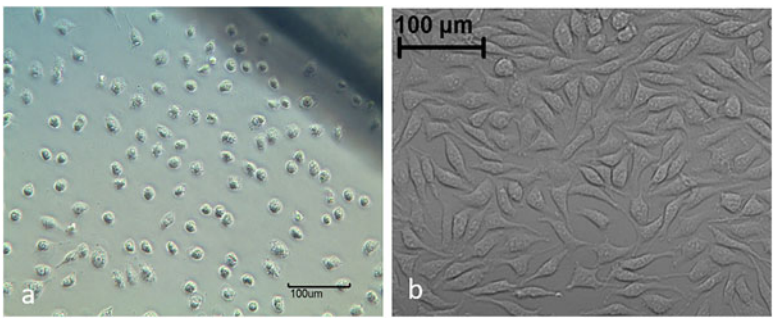

Fig. 1 (**a**) L929 cells around PVC-based RM material with positive reactivity. (**b**) With negative control; viable cells in proximity of the sample

sufficient fatigue strength. When used for orthopedic applications, they must have corrosion resistance, have excellent wear resistance, and need to support osseointegration. When used in vascular systems, they should not cause hemolysis. They have to be nontoxic and should not cause any inflammatory or allergic reactions in the human body. Improvement in the biocompatibility of materials is achieved by alloying pure metals, modifying material surfaces using different treatment methods, or providing coating, etc. Stainless steel 316 L, cobalt-chromium alloys (CoCrMo), titanium and its alloys (Ti-6Al-4 V), dental amalgams, gold, etc. were generally used in medical device development in the early days of biomaterial applications (Gad 2017). With time, biomedical researchers preferred more biocompatible metal alloys and corrosion and wear resistant than pure metals. In the early 1970s, titanium alloys become popular in medical device development due to their excellent specific strength, lower modulus, superior tissue compatibility, and higher corrosion resistance (Dowson 1992). CP Ti-commercially pure titanium-ASTM F67 was the first of its kind, with its natural oxide layer formation which had excellent osseointegration properties; that is, human bone cells bonded and grew on the titanium oxide layer quite effectively. But with low mechanical strength, its usage was limited in specific applications like hip prosthesis, dental implants, heart valves components, etc. Even though with a better performance of Ti-6Al-4 V, its usage is restricted by the presence of vanadium that causes cytotoxicity and other adverse tissue reactions in clinical use. Thus only a few of the alloying elements are identified as not to cause any harmful reactions when implanted inside the human body and having sufficient mechanical strength and machinability. Examples of such alloys are titanium, molybdenum, niobium, tantalum, zirconium, iron, and tin (Nag and Banerjee 2012).

In the recent past, Nitinol, shape memory and super elastic NiTi alloy, is being extensively used in vascular stents and various other applications such as orthopedic fixation devices. They are discovered by William J Buehler and his co-workers in 1963 in the Naval Ordnance Lab (NOL), and hence more commonly known as "Nitinol" where "Niti" stands for nickel-titanium and "Nol" stands for Naval Ordnance Lab (NOL), USA. It is a titanium-based inter-metallic material. Nitinol contains an equal amount of nickel and titanium and shows shape memory with super elastic properties due to thermoplastic martensitic transformation (Shabalovskaya and Van Humbeeck 2008).

Ideally, all biomaterials, whether stainless steel, Co-Cr alloys, titanium alloys, or Nitinol, should remain biocompatible under varying mechanical and electrochemical human physiological conditions. Studies report that a certain degree of toxicity resulting from the release of nickel ions into the human body is associated with the use of Nitinol (Oshida et al. 1990). This concern on Nitinol use has stimulated serious research on its surface modifications and coatings (Wadood 2016). Advancements in metallurgy and manufacturing technologies spur innovations in design and diversification in implantation material. Three-dimensional (3-D) printing technologies are being widely utilized to meet customized patient care needs in shapes and geometries using a variety of metals.

Fig. 2 An example of metallic reference material

Metallic Reference Materials

To satisfy regulatory criteria in a risk management platform, materials have to go through multiple biocompatibility evaluation matrices like cytotoxicity; sensitization; irritation or intracutaneous reactivity; acute, subchronic, and chronic systemic toxicity; material-mediated pyrogenicity; genotoxicity; implantation; hemocompatibility (hemolysis, complement activation, thrombosis); carcinogenicity; reproductive or developmental toxicity; and biodegradation (for absorbable materials). In such evaluations, the probable adverse effects at the local site of biomaterial or distant target tissues were validated with the use of appropriate RMs as positive or negative controls (USFDA 2019). RMs can be developed, qualified, and certified from appropriate commercially available materials according to the biological characterization procedure for which the CRM is to be produced.

ISO 10993-Part 12 suggests negative controls RMs of metallic materials made of stainless steel, cobalt/chromium alloys, and commercially pure (CP) titanium alloys (Fig. 2). In preclinical animal implantation studies, considering animal welfare and ethics, the use of positive controls are not recommended.

Polymers

Polymers, based on their origin, are classified as natural polymers, modified natural polymers, and synthetic polymers and are used widely in medical devices by altering the composition or physical properties such as molecular weight, polydispersity, crystalline, and thermal transitions. Most of the natural polymers are present in the tissues of living organisms; and they seem to be more biocompatible compared to synthetic polymers. But with less mechanical strength and rapid degradation characteristics, their use in modified forms is preferred for many applications. Unlike natural polymers, custom-made synthetic polymers can offer reproducibility of medical devices without any concern on disease transmission. Possibilities of designing and modification of biocompatibility parameters according to end-use make them more attractive. Synthetic polymers are the preferred choice of biomaterial because of their tailored properties and tuneable synthesis procedures. Natural polymers, including collagen, gelatin, chitosan, and synthetic polymers like poly(lactic acid) (PLA), poly(glycolic acid) (PGA), and polycaprolactone(PCL), are used in tissue regeneration applications (Ouchi and Ohya

2004; Puskas et al. 2004). Thus biocompatible polymers can directly be used in device development or used as a coating to minimize the chances of rejection when it comes in contact with the body. Advancements in technologies with shape memory materials, biodegradable polymers, tissue engineering, and coronary stents are some of the areas in which polymers find application (Isabel Cristina Celerino de Moraes Porto. 2012).

In tissue engineering (TE) applications, polymeric biomaterials are widely used for preparing scaffolds that provide the structural support for cell attachment and subsequent tissue development and growth. Additive manufacturing (AM) otherwise known as 3-D (three-dimensional) printing is the general method of scaffold preparation. In additive manufacturing, precise control of scaffold characteristics like porosity, pore size, pore connectivity, and internal flow channels that are vital for good scaffold function is possible with polymeric materials (Leong and Chua 2014). It is confirmed that tissue engineering requires artificial scaffolds with physicochemical, mechanical, and biocompatibility properties mimicking natural extracellular matrix (ECM) without causing immunological reactions and should degrade in a controlled manner with non-toxic products that can be excreted through metabolism. Specific additives to promote the formation of new tissues may be incorporated in the scaffold preparation. Since polymers own highly flexible design capability, their properties can be easily tailored to meet specific requirements by controlling their chemical compositions and structures (Shi et al. 2016).

Polymeric Reference Materials

Polymeric materials may contain traces of low-molecular-weight chemical substances such as catalysts, polymerization agents, or other additives, monomers, or oligomers.

Such toxicity leachable from polymer can migrate to the human tissues during use. In this scenario, any residue from the manufacturing processes, intentional or unintentional additives or contaminants, that may get integrated into biomaterials may have undesired performance of medical devices. The suitability of material can be assessed at different grades of biological reactivity like none, slight, mild, moderate, severe, etc. CRMs with certified properties can be used to compare and qualify biomaterials using (1) negative control RMs for reactivity "none" and (2) positive control RMs for reactivity's such as "slight," "mild," "moderate," or "severe." Polyethylene and silicon are the commonly used negative control materials, whereas PVC (polyvinylchloride), PU (polyurethane), natural rubber latex, Genapol X-080, etc. are used as positive controls (Fig. 3). Possible hazards derived from materials could be screened out when it is being evaluated against control RMs whose characteristic properties are well established.

Ceramics

Ceramic biomaterials otherwise called bioceramics are suitable for orthopedic and dental applications to support hard or soft tissue. Their mechanical and osseointegration characteristics and microstructure like grain size and porosity

Fig. 3 An example of polymer reference material. (Positive control material made of PVC)

make them suitable for medical device development. Generally, bioceramics can be grouped into bio-inert or bioactive materials. The bio-inert materials with their corrosion resistance, high wear resistance, and high mechanical resistance do not elicit adverse reactions with the surrounding tissue. Such properties are appropriate for orthopedic applications involving articulation and implantation sites subjected to loads and friction (Brunette et al. 2001).

Bioactive ceramics are materials whose surface characteristics contribute to bone-bonding ability or enhance new tissue formation. The bioactive ceramics are again categorized as resorbable or non-resorbable materials. At the interface of resorbable type implant material and the tissues, time-dependent changes are expected to support or restore the physiological functionality (Ducheyne and Q. 1999). In bone tissue engineering, defects are filled with appropriate mechanically strong bioceramic materials that could initiate bone growth. Such materials could get degraded in the growth rate of newly forming bone tissues (Gao et al. 2017). Physical forms of ceramics may be varied either in porous or dense bulk forms according to their molecular arrangement. Based on end- use, materials in the form of granules or coatings can be used (Huang 2007).

Aluminum oxides, calcium aluminates, titanium oxides, calcium phosphates, carbon, bioglass, etc. are the commonly used bioceramics. Alumina and zirconia belonging to the group of bio-inert ceramics and calcium phosphates, bioactive glasses, glass-ceramics, etc. are examples of bioactive ceramics. The presence of a wide range of oxides is common in bioactive ceramics. Crystalline hydroxyapatite is a bioceramic that has similar mineral properties to human hard tissues (Saenz and Rivera-Muñoz 1999).

Ceramic Reference Materials

The standard procedure for qualifying biocompatibility evaluations involves in vitro cell culture experiments, as a low-cost first step before going for in vivo use. But for ensuring the appropriateness of the biomaterials; researchers have to investigate and confirm the capability of biomaterials to stimulate or enhance tissue regeneration in preclinical in vivo conditions. The selection of RMs both negative and positive control RMs, to compare the cellular response, is therefore critical and essential (Wu 2009). The importance of using validated positive controls with well-known cytotoxicity is provided in relevant international standards for medical device evaluations. Commercially available latex is one example of a positive control

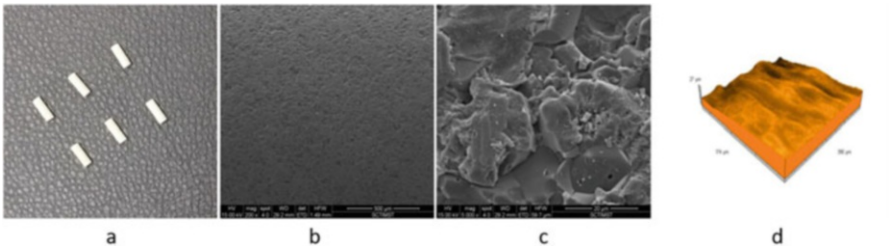

Fig. 4 (**a**) Ceramic reference materials (alumina), (**b**) and (**c**) SEM images of alumina RM at 200× and 5000× magnification, (**d**) surface profile of ceramic RM (alumina) – (imaged with Talysurf 1000)

used in in vitro testing (Lourenço et al. 2015). Even though biological evaluations and toxicity concerns are well understood, the selection of control materials for bioceramics is not defined with clarity (Thrivikraman and Basu 2014). According to research publications available, polymeric RM materials are widely used as control materials in the case of bioceramics also. Addressing the RM needs for ceramic biomaterials is an area that needs to be defined and established further (Fig. 4).

Evaluation Matrices and Methods of Evaluation

The products/materials intended for human application have to be thoroughly checked for their safety and efficacy before clinical translation. Devices have to get regulatory approval in both safety and efficacy terms with human safety being the primary concern for the regulators. Safety aspects can be considered only in comparative terms. Every device carries a certain amount of risk and could initiate complications in specific situations. The current approach to device safety is to estimate the potential of a device becoming a hazard that could result in safety problems and assessment of this harm or risk versus benefit.

The International Organization for Standardization (ISO) has produced a document (ISO 14971: 2019) providing the medical device manufacturers with a framework including risk analysis, risk evaluation, and risk control for risk management in medical device design, development, manufacturing, as well as monitoring the safety and performance of the device after marketing (ISO14971 2019). The standards specify that the evaluation strategies should follow a risk assessment-based approach for the safety clearance of biomaterials and medical devices. Device developers should identify all the possible risks associated with the usage of the intended medical device. There are a lot of processes involved in the manufacturing of medical devices (Fig. 5). At each stage, the potential factors compromising biocompatibility have to be identified. The extent of risk has to be estimated, and appropriate management strategies have to be adopted to mitigate or eliminate risk to the least extent possible to get regulatory approval. In this context, the selection of evaluation methodologies requires much attention.

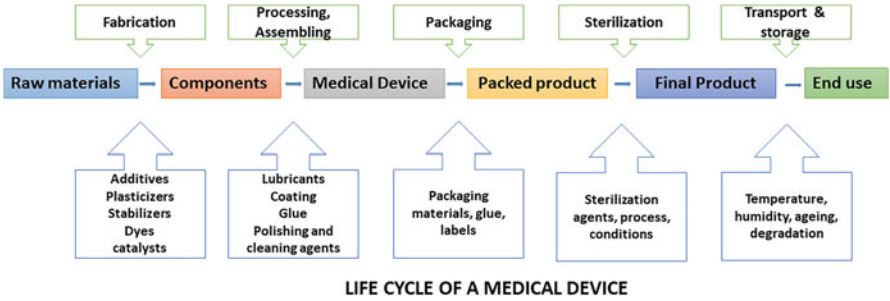

Fig. 5 Factors influencing the biocompatibility of a medical device

Table 1 Potential biological hazards encountered in a medical device development

Short-term effects	Long-term/specific effects
Acute toxicity	Sub chronic toxicity
Skin irritation	Chronic toxicity
Eye irritation	Sensitization
Mucosal irritation	Genotoxicity
Sensitization	Carcinogenicity/tumorogenicity
Hemolysis	Teratogenicity
Thrombosis	

ISO 10993, Part 1, is the primary horizontal standard for biological safety evaluation. It provides a framework to plan the biological evaluation of medical devices, selection of appropriate in vivo tests along with in vitro assays, and material/chemical characterization data. The standard specifically emphasizes that the evaluation should address all the relevant risks that could impact the biological safety of the final product (ISO10993-1 2018).

The potential biological hazards that are commonly encountered in a medical device development are given in Table 1.

Accordingly, the evaluation process should follow a tiered approach. Material characterization is the crucial first step. The extent of material characterization depends on the nature and duration of patient exposure, knowledge of raw materials, and available toxicological data. Possible residual processing aids, as well as the degradation profile of the component materials, should be evaluated before proceeding to biological evaluation.

Table 2 is an excerpt from the standard ISO10993, Part 1, depicting the evaluation methodologies to address the common potential factors encountered in medical device development compromising biocompatibility/safety of medical device

Reference Materials in Biological Evaluation

Reference material as per the definition is a particular form of measurement standards that are employed to check the quality and metrological traceability of products, to validate the methodologies, or to calibrate the instrument. Here the

Table 2 Evaluation methodologies for risk-based endpoint assessment

		Medical device category								
		Surface contacting device			Externally communicating device			Implant device		
Endpoints		Limited	Prolonged	Permanent	Limited	Prolonged	Permanent	Limited	Prolonged	Permanent
Physicochemical characterization		x	x	x	x	x	x	x	x	x
Cytotoxicity		x	x	x	x	x	x	x	x	x
Sensitization		x	x	x	x	x	x	x	x	x

Genotoxicity				x		x	x	x	x	x
Carcinogenicity							x			x

(Adopted from ISO10993 part 1)[2]

biological evaluation methodologies suggested by ISO standards also advocate the usage of certified reference material wherever possible. Reference materials are incorporated as 3 categories in the evaluation methodologies (a) Solvent control/vehicle control, (b) Experimental control, and (c) Controls for comparison

Solvent/Vehicle Control

The basis of biological application in medical device development is to identify all the potential factors that could affect the biocompatibility response of the biomaterials intended for the fabrication of particular medical devices.

Some of the factors include the following:

- Residual monomers.
- Residual solvents.
- Degradation products.
- Sterilization products.
- Formulation additives.
- Bacterial endotoxins.

For addressing all these, the device components/biomaterials are extracted in extraction media at a specific surface area/volume or mass/volume ratio. The sample preparation methodologies are detailed in ASTM (American Society for Testing and Materials) 619 and ISO 10993-12 Standards (ASTMF619–14 2014; ISO10993-12 2021). The prepared sample is used for subsequent in vivo analysis/assays. Generally, physiological saline and cottonseed oil are used for mimicking the hydrophilic (polar) and lipophilic (non-polar) physiological compartment of the human body. Other solvents that are used for extraction are alcohol saline, polyethylene glycol, cell culture medium, etc. for various biological assays. The solvent/extraction media are selected according to the different classes of polymers/plastics that are generally used for the fabrication of medical devices (Table 3).

Accordingly, in the evaluation of medical devices, the following in vivo biological assays use vehicle control/blank for the interpretation of test results.

- Systemic toxicity test.
- Intracutaneous reactivity test.

Table 3 Classification of plastics and extraction medium as per USP (USP31 <88>)

	Medical grade plastics/polymers classification as per USP					
Extraction media	I	II	III	IV	V	VI
Physiological saline	x	x	x	x	x	x
Alcohol-saline		x	x	x	x	x
Polyethylene glycol 400			x		x	x
Cotton seed oil/sesame oil			x	x	x	

- Animal skin irritation test.
- Special irritation tests.
- Sensitization tests.

In the above tests, the blank/reference control consists of the same quantity of extraction medium maintained in the same experimental conditions as that of test material extract. Extraction conditions as per standard are 37 °C for 72 hours/ 24 hours, 50 °C for 72 hours, 70 °C for 24 hours, or 121 °C for 1 hours. The control extract is administered to separate control animals or at different sites on the same animal as per the test procedure. Clinical observations and visual scoring will be done and for test materials and controls, and the test results will be interpreted accordingly. If there is an equivocal response on both control and test sites, the particular test will be repeated.

Experimental Controls

Incorporating concurrent controls (positive and negative control) improves the validation and acceptance of the assay performed. A positive control is a reference material that is known to produce a positive response under the conditions of the test. And a negative control is a reference material that particularly gives no reaction under the conditions of the test. The performance of positive and negative control determines the integrity of test results of the test procedure. They may further help in generating a historical control database that would further demonstrate the proficiency of the particular assay, specifically in a testing lab that works under a quality platform. Some of the biological assays that include positive and negative reference materials are cytotoxicity assays, genotoxicity assays, hemolysis tests, etc. A list of positive controls used in various assays is detailed below (Table 4). Generally, for in vivo biological assays, incorporation of positive control is not advised for every single test because of the animal welfare requirements. Nevertheless, the standard prescribes using a positive reference material (material known to produce some response) occasionally to ensure the proficiency of the particular in vivo assay.

Comparing the test results with that of positive control helps in estimating the extent of risk or probability of the material causing harm to the biological system. On the other hand, comparing the result with that of negative control would ensure the extent of safety associated with the exposure of the material to the physiological system. Employing statistical methods for the comparison of test results with both the experimental control results (positive and negative reference material) thereby significantly enhances the integrity of results of the biological evaluation.

Controls for Comparison

In biocompatibility evaluation, especially when the local tissue response of the material is evaluated, the test material is compared with a similar kind of reference

Table 4 List of positive controls used for biological evaluation

Assays	Chemicals/positive controls
Cytotoxicity assays	Sodium lauryl sulfate Zinc diethyldithiocarbamate Phenol Doxorubicin Triton X
Genotoxicity assays	Methyl methane sulfonate Mitomycin C 4-Nitroquinoline N oxide Cytosine arabinoside Benzo(a)pyrene Cyclophosphamide monohydrate Congo red 2-Aminoanthracene
Hemolysis	Washed Buna N rubber Vinyl plastisol
Sensitization/irritation assays	Sodium lauryl sulfate Mercaptobenzothiazole Hexyl cinnamic aldehyde Benzocaine 2,4-Dinitrochloro benzene

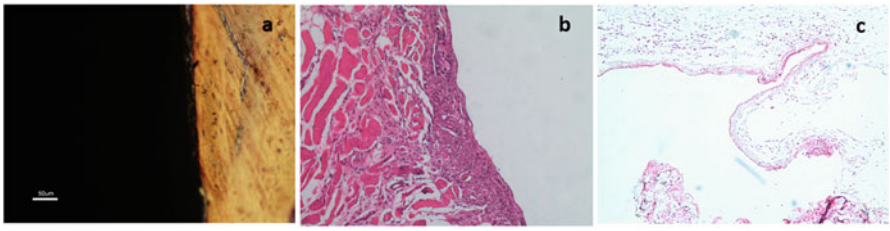

Fig. 6 Microphotographs of tissue surrounding the implant, (**a**) bone tissue, (**b**) muscle tissue, (**c**) subcutaneous tissue

material. In such a scenario, the reference material is of particular importance as the interpretation of test results depends on the control response. The local tissue response is evaluated by implanting the test materials in subcutaneous tissue or muscle tissue or bone tissue or any other clinically relevant sites (brain or vascular system) depending on the intended application. Reference material of the same class fabricated in similar dimensions as that of test material needs to be implanted at the control site in the same animals. At desired time intervals, both the samples are retrieved along with the surrounding tissue and are processed for histopathological examination. The cellular and inflammatory response around the material is microscopically scored and the test score is compared with that of the control score to report its response as non-irritant, mild, moderate, or severe irritant (Fig. 6).

Selection and Preparation of RM

Development of RMs involves the identification of the requirements and setting specifications required for reference material based on testing or evaluations. Relevant international standards draw guidelines in the selection of material type and their preparation. Commercially available industrial-grade materials after proper characterization are also allowed to use as RMs. It is a mandate that, appropriateness of relevant property values in line with the test or evaluation must be established before their routine use of proposed RMs. This confirmation shall be done through a series of physicochemical and biological evaluation series as directed by relevant international standards and ISO 10993 series. Standardization of procedures in RM preparation can then be followed to establish a system for development and production. ISO 10993 part 12 provides guidelines for the selection and preparation of RMs.

Physicochemical properties, biological response in a physiological environment, and the aging behavior of RM material are characterized and documented to generate material safety data. In routine production of RMs, the homogeneity of the samples in each batch of RMs with respect to the selected characteristic property is to be verified. ILC (interlaboratory comparisons) with the different participants can be employed to increase the acceptability of homogeneity test results. Based on the homogeneity and characterization studies, the material is assigned with a reference value. This could be qualitative or quantitative depending on its application. RMs with quantitative reference values could be assigned metrological traceability. But traceability establishment in RMs with qualitative reference values is not easy. In such cases, participation in interlaboratory comparisons (ILC) with multiple accredited laboratories may help to certify the assigned reference value. In general, steps in RM production can be summarized as follows:

- Material identification.
- Material preparation.
- assessment of homogeneity and stability,
- Material characterization.
- Assigning property values.
- Certification of RMs.

Maintaining RM Facility and Accreditation for RM Production

Reference material producers (RMP) shall define their scope of activities in terms of the types of reference materials, the properties to be certified, and the ranges of Assigned value, uncertainty, and best reference value capability of the reference materials they produce. Laid down procedures shall be followed for routine production of RMs. All metrological procedures of testing, calibration, and measurements in relation to homogeneity, stability and characterization assessments, etc. shall be available, and recorded results of measurement must be kept with RMP.

Accreditation for RM Facility

Since 2005, the availability of ISO Guide 34 and ISO 17025 in combination was the requirement for recommending accreditation of reference material manufacturers. ISO guides 30, 31, 35, etc. were the normative references at that period. With the publication of ISO 17034: General requirements for the competence of reference material producers in 2016, ISO guides became its informative references (TEC1–008 2019).

In the process of accreditation, the assessment body (AB) confirms that all aspects of ISO 17034 are complied by the RMP. ISO 17034 advocates the measurement procedures and metrological traceability in specifying accuracy of the RM property values should meet the requirements of ISO/IEC 17025. Concerning the methods and traceability, the RM producer shall pay special attention to the following aspects:

- Standard methods used are suitable for the intended use and in line with the latest published version.
- Non-standard methods used are developed by qualified personnel with adequate resources and are validated.
- Measuring equipment used in RM production must comply with relevant requirements of ISO/IEC 17025.

Market Availability and Use

With the increasing demand for satisfying regulatory criteria, evaluation phases of device development are expected to be employing international standards in a platform of risk-based thinking. Biological evaluation stages demand the use of RMs in relevant biomaterial classes. For addressing the requirement for a wider range of materials, it is not easy for the reference material producers to establish production facilities dedicated to RMs as control materials. One reason for this may be due to the greater risk of cross-contamination during the processing of positive control materials.

Joint Research Centre (JRC), one of the Directorate General of the European Commission, is an independent agency that provides scientific and technical support to community policy-making. They advised new dedicated facilities for individual reference material programs as batch production, for achieving targeted measurement benchmarks in response to changing requirements and environments. Hence a scientific and technical facility with dedicated laboratories and a multipurpose pilot plant for material processing is a requirement for large-scale RM production.

Very few research laboratories at national levels are available as RM sources for biological evaluations. IRMM (EU), National Institute of Standards and Technology (USA), United States Pharmacopeia (USA), and Hatano Research Institute(Japan) are the current major suppliers in the field.

In India, National Physical Laboratory (NPL), New Delhi, is the apex metrological body for facilitating national RM requirements in the area of physicochemical

characterization. Currently, Indian Reference Material or Bharatiya Nirdeshak Dravya (BND) available from NPL does not include RMs for biological evaluation. With respect to medical devices development and their evaluation, Sree Chitra Tirunal Institute for Medical Sciences, Kerala, an Institute of National Importance has an established system in a quality management platform of ISO 13485 and ISO 17025. Initiatives for the availability of RMs in metallic, polymeric, and ceramic classes are established for cytotoxicity evaluations, hemolysis studies, muscle and bone implantation studies, etc. at SCTIMST as an in-house RM facility. Both positive and negative control materials were validated through an interlaboratory comparison at this facility.

With the booming initiatives for medical device development across nations, indigenous RM facility is always the need of the hour in many countries. It is expected that India can become self-reliant in the BND availability along with expanding medical device industry.

Conclusion and Future Perspectives

Qualifying a device for safe clinical use depends on the physical and chemical nature of its materials in addition to the nature of the device's exposure to the body. There are chances for a biomaterial with good physical properties and cost effectiveness in a particular application may cause adverse toxicity effects in a different physiological environment due to its chemical properties. Properly designed biological evaluations help in such cases for determining potentially adverse or toxic effects of medical devices.

For regulatory approvals and global acceptance, such qualitative evaluations can be made traceable only through comparisons against certified reference material. An unlimited healthcare need around the globe compels the medical devices industries to operate in national or international regulatory framework. RM use explicitly stated in ISO 10993 standard series will then become an essential element in the evaluation of biomaterials. The non-availability of national-level RM sources in each country drives the need for establishing national facilities for the production and certification of RMs for biological evaluations.

Abstract

Alloys are a mixture of pure metals and are mixed to improve their performance and properties. A summarized detail of numerous alloy systems is discussed in this chapter. Metal alloys are classified in two categories, ferrous and nonferrous. Different steels thus fall into the first category, and other popular alloys like brass, bronze, invar, duralumin, hindalium, etc. fall into the second category. However, any alloy or any material for that matter has to be checked for its quality, production, and performance repeatability, and thus a standardization protocol is necessary. Any such standardization involves checking and benchmarking the acceptable composition range of that material. Many of the properties of such alloys are further dependent on different crystalline phases of the individual metals when they are mixed – so these also deserve to be benchmarked. Additionally, the properties of alloys are also dependent on the thermal cycling

processes, heat treatment procedures, and associated microstructure that they result in, i.e., on the thermodynamics of their preparation process. In some cases, it can also depend on the alloys' resistivity and magnetic properties. In order to achieve repeatability in their preparation process, all of these need to be standardized, i.e., measured, quantified, and cataloged. Such a process will result in production of standard alloys or certified reference materials (CRMs). They may be compared with any subsequent batch to batch product for checking consistency of expected properties. Thus, different national metrology institutes (NMIs) all over the world have been working on standardizing different alloys of their interest for growth of their own economies. Here we shall summarize the different standard alloy samples available with the major NMIs of the developed world like NIST-USA, PTB-Germany, NMIJ-Japan, and NPL-UK or their surrogates. The American Society for Testing and Materials (ASTM) or American Iron and Steel Institute (AISI) or Society of Automotive Engineers (SAE) has independently developed an extensive database for a large number of alloys, irrespective of whether similar data has been published or not by any NMI. Consequently, for trade purposes, several alloy makers from all over the world follow these standard data in situations where NMIs do not have specific standards of interest. A summarized discussion on all of them shall be made along with their consequences on their economies in this chapter. In the case of emerging economies like NMI-India, irrespective of what other NMIs have or have not worked on, this write up discusses how any alloy as a case study can be successfully standardized. It shall be worth the effort as that knowledge may be commercially exploited for the local and global market and extrapolated for making of other alloy standards and quality alloys in due time.

Introduction: Why Metal CRMs?

In this chapter, alloy systems (ferrous and nonferrous) are briefly summarized with major compositions tabulated. Ferrous alloy systems like cast irons, low-alloy steels, stainless steels, tool steels, and heat-resistant grades are briefly discussed. In the nonferrous category, aluminum (Al)-, copper (Cu)-, and titanium (Ti)-based alloys are summarized. We shall also discuss why all these alloys need better standardization parameters and how we could possibly implement them.

In case of any physical measurement or derived measurements involving primary SI units, its accuracy, precision, and repeatability are checked using established measurement methods that are acceptable to all national metrology institutes (NMIs) the world over. This is called validation of test results. These are traceable to the same primary SI units that are maintained by different NMIs globally.

However, for most materials sold in the market, such primary or secondary units do not exist. So, their quality is to be verified using a specific quality benchmark of a similar standard material prepared earlier that performs to a predefined performance level in a similar manner. As an example, let us take an example of brass. In order to specify its desirable quality, one may define its required expected density, composition, melting temperature, electrical resistivity, indentation hardness, a certain surface roughness in terms of reflectivity, surface stability in terms of discoloration upon keeping unused for 12 months in noncorrosive sulfur dioxide-less ambience, crack proofness upon hitting/exposing with a pressure of a certain pascal, etc. Or all these parameters can be compared in short using a known brass material that is known to conform to all of these parameters. Such an alloy material is called a reference alloy material, in this case a reference brass material. As another example, we could consider the case of setting quality standards for the widely used representative A4 paper characteristics as a reference material. It could be setting its acceptable discoloration rate in a decade, its weight uniformity in gms/cm^2, its minimum and maximum lignin content acceptance levels, its tear resistance uniformity in pascals/cm^2, its chemical and physical uniformity standards setting in terms of light intensity decrease on transmission, and its acceptable ink diffusion coefficient setting, i.e., smudging properties; else all of these can be compared in short with a reference A4 sheet that conforms to all of the above for brevity and simplicity and ease of measurement. So we can have scope and prospects for a reference A4 paper – it is compared with any batch of A4 sheet for declaring that batch as passed or failed the test in short. Zinc coating can be another example. Zinc coating is used for preventing oxidation of iron surfaces. But the issue that is always present is what should be the quality benchmark for this coating? This zinc can be melt-dip coated or electro-plated. The latter is much more expensive. The parameters under scrutiny will be what should be the minimum thickness of the zinc coating so that the material retains its noncorroded properties even 50 years after production, e.g., the telegraph and telephone poles and electric pylons and street lighting masts seen all over the country or steel rebars for construction of engineering structures or cheaper nails and screws for daily use. The more sturdy nails and screws are of stainless steel for durability. What should be its maximum and minimum acceptable surface roughness and porosity as well in SI units? A simplified comparison methodology for any routine batch could be to use a standard zinc-coated surface which meets all the set standards.

In this manner, it is seen that there is always a lot of scope for preparation and practical usage of standard alloy and other reference material samples for setting of better-quality benchmarks. Better quality benchmarks lead to better industrial products in the related segment and thus lead to better commercial success under ideal conditions. However, such better-quality products have a certain price tag that needs to be paid due to the procedure and protocols and checks it necessarily has gone through; it will not necessarily be the lowest quoted product (L1).

During sample analysis for elemental content using nondestructive analytical techniques, like energy dispersive X-ray analysis (EDAX) or X-ray fluorescence (XRF) or inductively coupled plasma optical emission spectrometry (ICP-OES),

accuracy of the measurements is improved if results obtained for an unknown sample can be compared with results for a sample of similar matrix and known composition. If such a reference sample is widely used due to the nature of usage, it may make sense to commercially characterize it and market them, after extensive analysis of its composition, phase, etc. It then leads to a standard reference material (SRM). So, in the case of analysis of an unknown gold sample, by EDAX or XRF would require a comparison with a gold sample of known purity, as analyzed by chemical and fire assay. This reference gold sample is thus an SRM.

A reference material (RM) is defined as "any material, which is satisfactorily stable and homogeneous with respect to one or more specific properties and which has been recognized for its intended use in a metrological activity." Certified reference material (CRM) or standard reference material (SRM) is defined as an RM described by a metrologically valid procedure for one or more specified parameters or properties and which is accompanied by a certificate of analysis that provides a specific value of the specified property and its associated uncertainty along with a statement of metrological traceability, i.e., how directly or indirectly it is attributable to one or more primary or secondary SI units (ISO Guide 30 2015). Several national metrological institutes (NMIs) or their associating agencies across the world produce alloy-based CRMs/SRMs for the requirements over the globe. Among them, alloy CRMs produced by the developed economies/NMIs, such as National Institute of Standards and Technology (NIST)-USA, Physikalisch-Technische Bundesanstalt (PTB)/BAM-Germany, National Metrology Institute of Japan (NMIJ)-Japan, and National Physical Laboratory (NPL)/LGC Standards-UK, are discussed. Later in this chapter, the status of alloy-based CRMs with Council of Scientific and Industrial Research-National Physical Laboratory (CSIR-NPL), India, is also discussed, which is currently one of the developing economies/NMIs in the world.

It needs to be borne in mind that there are several metallurgical methodologies for preparation of different alloys. The preparation method to be used depends on what type of alloys needs to be prepared. The methods used for different steels are not the same as that for different aluminum-, gold-, copper-, or titanium-based alloys. Details on aluminum-based alloy preparation are discussed by Persson (Persson 2011). Iron-based alloy production methodologies are discussed by Neveille and Cain (Neville and Cain 2013). Gold and such precious metals are prepared by a combination of chemical melt and electrochemical refining. Due to their high price, such methodologies are suitable only for such precious metals. Information on different copper-based alloy preparation are discussed by Zahner (Zahner 2020). Details on preparation methodologies of titanium alloys are to be found in the book by Sanchez (Sanchewz 2010). As will be realized, each metal is unique in its preparation process as much as in its properties. Alloys are mostly about special properties related to their special performance, their performance stability, and repeatability over thousands of times over several years. Since these have a distinct commercial connotation, in each case, their exact preparation process, related parameters and repeatability issues, related production data, and mostly commercial secrets of each of the companies that prepare and market them are often proprietary

items. Since alloys are mostly about performance, it is not always possible quantify all the desirable parameters, though mathematically definable properties in terms of primary units can be measured and are enforceable. But parameters like corrosion resistance-related performance for a few years or a knife's cutting edge's ability to cut certain items at a certain speed repeatedly for a certain number of months without sharpening or say the metallic properties of a gun barrel to fire certain number of rounds without cooling with a certain accuracy and then maintaining this ability for a certain number of years may or may not be totally quantifiable in terms of primary SI units. The ability of a specific composition-based alloy to maintain its shape upon repeated cyclic bending in a certain format up to a limit may or may not be totally quantifiable. The ability of a metal plate of a certain composition to maintain its overall physical shape and composition upon random shock or projectile impregnation and related fires may or may not be totally quantifiable. But it is for these "no totally quantifiable properties and parameters" that specific alloys are preferred and used in special applications. It is not always thus possible to have reference materials for these as all of their properties are not always totally quantifiable. Most known alloys fall into this category. Now, it may be noted that a reference material is a material that is used for standardizing or checking the quality in terms of a quantifiable specific predefined property of a similar material in terms of expected properties. It is not necessary to discuss about how it was prepared. It is not a patented item that its preparation details have to be disclosed in detail. After several years or several decades, such information may come into the common man's domain. So discussing preparation methodology in general for alloys is not practically feasible. Only those few metal alloys that are very well-defined, including its composition, with known unique preparation methodology and numerically definable performance parameters, can be classified into the category of reference materials. Otherwise, different alloy manufacturers often use their own preparation standards and secretive parameters to obtain repeatability in performance. No NMI can fully replicate these due to absence of all information. As an example, let us consider the case of stainless steel of certain grades. In terms of ASTM standards discussed here, it will be seen that it discusses the expected alloy composition profile alone with ranges to their possible values but discusses nothing on the preparation methodology, the acceptable metallic crystalline profiles, or different possible acceptable crystalline profiles. So it is seen that commercial stainless steel of many producers the world over has different crystalline profiles, even though they may have the same ASTM grade in terms of composition (Karar et al. 2022).

In this way, most current standards of alloys in general, as discussed below, talk of possible-acceptable element-wise composition ranges, with no information on acceptable production processes or density. Their microhardness or general hardness profiles, resistivity profile, and/or magnetization profile, perhaps their Young's modulus at times, and at best some representative information on their microstructure in terms of some representative etched micrographs are described only in cases where specific alloys are patented. As a representative case, the Hitachi coarse-grained oxide (CRGO) alloy for transformer core material-related patent can be cited [Metglas] (World Intellectual Property Organization 2016). There is no standard

reference material for this sort of alloy for use as transformer core material. The only parameter of concern is its magnetic property and nothing else – though all of those stated above, i.e., composition, resistivity, density, and crystalline properties, can be of practical significance in terms of checking its repeatability and quantification. They contain no information on the acceptable crystalline phases in terms of X-ray diffraction profile (XRD) and their full width at half maximum (FWHM) values or their correlatable Raman spectral data, which are both quantitative in nature and can in principle substitute the qualitative micrographs, in terms of repeatability. If not under patent, all alloys of need can in principle be quantified by NMIs using all possible parameters as stated above, much more than what current practice states. It then becomes a reference material. If there is a certificate issued with details of the quantitative analysis along with the related uncertainty value in the measurement parameters studied and certified and how these are traceable to the primary or secondary SI units, one gets the certified reference material (CRM). The SI units are maintained by the major NMIs of most major developed countries. These reference materials are internationally recognized because irrespective of which national NMI does a recheck of the measurement by a particular internationally acceptable method, the results obtained are expected to be the same within the uncertainty limits. As another example, we can state the case of hardness blocks. These are metal alloys of a particular shape and dimension that have to withstand hardness-related repeated indentations and still give the same expected value year after year, within a certain error level. It does not matter what is its resistivity, microstructure, magnetic property, composition, preparation methodology, or heat tempering cycle. The only parameter of concern here, in this context, is its repeatable hardness value. In case of precious metals like gold, current standards and norms are concerned only about how much purity a certain gold item is of, and density, not what is its microstructure or what is its resistivity or its magnetic property. So the only parameters of concern in a reference material are those parameters that give it the desired repeatability and the market value to the materials with which they are compared.

Ferrous Alloy Systems

Ferrous alloy systems include different alloying elements including iron (Fe) usually as the principal component. Some examples of alloying additions are C, Si, Mn, Cr, Ni, Mo, V, Nb, etc. Typical properties of ferrous alloys are durability, high yield and tensile strength, poor corrosion resistance, recyclable, good thermal conductivity, good conductor of electricity, etc. Various types of ferrous alloy systems broadly include different grades of cast irons, low-alloy steels, stainless steels, tool steels, heat-resistant steels, etc. Selected nominal compositions of different types of cast irons, case hardening (low alloy) steels, different grades of stainless steels, different tool steels, and heat-resistant casting alloys have been listed in Table 1 (Radzikowska 2004; Guide to Engineered Materials 2001), Table 2 (Vander Voort 2004a), Table 3 (Vander Voort 2004b), Table 4 (Vander Voort et al. 2004), and

Table 1 Range of composition for typical non-alloyed and low-alloyed cast irons (Radzikowska 2004; Guide to Engineered Materials 2001)

	Composition (wt%)				
Type of iron	C	Si	Mn	S	P

Malleable (TG)	2.2–2.9	0.9–1.9	0.15–1.2	0.02–0.2	0.02–0.2

Table 5 (Vander Voort et al. 2004; Nickel Development Institute, Canada 2009), respectively.

"**Cast iron** is an iron-carbon (Fe-C)-based alloy also containing other elements of the periodic table and is made by remelting of pig iron, iron scrap, etc." In order to differentiate these from steel and cast steel, these may be described as a cast alloy having carbon content more than 2.03%. Its composition leads to an eutectic solidification. Alloying or non-alloying of cast iron is possible and depends upon the chemical composition. Table 1 (Radzikowska 2004; Guide to Engineered Materials 2001) illustrates the list of compositions of non-alloyed cast irons. The possible range of alloys that can be made in cast iron format is much wider, and many of these may consist of higher percentages of other elements, e.g., Si, Mn, or other special elemental additions.

"**Steel** may be defined as an alloy containing a minimum of 50% of iron and, in addition, one or more other alloying elements. These possible alloying elements may include C, Si, Mn, Ni, Mo, Cr, P, Cu, V, Ti, B, Nb, or Al." "Alloys designated as low- and very low-carbon steels are those that contain carbon less than 0.25%." "Carbon steels, usually called plain carbon steels, have their carbon content from approximately 0.10% to below 2.0% and are generally classified into three categories, i.e., low-carbon steels, medium-carbon steels, and high-carbon steels." In the USA, examples of plain carbon steels are AISI/SAE 1020, 1040, 1080, etc. "The American Iron and Steel Institute (AISI) along with the Society of Automotive Engineers (SAE)" have developed a coding system for different plain carbon steels, low-alloy steels, and stainless steel grades. It is a four-digit number designation for different types of steel. In the given three examples above, first two digits, i.e., "10," specify the steel of the class plain carbon steel, and the last two digits, i.e., "20," "40," and "80," represent the nominal carbon content and are stated in 0.01% increments in carbon. Hence, AISI/SAE 1020 steel can be described as the plain carbon steel having carbon content of 0.20%. Similarly, AISI/SAE 1040 steel can be described as the plain carbon steel having carbon content of 0.40% and so on. For surface hardening of steels, different processes are developed to allow diffusion of alloying elements through surface layers. "Such thermochemical processes include carburizing, nitriding, carbonitriding, nitrocarburizing, etc." These processes are usually found suitable for the low-carbon steels (containing carbon below 0.25%) and allow development of a case of high hardness. The advantage of this methodology

[a]Bal. Fe for all compositions. Mn content: 0.35–0.65% for HA, 1% for HC, 1.5% for HD, and 2% for the other alloys. P and S contents: 0.04% (max) for all. Mo is intentionally added only to HA, which has 0.90 to 1.20% Mo; maximum for other alloys is set at 0.5% Mo. HH also contains 0.2% N (max)

is achieving the case of high strength and wear resistance that cannot be attained by the core metal. "Nitriding is a thermochemical treatment that is usually suitable for medium-carbon low-alloy steels (containing carbon in the range of 0.25–0.6%), although stainless steels and tool steels can also be taken through the nitriding process." Table 2 (Vander Voort 2004a) depicts composition of some of the more common case-hardening steels. Most steels that may contain an initial carbon content of 0.10–0.25% are subjected to carburizing or carbonitriding process to achieve desirable properties. Medium-carbon steels (containing 0.25–0.6% C) are occasionally carburized so that they may satisfy specific property requirements.

"**Tool steels** are high-alloy steels, and they are usually heat treated in different ways in order to achieve much higher hardness values than what most carbon or alloy steels can offer." Table 3 (Vander Voort 2004b) summarizes typical composition for various grades of tool steels. "The different tool steel grading methodologies include the most common water hardening (W-grade) or air hardening (A-grade, cold working), shock resisting (S-grade), D-type (cold working), oil hardening (O-grade), and hot working (H-grade)." "W-grade tool steels are basically high-carbon steels and usually water quenched. These steels can attain high hardness but are relatively brittle as compared to other tool steels. A-grade tool steels are

characterized by higher content of chromium (Cr) that provides better response to heat treatment. The A-grade tool steels can depict high machinability. Additionally, they also possess great wear resistance along with toughness. D-type tool steels combine the general characteristics of W-grade and A-grade. The D-grade tool steels contain a higher amount of carbon as compared to W-grade; however, they have the properties described above that are typical to the air hardening type (A-grade)." "Due to the higher chromium content, the D series tool steels may also be categorized as stainless, but their corrosion protection is pretty limited. The abrasion resistance properties are high for the D-type tool steels. The O-grade tool steels are general purpose oil hardening-type tool steels. They are characterized by good abrasion resistance and toughness for a comprehensive range of applications. S-grade tool steels are usually designed to counter shock at low or high temperatures. Their low carbon content is essential to achieve the required toughness. This grade of tool steels possesses high impact toughness but low abrasion resistance. Finally, the H-grade tool steels are suitable to cut materials at high temperatures. The H-grade tool steels are designed to have sustainable extra strength along with hardness at elevated temperatures. They are low in carbon content and moderately high in alloying additions."

"**Stainless steels** are multielement alloys containing at least 11% Cr along with other elements and have different grades like austenitic, ferritic, duplex, martensitic, and/or precipitation-hardenable grades." The nominal composition of typical standard wrought stainless steel grades has been given in Table 4 (Vander Voort et al. 2004). Stainless steels are commercially important due to their exceptional corrosion resistance properties. Stainless steel is normally 200 times more corrosion resilient than any form of mild steel or low-carbon steel grades. Stainless steels (SS) are divided into five groups as mentioned above. "Austenitic SS is the most weldable grade among all stainless steels and can be loosely divided into three subgroups: the more common chromium-nickel (300 series), the manganese-chromium-nickel nitrogen based (200 series), and the more specialty alloys." All these grades are generally nonmagnetic and are non-heat-treatable. "The ferritic SS are composed of trace amounts of Ni, 12–17% Cr, and less than 0.1% C and have other alloying additions like Mo, Al, Ti, etc." These alloy grades have good ductility and formability; however, their strength at high temperatures is poor as compared to similar austenitic grades. They are magnetic but cannot be heat treated. They are strengthened using cold working processes. "Martensitic SS contains at least 11–17% Cr, less than 0.4% Ni, and up to 1.2% of C. Such carbon contents of these steels make them hardenable but affect their forming and welding characteristics." In order to achieve beneficial properties and prevent any cracking, compulsory preheating and post-welding heat treatment are necessary. "Martensitic SS, e.g., 403, 410, 420, etc., are magnetic and heat treatable as well." "Duplex SS typically contain, along with Fe, 5% Ni and 22–25% Cr, along with traces of Mo and N." These steels have higher yield strength and better stress corrosion cracking resistance against chloride as compared to austenitic stainless steels. Finally, "precipitation hardening SS are Cr-Ni grades that also contain other alloying elements, such as Al, Cu, or Ti."

These alloys are hardened by a combination heat treatment of solution and aging. After aging, these grades could be either austenitic or martensitic.

The Alloy Casting Institute (ACI) has given nominal compositions for cast stainless steels, in keeping with the designations as above, in Table 5 (Vander Voort et al. 2004; Nickel Development Institute, Canada 2009) for the **heat-resistant SS grades**. These heat-resistant grade steels have relatively higher carbon contents for strengthening as compared to steel castings in corrosion-resistant grades. "The heat-resistant casting alloys comprise of those compositions that contain more than 12% Cr which are capable of sustaining adequately when used for applications at temperatures more than 650 °C." "Heat-resistant compositions, as a group, are higher in alloy content as compared to the corrosion-resistant-type steels." These alloys are composed primarily of iron (Fe), chromium (Cr), and nickel (Ni), along with a small percentage of other elements. Castings developed using these alloys are expected to satisfy two basic requirements: (i) a better surface film stability (in terms of oxidation and corrosion resistance) under different atmospheric conditions and also at the temperatures to which they are exposed and (ii) they should have sufficient mechanical ductility and strength in order to attain high-temperature usage requirements. "The ACI designations 'H' indicates alloys used in conditions where the metal temperature may exceed 650 °C." "The second alphabet denotes nominal nickel content, increasing from alphabet A to alphabet X. These alloys can be classified mainly in three groups (Vander Voort et al. 2004): i) Cr-Fe alloys: HA, HC, HD; ii) Cr-Ni-Fe alloys: HE, HF, HH, HI, HK, HL; and iii) Ni-Cr-Fe alloys: HN, HP, HT, HU, HW, HX. The Cr-Fe alloy group is composed of alloys having predominantly Cr with maximum 30% Cr and 7% Ni." These alloys are ferritic and possess relatively low high-temperature strength. The second type of Cr-Ni-Fe alloys have better high-temperature strength, hot and cold ductility, and also resistance to oxidizing and reducing conditions. They contain 8–22% Ni and 18–32% Cr and may have either a partial or completely austenitic microstructure. The third type, Ni-Cr-Fe alloys, is fully austenitic and contains 25–70% Ni and 10–26% Cr. These alloys can be satisfactorily used up to the temperature of 1150 °C, as there is no brittle-phase formation. They have good weldability along with high machinability.

Nonferrous Alloy Systems

"Nonferrous alloy systems could be any metal matrix system other than iron-based alloys, such as copper alloys, zinc alloys, aluminum alloys, magnesium alloys, titanium alloys, nickel alloys, lead alloys, etc." However, in this chapter, three more common alloy systems, i.e., based on aluminum, copper, and titanium, will be discussed. A**luminum alloys** primarily cover a variety of range of chemical compositions and product forms that could be fabricated by numerous metalworking processes and standard casting routes. Pure aluminum (Al) and Al-based alloys could be manufactured in various standard forms, e.g., sheet, plate, rod, bar, tube, wire, pipe, foil, etc. These alloys can also be shaped in numerous engineering forms for specific applications by various metal-forming processes, like extrusion, forging,

stamping, machining, and powder metallurgy. Aluminum alloys may encompass more than 300 commonly documented alloy compositions and several additional variations optimized as a result of supplier-consumer chain relationships. Usually, the commercial Al alloys contain some Fe and Si as well as two or more other elements purposefully added to achieve improved characteristics. The major groups of commercial Al alloys have been classified in Table 6 (Warmuzek 2004; Hatch 1984). The primary objectives of Al alloying are strengthening using components like Si, Cu, Mn, Zn, Mg, Mg + Si, etc. in combination with strain hardening, heat treatment, or both.

"Aluminum alloys are principally divided in two major categories: **castings** and **wrought compositions**." Further, subdivision of these alloys is based on "**heat-treatable** and **non-heat-treatable alloys**." "Cast and wrought aluminum alloy-related nomenclature as is currently used globally in this trade was developed by the Aluminum Association System in the USA." In **wrought aluminum alloys,** again "a four-digit system has been commonly used to segregate the following groups of wrought compositions":

- 1*xxx* Controlled unalloyed (pure) composition.
- 2*xxx* Alloys comprised of Cu as the main alloying constituent.
- 3*xxx* Alloys wherein Mn is the main alloying constituent.
- 4*xxx* Alloys having Si as the major alloying element.
- 5*xxx* Alloys wherein Mg is the major alloying constituent.
- 6*xxx* Alloys where Mg and Si are the primary alloy additions.
- 7*xxx* Alloys composed of Zn as the major alloying element.
- 8*xxx* Alloys which also contain Sn and some Li – they are characterized as miscellaneous compositions.

In the same manner, "**casting compositions** are described in this trade using a three-digit system followed by a decimal value. The decimal (i.e., 0.0) in all such cases concerns with the limits of cast alloying. Decimals 0.1 and 0.2 represent those ingot compositions, which are obtained after melting and processing. For casting compositions, the alloys are grouped in the following manner":

- 1*xxx* represents controlled but unalloyed, i.e., pure compositions.
- 2*xxx* alloys have Cu as the primary alloying element but may include additional alloying elements that may be specified.
- 3*xxx* are those alloys wherein Si is the primary alloying element; however, other elements, e.g., Cu and Mg, may also be specified.
- 4*xxx* are those alloys that have Si as the other primary element.
- 5*xxx* are those alloys in which Mg is the major alloying constituent.
- 6*xxx* designation is currently unused.
- 7*xxx* designation denotes alloys where Zn is the main alloying addition, but other constituents, e.g., Cu and Mg, may be specified.
- 8*xxx denotes* alloys in which Sn is the primary alloying constituent.

Table 6 Nominal alloy composition range for various groupings of commercial aluminum alloys (Warmuzek 2004; Hatch 1984)

[a]Balance: aluminum

Heat-treatable Al alloys are those whose strength can be increased by a controlled cyclic heating and cooling. Al alloys that are usually denoted as above in the 2*xxx*, 6*xxx*, and 7*xxx* series are solution heat treatable and are strengthened by such cyclic quenching. Additional strengthening may be achieved by controlled deformation at room temperature. Another example of heat treatment is fully annealed O-temper Al alloy 2024. It has yield strength of approximately 186 MPa. After such cyclic treatment, followed by natural aging (T-3 temper), the yield strength can get enhanced up to 483 MPa.

There are also some **non-heat-treatable Al alloy groups** which are hardenable only by cold working and not using any heat treatment methods. The preliminary strength of such alloys, usually in the 1*xxx*, 3*xxx*, 4*xxx*, and 5*xxx* series, come from the alloying-related hardening effects alone. Their strength can be increased further by applying cold working denoted by H-temper. Cold working can significantly enhance strength properties of the aluminum alloys. As an example, the ultimate tensile strength (UTS) in Al alloy 3004 could be increased to up to 283 MPa after H-38 temper as compared to 179 MPa in its O-temper condition.

Copper and copper alloys have performed an important role in the human life and human evolution since ages. The combination of exceptional thermal and electrical conductivity, strength, workability, corrosion resistance, and their abundance makes these copper-based alloys essential to all societies and industries all through the ages. "Copper alloys have conventionally been classified by composition and as wrought or cast in the groups depicted in Table 7 (Caron et al. 2004; Joseph 1999). These alloys are listed by the UNS designation which is managed by the Copper-Development Association, USA." Chosen alloys for each group are classified in the table. The alloys designated as coppers may contain a minimum of 99.3% copper. These alloys possess highest thermal and electrical conductivity. Impurities, such as phosphorous (P), tin (Sn), selenium (Se), tellurium (Te), and arsenic (As), are detrimental to their electrical conductivity and recrystallization temperature. However, if intentionally alloyed, then these additions can improve other specific desirable characteristics. High-copper alloys contain about 96 to 99.3% copper in the wrought products. In the case of cast alloys, copper content is more than 94%. The major alloying elements are cadmium (Cd), beryllium (Be), and chromium (Cr). Copper-zinc-based alloys (i.e., different grades of brasses) contain Zn as the other major alloying constituent. Such alloys in wrought form "are further categorized as copper-zinc alloys, copper-zinc-lead (leaded brass), and copper-zinc-tin (tin brasses)." Cast brasses have four subdivisions: "(i) copper-zinc-tin- and copper-zinc-tin-lead-based alloys (they are colloquially denoted as red and leaded red, semi-red and leaded semi-red, and leaded yellow brass), (ii) copper-manganese-zinc and copper-manganese-zinc-lead (high-strength and leaded high-strength brass), (iii) copper-silicon (i.e., silicon-based brasses and bronzes), and (iv) copper-bismuth and copper-bismuth-selenium (i.e., copper-bismuth- and copper-bismuth-selenium-based alloys)." Bronzes may include copper-based alloys that do not contain Zn or Ni as the principal alloying constituent. The four subgroups of wrought alloys are "(i) copper-tin-phosphorous (phosphor bronze), (ii) copper-tin-phosphorous-lead (leaded phosphor bronze), (iii) copper-aluminum (i.e., aluminum

Table 7 Nominal alloy composition for typical copper and copper alloys (Caron et al. 2004; Joseph 1999)

UNS No.	Name	Composition (wt%)
Wrought copper		
C10100	Oxygen free electronic copper (OFE)	99.99 (min) Cu
CI1000	Electrolytic tough pitch copper (ETP)	99.90 (min) Cu
C12500	Fire-refined tough pitch copper (FRTP)	99.88 (min) Cu
Wrought high copper alloys		
C17200	Beryllium copper	Bal Cu, 1.90 Be, 0.40 Co
C18200	Chromium copper	Bal Cu, 0.9 Cr
C18700	Leaded copper	Bal Cu, 1 Pb, 0.05 P
Wrought brasses		
C26000	Cartridge brass, 70%	70 Cu, 30 Zn
C26800	Yellow brass, 66%	66 Cu, 34 Zn
C28000	Muntz metal, 60%	60 Cu, 40 Zn
C36000	Free-cutting brass	62 Cu, 3 Pb, 35 Zn
C44300	Admiralty, arsenical	71.5 Cu. 27.5 Zn, 1 Sn (0.04 As)
C46400	Uninhibited naval brass	61 Cu, 38 Zn, 1 Sn
Wrought bronzes		
C51000	Phosphor bronze, 5% A	Bal Cu, 5.0 Sn, 0.2 P
C63000	Aluminum bronze, 10%	82.2 Cu, 10A1, 3 Fe, 4.8 Ni
C64700	Silicon-nickel bronze	Bal Cu, 1.9 Ni, 0.6 Si
C68700	Arsenical aluminum brass	77.5 Cu, 20.3 Zn, 2.2 Al, 0.04 As
Cast high-copper alloy		
C81500	Chromium copper	98 (min) Cu, 1.0 Cr
Cast brasses, bronzes, and Ni silver		
C83600	Leaded red brass	85 Cu, 5 Sn, 5 Zn, 5 Pb
C86200	Manganese bronze	64 Cu, 26 Zn, 4 Al, 3 Fe, 3 Mn
C90300	Tin bronze	88 Cu, 8 Sn, 4 Zn
C92600	Leaded tin bronze	87 Cu. 10 Sn, 2 Zn, 1 Pb
C95300	Aluminum bronze	89 Cu, 10 Al, 1 Fe
C95500	Nickel aluminum bronze	81 Cu, 11 Al, 4 fe, 4 Ni
C95600	Silicon-aluminum bronze	91 Cu, 7 Al, 2 Si
C97800	Nickel silver	66 Cu, 25 Ni, 5 Sn, 2 Zn, 2 Pb

bronze), and (iv) copper-silicon (i.e., silicon bronze). The cast bronzes are colloquially known as copper-tin (i.e., tin bronze), copper-tin-lead (i.e., leaded and high-leaded tin bronze), copper-tin-nickel (i.e., nickel-tin bronze), and copper-aluminum-iron and

Table 8 Nominal alloy composition for typical commercial titanium alloys (Donachie 2000; Stefanescu and Ruxanda 2004)

Designation	Composition (wt%)				
	Al	Sn	Mo	Zr	Others
α alloys					
Ti-0.3Mo-0.8Ni	–	–	0.3	–	0.8Ni
Ti-5Al-2.5Sn	5	2.5	–	–	–
Ti-6Al-2Sn-4Zr-2Mo	6	2	2	4	0.08Si
Ti-6Al-2Nb-1Ta-0.8Mo	6	–	1	–	2Nb, 1Ta
Ti-2.25Al-11Sn-5Zr-1Mo	2.25	11	1	5	0.2Si
α-β alloys					
Ti-6Al-4V	6	–	–	–	4V
Ti-6Al-6V-2Sn	6	2	–	–	0.75Cu, 6V
Ti-7Al-4Mo	7	–	4	–	–
Ti-6Al-2Sn-4Zr-6Mo	6	2	6	4	–
Ti-6Al-2Sn-2Zr-2Mo-2Cr	5.7	2	2	2	2Cr, 0.25Si
Ti-4Al-4Mo-2Sn-0.5Si	4	2	4	–	0.5Si
β alloys					
Ti-10V-2Fe-3Al	3	–	–	–	10V
Ti-13V-11Cr-3Al	3	–	–	–	11Cr, 13V
Ti-3Al-8V-6Cr-4Mo-4Zr	3	–	4	4	6Cr, 8V

Ti-15V-3Cr-3Al-3Sn	3	3	–	–	15V, 3Cr

copper-aluminum-iron-nickel (i.e., aluminum bronze)." Copper-nickels are obtainable as wrought and cast alloy forms. Copper-nickel-zinc-based alloys (in such wrought or cast format) are colloquially called nickel silvers. Other copper alloys comprise groups of specialty alloys, copper leads, and brazing alloys. Oxygen and hydrogen cause interference with the conductivity of copper and/or copper alloys. However, very small and controlled amounts of oxygen are in fact advantageous for the conductivity improvement since oxygen can combine with and remove from solution other impurities, such as iron that is far more detrimental.

A brief summary of selected commercial **titanium-based alloys** is presented in Table 8 (Donachie 2000; Stefanescu and Ruxanda 2004). Titanium alloys are a mixture of titanium and other elements of the periodic table. They show extremely high toughness and tensile strength (even at elevated temperature conditions) as compared to the above-discussed aluminum and copper alloys in the nonferrous category. Titanium alloys are light, display extraordinary corrosion resistance, and can withstand extreme temperatures. They are commonly classified into three major alloying phase groups, "designated as α, α + β, and β. The commercially used fully α alloys have several grades of pure Ti or ternary Ti-Al-Sn. In the α+β alloys, additional elements are included to stabilize and strengthen the α phase together with 4–6% of β-phase stabilizing additions. These alloys may contain 10–50% β-phase at ambient temperature. The α+β alloys have the maximum commercial

viability as per the current world scenario. Ti-6Al-4V alloy is the single composition which has up to 50% 'commercial market share' among all α+β Ti-based alloys, both in Europe and the USA." Consequently, wrought Ti-6Al-4 V alloy is considered the standard alloy when shortlisting any titanium-based alloy for any specialist requirement. The high-temperature stability of Ti-6Al-4 V alloy is only up to 400 °C. Therefore, for more elevated-temperature applications, Ti-6Al-2Sn-4Zr-2Mo (+Si)-based alloys are preferred. During the last few decades, numerous other titanium alloys have also been developed. However, none of them could match the price and performance of Ti-6Al-4 V alloy. Other Ti alloys for high-performance applications include Ti-10 V-2Fe-3Al, Ti-6Al-6 V-2Sn, and Ti-13 V-11Cr-3Al. The other titanium alloys mentioned in Table 8 are presently in various stages of development.

Standardization in Measurements: Pathway to CRMs/SRMs

In the world of metrology, the result of any measurement for an unknown value is obtainable only after it can be tallied with a known value. A standard is a benchmark in terms of dimensions or performance of known quantity in terms of measurement units that can be compared. So a standard is always used for comparison or as a reference point for the evaluation of an unknown thing. Global quality control lexicon mandates use of acceptable standards for all measurements. According to ISO 9001:2015 (ISO 9001 2015) guidelines, "Quality assurance is based on a methodology that ensures that a product, process, or service will fulfill the expected quality requirements," and quality control is "a way to follow the operational flow chart required to meet due Quality requirements." Certified reference materials (CRMs) ensure two issues to be taken care (Pant 2018). The first is preparing these materials and second is their characterization. Hence, CRMs need to be produced or at least supervised carefully by specialized agencies, such as different national metrology institutes (NMIs). In the Indian context, a metal or alloy-based CRM can be prepared by CSIR-National Metallurgical Laboratory (CSIR-NML), Jamshedpur, whereas a cement-specific CRM can be produced by the cement research institute in association with CSIR-NPL, New Delhi. The National Council for Cement and Building Materials (NCCBM), Ballabgarh, has an association with CSIR-NPL for the development of CRMs in the field of cement and allied materials, which are marketed in India and abroad with the trade name Bharatiya Nirdeshak Dravyas (BNDs). The International Organization for Standardization (ISO) has laid down specifications through ISO Guide 35:2017 (ISO Guide 35 2017) for such preparation and characterization activities. As the custodian of the national standards for physical measurements, CSIR-NPL, New Delhi, characterizes and shares all data for reference materials. It issues characterization certificates, listing their specific measurand properties (as mean value) along with related uncertainty data.

The world over, in all capitalist economies, CRMs have multiple valuable utilities. They are routinely used globally for engineering and industrial process

quality control by all quality control and quality conscious organizations. They are useful for the calibration of instruments and methods and for round-robin intercomparison between different similar instruments in participant laboratories. This activity ensures compatibility between the measurement laboratories and leads to metrological traceability of measurements to national standards. The developed economies/NMIs, such as NIST-USA, BAM-Germany, NMIJ-Japan, NPL-UK/LGC Standards, etc., provide SI traceable CRMs to the global market. NIST-USA has developed more than 1300 standard reference materials (SRMs) in the areas of industrial materials, for environmental monitoring and for health safety control (Montgomery and Crivellone 2021). Bundesanstalt für Materialforschung und–prüfung (BAM), Germany, produces more than 400 CRMs for analysis of chemical composition and control of industrial and engineering products (Recknagel 2021). The European Union as a whole has around 800 CRMs in diverse areas of food hygiene and safety analysis, environmental impact control, engineering, medical applications, etc. (Certified Reference Materials 2022). NMIJ-Japan has developed different CRMs for process control of their industrial materials, high-purity inorganics, polymer materials, different gases, etc. (NMIJ CRM Catalog 2021–2022 2021; NMIJ Certified Reference Materials (NMIJ CRMs) n.d.). On the other hand, the developing economies/NMIs, such as CSIR-NPL (India), have developed till date about 120 CRMs (with the tradename BND®) in various fields, such as chemicals, cement, petroleum products, hardness, ores, minerals, precious metals, etc. (https://www.nplindia.org/wp-content/uploads/2021/11/Available-Bharatiya-Nirdeshak-Dravya-list-251220.pdf; Singh et al. n.d.).

Most of the time, there is little overlap in the category and types of CRMs developed by the NMIs of different countries. There is no upper limit to the number of different metal and alloy-based reference materials that can be produced and marketed. Essentially in the practical sense, it all depends on what is the marketability of any reference material that is produced. If the market demands it, then it can be produced and sold. Else, in our opinion, it is only an academic exercise. In general, once any patent-protected proprietary alloys are mass manufactured by several other manufacturers, within the same country or globally, then for the sake of standardization of quality, reliability, and benchmarking, it may be necessary to produce a related reference material. Again, CRGO steel, Metglas, different military-grade alloys, or different shape memory alloys can be taken as an example in this context. In any country, as and when manufacturing picks up in any industrial segment, related reference material preparation and production also pick up, and they need to compete globally in terms of quality and value for money. In the context of many developing countries, so long as their trading community has the political power, it is only material trading that happens, rather than local manufacturing. As and when the local educated class evolves and learns to also enjoy the political power in such developing country, the local manufacturing picks up pace. Only then can the related reference material preparation and commercialization pick up pace in general.

"NIST"-Traceable Ferrous and Nonferrous SRMs/CRMs

"The National Institute of Standards and Technology (NIST) certifies and provides more than 1300 standard reference materials (SRMs) or CRMs through their precise and harmonious measurements (Montgomery and Crivellone 2021)." These CRMs are accompanied with scientific data on well-characterized properties and compositions. Their CRMs are globally used for instrument calibrations in quality monitoring programs. Industry, academia, and government agencies make use of NIST CRMs to expedite commerce and trade and also to accelerate R&D activities. In the USA, NIST CRMs also facilitate the mechanism for supporting measurement traceability. Each NIST CRM/SRM comes with a "certificate of analysis" and a "material safety data sheet (MSDS)." The NIST CRMs are commercial reference materials with well-documented metrological traceability relationship to different existing NIST standards. This traceability relationship is recognized through norms and protocols maintained by NIST.

Table 9 (Montgomery and Crivellone 2021) illustrates typical ferrous-based CRMs/SRMs supplied by the NIST-USA. This table comprises a short description of the CRMs in different categories, such as low-alloy steels, plain carbon steels, stainless steels, high-alloy steels, and different grades of tool steel. The available form of CRMs, i.e., chips (small metal turnings), rod, disk, or any other form, is mentioned. The SRM/CRM number is also mentioned in the table. These CRMs are used for the calibration of optical emission and X-ray fluorescence (XRF) spectrometers and different other possible analytical instruments for chemical analysis. They have used different steel alloys for getting a wide range in values of elemental content. Similarly, Table 10 (Montgomery and Crivellone 2021) illustrates selected nonferrous (Al, Cu, and Ti alloy)-based CRMs/SRMs supplied by the NIST-USA. They include titanium-based, copper-based, and aluminum-based alloys among others. The available form of the CRM (i.e., chips, disk, or block form) is also mentioned in the table along with the CRM number. The aluminum-based CRMs are usable in chemical and/or instrumental methods for analysis of aluminum-based alloys. Similarly, copper-based and titanium-based CRMs are used for the analysis of copper alloys and titanium alloys, respectively, by chemical and instrumental methods. The certificate of analysis usually includes the following details: i) certified mass fraction values of elements in the ferrous/nonferrous CRM, ii) date of expiry of the certificate, iii) instructions for the maintenance of the CRM certification, iv) instructions for handling storage and use of the CRM, v) method/s employed for the preparation and analysis of the CRM, etc. The material safety data sheet (MSDS) of each CRM usually provides the following information: a) substance and source identification, b) its extent of hazardousness, c) composition and information of hazardous constituents, d) recommended first aid measures, e) possible firefighting methodologies, f) handling of accidental release situations, g) all storage and handling issues, h) requirements on exposure control and personnel protection (PPE), i) physical and chemical properties of the CRM, and j) stability and reactivity of the CRM in different ambients.

Table 9 Typical ferrous CRMs available with NIST-USA (Montgomery and Crivellone 2021)

Category and form	NIST CRM no. and description
Plain carbon steels (chip form)	**8k**: Bessemer steel, 0.1% C; **12h**: basic open-hearth steel, 0.4%C; **13g**: 0.6% C steel; **14g**: carbon steel (AISI 1078); **19h**: basic electric steel, 0.2%C; **20g**: AISI 1045 steel; **178**: 0.4C basic oxygen furnace steel; **368**: carbon steel (AISI 1211)
Low-alloy steel (chip form)	**30f**: Cr-V steel (SAE 6150); **32e**: SAE 3140; **33e**: nickel steel; **72g**: low-alloy steel (AISI 4130); **100b**: Mn steel; **125b**: LA steel, high Si; **129c**: LA steel, high sulfur; **139b**: Cr-Ni-Mo steel; **155**: Cr-W steel; **163**: Cr steel; **291**: Cr-Mo steel (ASTM A-213); **2171**: LA steel (HSLA 100)
Low-alloy steels (disk form)	**1134**: low-alloy high-Si steel; **1135**: LA steel, high Si; **1224**: LA steel, carbon (AISI 1078); **1225**: LA steel (AISI 4130); **1226**: LA steel; **1228**: LA steel, 0.1% C; **1264a**: LA steel, high C; **1265a**: electrolytic Fe; **1269**: line pipe (AISI 1526 modified); **1271**: LA steel (HSLA-100); **1286**: low-alloy steel (HY 80); **1761a**: low-alloy steel; **1762a**: low-alloy steel; **1763b:** low-alloy steel; **1764a**: low-alloy steel; **1765**: low-alloy steel
High-alloy steels (chip form)	**126c**: high-Ni steel; **344**: 15 Cr-7 Ni steel; **345b**: Fe-Cr-Ni alloy UNS J92180; **346a**: valve steel; **862**: high-temperature alloy L605; **868**: high-temperature alloy (Fe-Ni-Co)
High-temperature alloys (disk form)	**1230**: high-temperature alloy A286; **1246**: Incoloy 800; **1247**: Ni-Fe-Cr alloy UNS N08825; **1250**: high-temperature alloy Fe-Ni-Co; **C2400**: Fe-Cr-Ni alloy UNS J92180
Stainless steel (disk form)	**C1151a**: SS, 23Cr-7Ni; **C1152a**: SS, 18Cr-11Ni; **C1153a**: SS, 17Cr-9Ni; **C1154a**: SS, 19Cr-13Ni; **1155a**: SS, Cr 18 Ni 12 Mo 2 (AISI 316); **1171**: SS, Cr 17-Ni 11-Ti 0.3 (AISI 321); **1219**: SS, Cr16-Ni2 (AISI 431); **1223**: Cr Steel; **1295**: SS (SAE 405); **1297**: SS (SAE 201)
Tool steels (chip form)	**50c**: W-Cr-V steel; **132b**: tool steel (AISI M2); **134a**: Mo-W-Cr-V steel
Specialty steels (disk form)	**1157**: tool steel (AISI M2); **1158**: high-Ni steel; **1772**: tool steel (S-7)

"BAM" Traceable Ferrous and Nonferrous CRMs

"The Federal Institute for Materials Research and Testing (German: Bundesanstalt für Materialforschung und–Prüfung or BAM) is a scientific and technical federal organization in Berlin, Germany. It is under their Federal Ministry for Economic Affairs and Energy. It performs the duties of testing, conducting research, and advising their government for protecting people, the environment, and their material goods." The BAM provides its clients around the world with high-quality reference materials targeted to their needs. Globally BAM is one of the oldest certified reference materials' producers. Started in 1912 with a "normal steel" for the determination of carbon, their development of CRMs has increased progressively. Since 2016, Deutsche Akkreditierungsstelle GmbH (DakkS) has accredited BAM as a producer of certified reference materials within ISO 17034:2016 (ISO 17034 2016).

Table 10 Typical nonferrous CRMs available with NIST-USA (Montgomery and Crivellone 2021)

Category and form	NIST CRM no. and description
Aluminum base alloys (chip form)	**87a:** Si-Al alloy; **853a**: Al alloy 3004; **854a**: Al alloy 5182; **855a**: Al casting alloy 356; **856a**: Al casting alloy 380; **858**: Al alloy 6011
Aluminum base alloys (disk form)	**1240c**: Al alloy 3004; **1241c**: Al alloy 5182; **1255b**: Al alloy 356; **1256b**: Al alloy 380; **1258-I**: Al alloy 6011 (modified); **1259**: Al alloy 7075
Copper base alloys (chip form)	**158a**: Si bronze; **458:** Be-Cu (17510); **459**: Be-Cu (17200); **460**: Be-Cu alloy; **871**: phosphor bronze (CDA521); **872**: phosphor bronze (CDA 544); **874**: cupronickel, 10% (CDA 706) "high purity"; **875**: cupronickel, 10% (CDA 706) "doped"
Copper base alloys (disk form)	**1107**: naval brass UNS 46400; **1110**: red brass B; **1111**: red brass standard; **1112**: gliding metal; **1113**: gliding metal; **1114**: gliding metal; **1115**: commercial bronze standard; **1124**: free cutting brass (UNS C36000); **1276a**: cupronickel (CDA 715)
Copper base alloys (block form)	**C1115:** commercial bronze A; **C1117**: commercial bronze C; **C1251a**: phosphorus deoxidized copper-Cu VIII; **C1252a**: phosphorus deoxidized copper-Cu IX; **C1253a**: phosphorus deoxidized copper-Cu X
Titanium base alloys (chip form)	**173c**: Ti alloy UNS R564000; **647**: Ti alloy, Al-Mo-Sn-Zr; **648**: Ti base alloy 5Al-2Sn-2Zr-4Cr-4Mo; **649**: Ti base alloy (15V-3Al-3Cr-3Sn); **2431**: Ti base alloy (6Al-2Sn-4Zr-6Mo); **2432**: Ti base alloy (10V-2Fe-3Al); **2433**: Ti base alloy (8Al-1Mo-1V); **2452**: hydrogen in Ti alloy
Titanium base alloys (disk form)	**641**: spectroscopic Ti base standard Ti alloy, 8Mn (A); **643**: spectroscopic Ti base standard Ti alloy, 8Mn (C); **654b**: Ti alloy, Al-V; **1128**: Ti base alloy (15V-3Al-3Cr-3Sn)

Their scope of accreditation comprises CRMs in numerous categories, i.e., nonferrous metals and alloys, glass and ceramics, soils, lubricants, fuel, solutions of ethanol/water, stable isotopes in aqueous solutions, packaging of food, etc. The BAM-Webshop currently offers online access to more than 400 CRMs (EURONORM CRMs) in various diverse areas, such as iron and steel, polymers, environment, food, etc. (https://www.webshop.bam.de/default.php?cPath=2321_3161&sort=1a&page=1&language=en). If the matrix and analyte levels of a CRM compare closely with those of an unknown sample, the analyst is capable to assure that the measurements are conducted adequately up to the required level of precision. "EURONORM-certified CRMs are prepared under the umbrellas of the European Committee for Iron and Steel Standardization (ECISS) in collaboration between the different national producing organizations including BAM." The following types of CRMs are presently available as EURONORM CRM: unalloyed steels {0}, alloyed steels {1}, highly alloyed steels {2}, special alloys {3}, cast iron {4}, ferro-alloys {5}, ores {6}, ceramics {7}, and slags {8}. Their above system of sample numbering permits an easy idea about the type of material. The "first digit of the sample number designates the type of material (0 represents unalloyed steel, 1 represents low-alloyed steel, 2 represents highly alloyed steel, 3 represents special alloys, etc.).

Table 11 Typical ferrous CRMs supplied by BAM-Germany (Recknagel 2021)

Category and form	BAM CRM no. and description
Unalloyed steels (chip form)	**D 030-4**; **D 031-3**; **D 032-2**; **D 035-2**; **D 036-1**; **D 042-1**; **D 077-3**; **D 079-2**; **D 082-1**; **D 083-1**; **D-083-2**

Copper base alloys (disk form)	**BAM-368**: CuZn20Al2; **BAM-369**: OF-Cu; **BAM-370**: OF-Cu; **BAM-371**: OF-Cu; **BAM-372**: OF-Cu; **BAM-374**: CuSn8; **ERM-EB375 (BAM-375)**: CuZn39Pb3; **BAM-M376a**: pure copper; **ERM-EB377 (BAM-377)**: CuSn6; **ERM-EB378 (BAM-378)**: CuSn6; **BAM-M381**: pure copper; **BAM-M383b**: pure copper; **BAM-M384a**: pure copper; **BAM-M384b**: pure copper; **BAM-M385a**: pure copper; **ERM-EB387 (BAM-M387)**: CuZn20Ni5; **ERM-EB388 (BAM-M388)**: CuAl5Zn5Sn; **ERM-EB389**: CuNi25; **ERM-EB393a**: CuZn21Si3P; **BAM-M394**: CuZn40Pb2; **BAM-M394a**: CuZn40Pb2; **BAM-M396**: CuZn33Pb1AlSiAs; **BAM-M397**: CuSn4Zn2PS; **BAM-M397a**: CuSn4Zn2PS

Their second and third digit designate the specific sample. Another digit, if any, separated by a hyphen suggests the number of editions the material has passed through." Table 11 enlists typical ferrous CRMs, whereas Table 12 enlists typical nonferrous CRMs supplied by the BAM in various forms, such as chips and disks forms (Recknagel 2021). Many of these CRMs are also available in other forms like powder, pins or balls, etc.

Content of the CRM certificate. Each EURONORM CRM is provided with a certificate of analysis. The EURONORM number and the type of material of the CRM are given on the top. The mean values of the laboratories associated in the

certification are provided in a table together with the indicative values. The mean values of the parameter data sets, their overall standard deviations, and the standard deviations of the each of the laboratories are also reported in the table. "The certified reference values are given in a second table along with the associated uncertainties. The additional information made available includes a) the specific European owner lab, b) characterization methodology to be used for, c) laboratories involved in the certification process, d) the methodologies used in the elemental determination, etc."

The aluminum and copper alloy CRMs shown in Table 12 are produced and certified by BAM. This is carried out in association with the working groups of the Committee of Chemists of the Society of Metallurgists and Miners (GDMB Gesellschest der Metallurgen und Bergleute e.V.). The analyses are carried out in BAM and in other sister research laboratories. They are available in glass bottles with 100 g each. Cylindrical sample blocks are developed for a) arc/spark optical emission spectrometers (OES) and b) X-ray fluorescence (XRF) spectrometers. In interlaboratory comparisons, they use aluminum disks having height of 2.5 to 5 cm and diameter of 4 to 6 cm. Their copper blocks in cylindrical shape have a height of approximately 3 cm and 4 cm diameter. Each CRM is disseminated along with a certificate that shows the certified values together with their uncertainties and the indicative values. Other details in their certificate include a) the mean values of the accepted parameter data sets, b) their overall standard deviations, and c) the standard deviations from individual participating laboratories.

"NMIJ"-Traceable Ferrous and Nonferrous CRMs

The National Metrology Institute of Japan (NMIJ) has four types of research institutes under its umbrella, i.e., engineering measurements, physical measurements, materials-chemical measurements, and standardization of analytical instruments. These four types of research institutes take charge of supplying measurement standards in the activities primarily related to all measurement standards. The Center for Quality Management of Metrology takes care of processing administrative tasks, whereas the Research Promotion Division of NMIJ is responsible for overall planning and coordination. NMIJ produces CRMs to estimate measurement values in chemical measurements, such as calibration of analytical instruments and evaluation of different analytical procedures. In various aspects of Japanese and Asian social lives, an indispensable role is played by the NMIJ CRMs. The NMIJ CRMs are essential for industrial technology and R&D, commercial activities, environmental protection, and human health and well-being. NMIJ makes available these CRMs not only in Japan but also for the global users. A representative example can be the successful Japanese automobiles and analytical instruments and their related production methodology. As compared to NIST-USA and BAM-Germany, NMIJ-Japan has limited number of CRMs in the areas of ferrous and nonferrous alloys. Table 13 (NMIJ CRM Catalog 2021–2022 2021; NMIJ Certified Reference Materials (NMIJ CRMs) n.d.) illustrates various types of ferrous and nonferrous CRMs developed

Table 13 Ferrous and nonferrous CRMs supplied by NMIJ-Japan (NMIJ CRM Catalog 2021–2022 2021; NMIJ Certified Reference Materials (NMIJ CRMs) n.d.)

Category and form	NMIJ CRM no. and description
Industrial material CRMs for EPMA[a] (block form)	**1001-a to 1005-a**: Fe-Cr alloy; **1006-a to 1010-a**: Fe-Ni alloy; **1017-a**: stainless steel; **1018-a**: Ni(36%)-Fe alloy; **1019-a**: Ni(42%)-Fe alloy; **1020-a**: high-Ni alloy

[a]Electron probe microanalysis (EPMA)

and supplied by the NMIJ. The table shows category of the CRM and form, CRM no., and short description of the alloy system.

The certificate of each NMIJ CRM includes its scope, the measurand certified value, sample form, the preparation methodology used, analytical method used, instructions for use, etc. In some instances, indicative values are also provided. Most NMIJ CRMs have decent homogeneity and long-term stability. However, their stability can vary and some of these CRMs may have a short shelf file. The expiry date and storage conditions are specified in the certificate and attention should be paid to them. NMIJ frequently participates in the international interlaboratory comparison. In addition, like other NMIs, NMIJ is also regularly assessed for technical capability by other overseas NMIs. "The calibration and measurement capabilities (CMCs) and the range of determining the certified value for NMIJ CRMs and in fact most other NMIs are available in the key comparison database [KCDB: CIPM MRA Appendix-C (CIPM-MRA Key Comparison Data Base (KCDB) n.d.)]. The 'KCDB' is a comprehensive database managed by the International Bureau of Weights and Measures (BIPM)-France and is published on the website of BIPM. Most of the NMIJ CRMs are registered in this database and are internationally recognized."

"UK-Alloy Standards-LGC Standards": Ferrous and Nonferrous CRMs

NPL-UK as an NMI does not directly seem to have its own or outsourced metal or metal alloy CRMs. However, LGC is a British reference material producer and markets a lot of CRMs whose details are given herein, possibly taking their standard references from global NMIs including NPL-UK and NIST-USA. LGC Standards is a leading global producer and distributor of reference materials. LGC Standards is part of the LGC Group and is headquartered in Teddington, Middlesex, UK. LGC is the UK's designated national measurement institute (NMI) for chemical and bioanalytical measurements. They have expertise to produce as per highest expected

standards, by following norms set in ISO/IEC 17025:2017 (ISO/IEC 17025 2017) and ISO 17034:2016 (ISO 17034 2016). Their wide range of reference materials and proficiency testing schemes and skills is acknowledged by their experience in outsourcing and customized products. On the other hand, US-based Analytical Reference Materials International (ARMI), now part of LGC, manufactures an extensive range of high-quality metal alloy certified reference materials. In 2018, LGC, ARMI, and MBH Analytical merged into one company, creating the largest portfolio of metal alloy reference materials in the metal and alloy industry. The LCG-ARMI-MBH currently provides a wide range of CRMs including metal alloy CRMs, CRMs for nonmetallic standards, and reference materials for other industrial and for geological usage. Their CRMs are available in disks, chips, and other forms to suit various analytical techniques including optical emission spectrometry (OES), X-ray fluorescence (XRF) spectrometry, inductively coupled plasma optical emission spectrometry (ICP-OES), etc. As of today combined LGC group catalog advertises more than 600 different CRMs that include low-alloy steels, carbon steels, high-temperature and stainless steels, copper, nickel, cobalt, titanium, aluminum, and organic materials for different possible global requirements.

ARMI's typical ferrous and nonferrous CRMs are enlisted in Tables 14 and 15, respectively (Certified Reference Materials: Products and Services Catalogue 2015;

gsometal.ru/Catalogues%202011/ARMI.pdf). A key feature to these CRMs is the metrological traceability of each CRM to values from the NIST and other international certifying bodies (NMI). "These CRMs are available in the form of thin disks and chips as well depending upon the requirement. For example, thin disks may be used for X-ray fluorescence (XRF) analysis, whereas chips may be used for inductively coupled plasma optical emission spectrometry (ICP-OES) analysis." All LGC/ARMI CRMs are accompanied with a comprehensive certificate of analysis. These certificates provide a full description of the material to which they relate and summarize the analysis undertaken during the characterization process. Their certificates of analysis are prepared in compliance with ISO Guide 31:2015 (ISO Guide 31 2015), which specifies content, describing reference materials and required specifications in the certificates, and clarifies different labeling issues.

"CSIR-NPL, India": The Developing Economy/NMI and Prospects of Ferrous and Nonferrous CRMs

As discussed above, the certified reference materials (CRMs) are purposed for precise calibration of testing equipment. These CRMs are SI traceable and produced under rigorous conditions following the international standards. This is a generic requirement for achieving quality assurance in laboratories and industries. They are also used in checking calibration, testing, quality control, method validation, assigning a value to different test parameters, and establishing of traceability. In India, on behalf of the Indian government, by an Act of Parliament, maintenance of all primary and secondary standards linked to SI units and their methodologies that are acceptable globally is the mantle of CSIR-National Physical Laboratory (NMI of India). Reference materials have been developed and marketed on a limited scale by CSIR-NPL since 1984 onward. Initially these involved most essential daily life-related standard materials like water quality, calibration of alcohol meters, etc. Later, with progressive development of national industrial production base, these CRMs which were initially developed in-house have also been developed in collaboration with other national testing and certification organizations or reference material producers (RMPs). Subsequently, reference materials developed by the CSIR-NPL have started to be registered with the trademark (TM No. – 3669341) of Bharatiya Nirdeshak Dravyas (BND®). The Indian government, through its different ministries, has started to more actively support and encourage development, production, and use of such locally produced reference materials (BNDs). In the form of collaborative development of reference materials by different vendors with support from the Indian government through CSIR-NPL, over the last few years, there has been a gradual competency and capability development in the private sector. It also leads to growth of analytical laboratories, better quality control of local products, and better employment prospects for local educated youth. This is not a 1-day or a one-off process. It needs continuous support, monitoring, and often long-term handholding. In addition, these BNDs are used by government sectors and institutions, academia, private industries, etc. They are being marketed to other countries worldwide as well. If used properly, these BNDs ensure prime accuracy and reliability of their published data, with minimum uncertainties in measurements.

In the Indian context, the primary responsibility of alloy-related research and development lies with CSIR-NML. They also have their portfolio of reference materials within the alloys and related raw material items. Military usage-related niche sector alloys and their quality issues are handled by a few specific laboratories of Defense Research and Development Organization (DRDO). It is expected that CSIR-NML will slowly improve their portfolio of reference materials within the BND® brand. Large-scale steel production in India has been traditionally handled by Steel Authority of India Ltd. (SAIL). However, in the recent past, a lot of private players have started slowly entering this field. So there needs to be a standardization and quality control of all their products. In addition, there are also a lot of cheap/economic imports of different grades of alloys but of questionable quality (Karar et al. 2022; Paul 2009). All of these need uniformity of quality so that the Indian

population is not cheated of their hard-earned money. Steel Authority of India Ltd. (SAIL) has been traditionally getting its quality control done by its in-house Research and Development Center for Iron and Steel (RDCIS). It is thus possibly imperative that in the long term, RDCIS in association within CSIR-NML also slowly comes within the BND® umbrella for all steel-related reference materials for better control of all local and imported steel items. Currently, there is no Indian-made reference material for aluminum- or titanium-related alloys, even though India has significant deposit of its ores and is currently extracting both these metals and producing related alloys. In the medium and long term, CSIR-NML may, in due course, release related BNDs for better quality control of these too.

CSIR-NPL has recently initiated a mission mode program for greater dissemination of different BNDs through different reference material producers (RMPs) in the country primarily accredited for their ISO 17034:2016 scope by the National Accreditation Board for Testing and Calibration Laboratories (NABL), Gurugram (India). Under the aegis of this national-level initiative, CSIR-NPL shall establish the measurement traceability of all such BNDs, in various possible commodities, like chemicals, cement, petroleum products, food, textile, precious metals, instruments, ores and minerals, etc. Related agreements have been signed by CSIR-NPL with numerous RMPs, viz., Aashvi Technologies LLP, Ahmedabad; NCCBM, Ballabgarh; HPCL, Vizag; FARE Labs Pvt. Ltd., Gurugram; Global PT Provider Pvt. Ltd., New Delhi; MINT, Mumbai; BPCL, Mumbai; Jalan and Co., New Delhi; CSIR-IITR, Lucknow; etc., in various sectors like chemicals, cement, petroleum-based products, food safety, hardness blocks, precious metals, pharmaceuticals, etc. As of today, close to 120 BNDs were established by CSIR-NPL in the above-described sectors in collaboration with the different RMPs and also under the in-house BND® development program (https://www.nplindia.org/wp-content/uploads/2021/11/Available-Bharatiya-Nirdeshak-Dravya-list-251220.pdf; Singh et al. n.d.; Pant et al. 2020).

Each BND® certificate supplied by CSIR-NPL contains, on the top, the BND® no. and BND® name, parameter certified, and certificate number. The BND® supplier name, its intended use, packing details, method of certification, and details of standards followed are given. The certificate also contains details, such as certified value of the parameter and expanded uncertainty, traceability, instructions for storage, usage, and precautions for handling. Additionally, the date of certification and expiration period, conditions for maintenance of certification, etc. are also given in the certificate. A disclaimer is also given in the certificate incorporating zero liability for damages due to any misuse of information, material, apparatus, process, or method disclosed in the certificate or any warranties for material safety. In spite of tremendous efforts made by CSIR-NPL on numerous fields of BND® development, the development of ferrous- and nonferrous-based CRMs/BNDs is yet in the initial stages. In this line, CSIR-NPL has recently developed precious metal BNDs (such as high-purity gold and silver and their alloy BNDs) in collaboration with MINT, Mumbai, and Jalan and Co., New Delhi. Although a long way to go, the huge initiatives of CSIR-NPL for CRMs, under the "Make in India" program of the government of India in the long run is expected to bring an enhancement in quality

of products in the country for local consumption, export, and import. Production and certification of BNDs will accelerate economic growth and employment in the country and enhance global viability of Indian products.

Summary and Conclusion

Certified reference materials (CRMs), as defined above, have a vital significance in the economic growth of any country. Numerical values measured using a comparison with different CRMs are considered accurate and reliable Standard Reference Material (SRM). In this manner, all CRMs are used in the calibration of different analytical equipment. They ensure reliability and traceability to the international measurement system (SI units). CRMs available with developed economies/NMIs, such as NIST-USA, BAM-Germany, NMIJ-Japan, and ARMI (part of LGC Standards, UK), have been discussed in this chapter. In earlier sections, a summarized discussion is made on different types of cast irons, steels, tool steels and stainless steels Ferrous Alloy Systems and aluminum alloys, copper alloys and titanium-based alloys Non Ferrous Alloy Systems developed internationally. In the later sections, the ferrous- and nonferrous-based CRMs are paid attention during the discussions. While NIST-USA on an overall supplies more than 1300 CRMs, BAM-Germany produces more than 400 CRMs; the LCG-ARMI-MBH group has catalogued more than 600 different CRMs in a variety of fields; therefore, their impact on the global economy is enormous. The NIST-USA, BAM-Germany, and LGC-UK (with ARMI) produce a significantly large number of ferrous and nonferrous CRMs (see Table 9, Table 10, Table 11, Table 12, Table 14 and Table 15). In contrast, NMIJ-Japan produces only limited number of these CRMs (see Table 13). CSIR-NPL, India, is a developing NMI and produces close to 120 CRMs as of today with the tradename BND® in the areas of chemicals, cement, fuels and petroleum products, food, textile, hardness blocks, ores and minerals, precious metals, etc. The CSIR-NPL's CRM/BND development initiatives fall under the "Make in India" program of the government of India. However, CSIR-NPL is in the initial stages of development of ferrous- and nonferrous-based CRMs/BNDs. Finally, it may be concluded that CRMs play an important role in the human life today and they are essentially needed for the economic growth of the developed as well as developing countries/NMIs. Further, it is concluded that the developed economies/NMIs contribute to the major share of ferrous and non-ferrous based CRMs supplied to the international market today and the developing economies/NMIs have yet to make a visible impact in this frontier area of Science and Technology.

Abstract

Cement industry plays a vital role in the growth and economic development of the country because of its strong linkage to other sectors such as infrastructure, construction, housing, transportation, coal, power, etc. To ensure the conformity of products,

cement manufacturers are calibrating the equipment with Certified Reference Materials (CRMs) from time to time to improve the quality of the products and fulfill the norms set by BIS, the standardization body of GoI. These CRMs help to maintain the quality control and quality assurance of the products with accurate and precise measurements, which will improve the country's quality infrastructure.

Introduction

India has emerged as one of the fastest-growing major economies in the world and is expected to be one of the world's top five to six economic powers shortly (https://www.ibef.org/economy/indian-economy-overview). Among the eight core industries of India, the cement industry plays a vital role in the growth and economic development of the country because of its strong linkage to other sectors such as infrastructure, construction, housing, transportation, coal, power, etc. The recent focuses of the Government of India (GoI) on Housing for all by 2022, Make in India, World Class Cement Concrete Highways, Creation of 100 Smart cities, Dedicated Freight Corridors, Clean India Mission, Ultra Mega Power Projects, Connectivity improvement including Water Transport are bringing a big boost in infrastructure developments and housing sectors. The cement industry has to play a pivotal role in the success of these initiatives of GoI.

In the global cement market, India is the second largest cement producer in the world after China and it has evolved to become one of the best in terms of energy efficiency, quality control, and environmental improvements. Nonetheless, the cement industry has strongly contributed to employment, fiscal revenue, and community development while achieving manufacturing and technological advancement/excellence. The installed capacity of the cement industry in India as per a survey (NCCBM) in 2018–2019 has shown to be 537 million tonnes, with cement production of around 337 million tonnes, which comprises 145 integrated large cement plants, 107 grinding units, 62 mini cement plants, and 5 clinkerization units (NCCBM 2019). Cement consumption in India is still around 235 kg/capita against the global average of 520 kg/capita, which shows significant potential for the growth of the industry (https://www.business-standard.com/article/news-cm/domestic-cement-consumption-around-235-kg-per-capita-against-global-average-of-520-kg-per-capita-119020600509_1.html).

To ensure the conformity of products, cement manufacturers are calibrating the equipment with Certified Reference Materials (CRMs) from time to time to improve the quality of the products and fulfill the norms set by BIS, the standardization body of GoI. These CRMs help to maintain the quality control and quality assurance of the products with accurate and precise measurements, which will improve the country's quality infrastructure.

About CRMs

In the present scenario of globalization of economy, globally acceptable measurements are required where the availability of Reference Materials becomes crucial for universal acceptance of products and test reports. Reference material is characterized

by a metrologically valid procedure for one or more specified properties, accompanied by a reference material certificate that provides the value of the specified property, its associated uncertainty, and a statement of metrological traceability. These materials ensure high quality in measurement and provide SI traceability to analytical measurements. Certified Reference Materials (CRMs) of cement and cementitious products are regularly used in the cement and concrete industry. CRMs are an important tool in realizing several aspects of measurement quality and are used for calibration of online and offline X-ray analyzers, validation of test methods, establishing purity of materials, and studying microstructural & phase compositions.

In the broader sense, CRMs ensure:

- Clearly defined customer requirement
- Validated methods and equipment calibration
- Global comparability of measurements
- Independent evidence of performance through proficiency testing
- Well-defined QC and QA procedures

Reference materials of various commodities such as cement, ores, rocks, semi-processed ores, food, drugs, and many more are being produced by several organizations. The top contributors in the area of reference materials are NIST (National Institute of Standards and Technology, USA), Certipur Reference Materials, PTB, Germany, China Reference Materials, NIM, China, European Reference Materials, JRMM, Belgium, Thailand Reference Materials, NIM, Thailand, etc. Besides, many ISO 17034 accredited laboratories are also producing CRMs in the areas of Food, water, cement, petroleum products, metal, etc.

Recently, National Physical Laboratory (CSIR-NPL), India, has taken a step forward to develop CRMs named BND in various commodities like Cement, Water, Petroleum, food, etc. CSIR-National Physical Laboratory (NPL-India) is mandated to be India's "National Measurement Institute" (NMI) by the act of Parliament. It is the custodian of "National Standards" with responsibility for the dissemination of measurements to the needs of the country. It brings a boost to harmonize the quality infrastructure of the country and improve the economy of the Nation.

Cement-Related CRMS

Reference Materials (RM) in the area of cement and cementitious materials around the world (Standard Reference) are Portland Cement Fineness, Portland Cement (Blended with Slag), Portland Cement (Blended with Fly Ash), Calcium Aluminate Cement, White Portland Cement, Portland Cement (Blended with Limestone), Calcined Clay Cement, Portland Cement Clinker, Coal Fly Ash, Bituminous Coal, Silica Fume, Bauxite, Calcined Clay, Hydrated Lime, Petroleum Coke, Feldspar, Iron Ore, Laterite, Limestone, etc.

Requirement/Consumption of CRMS in Indian Cement Industry

In India, there are 145 integrated large cement plants, 107 grinding units, 62 mini cement plants, and 5 clinkerization units and 3400+ accredited testing laboratories as per ISO 17025, out of which >1350 laboratories are (Directory of Accredited) serving the construction industry wherein they require CRMs for their regular quality checks. On average, with a minimum of 10 units of CRM consumption in cement plants/laboratories, the annual requirement of CRM units would be around 17,000 units. As the construction industry and cement plants are growing consistently, the industry's requirement for CRMs is increasing yearly.

Currently, in India, there are 17 reference material producers in various fields as per ISO 17034 and NCB is the leading organization among them which develops CRMs in cementitious materials. NCB has been facilitating the cement and construction laboratories by supplying reference materials of cement and Cementitious materials since 1990. Besides, NCB is accredited with ISO 17034:2016 as a Reference Material Producer (RMP) in India and follows all the relevant standards while developing the CRMs to meet the specific requirement. Annually approx. 12,000 units of CRMs are being supplied to the cement and construction laboratories, saving approximately the import of CRM's worth INR 250 lakhs/annum (source: NCB databank).

Production Process of CRM

The process for developing Certified Reference Materials (CRMs) is very important and a systematic approach is retained to establish the reference material's property value.

The process is covers the following (ISO17034:2016):

- Material selection
- Verification of the identity of the material
- Maintaining suitable environments for all the aspects of production
- Material processing
- Choice of measurement procedures
- Validation of measurement procedures
- Verification and calibration of measuring equipment
- Specification of acceptance criteria for, and assessment of homogeneity, including sampling
- Specification of acceptance criteria for, and assessment and monitoring of, stability, including sampling
- Designing and organizing appropriate characterization, including sampling
- Assigning property values
- Establishing uncertainty budgets and estimating uncertainties of certified values
- Defining acceptance criteria for measurand levels and their uncertainties
- Establishing metrological traceability of measurement results and certified values

An example of chemical parameters and physical parameters of cement and cementitious materials are illustrated hereunder.

Chemical Parameters

The raw materials used to manufacture cement consist of CaO, SiO_2, Al_2O_3, Fe_2O_3, MgO, Na_2O, K_2O, and SO_3. Cement consists of lime (CaO) at about 60–67%, and it is cement's important and major ingredient. Lime is the main material for the manufacture of cement. Lime imparts strength and soundness to the cement; if it presents in excess quantity, it makes it expand and disintegrate. It adds strength and usability to cement. If the amount is too much, it makes cement expand and disintegrate. Silica is the next major ingredient in cement. The composition of silica in cement is about 14–25%. Adding a sufficient quantity of silica imparts strength to the cement. However, excess silica in cement will increase cement's strength, but cement's setting time also increases. Alumina is about 3–8% in cement, giving the cement an instantaneous setting property. It acts as a flux and reduces the clinkering temperature. An excessive amount of alumina reduces cement fixed time but, simultaneously, reduces cement strength. Iron oxide is around 0.1–5.0% in cement. It imparts color to cement and acts as a flux. It enters into a chemical reaction with calcium and aluminum at very high temperatures to form tricalcium alumino-ferrite. Tricalcium aluminum ferrite gives hardness and resistance to cement. Also it contains MgO (0.1–4.0%), Na_2O and K_2O (0.1–1.3%), and SO_3 (1–3%) (Taylor 1997).

NCB develops several raw materials and cement BNDs such as coal, fly ash, raw meal, limestone, clinkers, OPC, PPC, and composite cement. The developed BNDs are validated and certified for their chemical parameters per Indian Standards. These standard methods are essential adjuncts to the cement specifications because defective test methods may lead to wrong conclusions about cement quality. Parameter such as Loss of Ignition (LOI) is estimated as per IS 1760 (Part 1):1991, SiO_2 as per IS 1760 (Part 2):1991, and Fe_2O_3, Al_2O_3, CaO, MgO as per IS 1760 (Part 3):1992. The amount of SO_3 is evaluated as per ASTM – C-25:2017 and TiO_2 as per IS 12423:1988. The analysis of Mn_2O_3 and P_2O_5 has been carried out as per the NCB monograph (MS-5-79). Estimating Cl is as per IS 1760: (Part 5):1991. However, in the case of clinkers and cement, including OPC and PPC, LOI, CaO, SiO_2, Fe_2O_3, Al_2O_3, MgO, SO_3, IR, and Cl have been estimated carried out as per IS 4032:1985. The Alkalis such as Na_2O and K_2O are analyzed as per NCB standard procedure, MS-13-2010. The associated measurement uncertainty was calculated at a 95% confidence level with coverage factor $k = 2$, considering significant sources of uncertainty, including measurement replication, instrument background, the mass taken, possible heterogeneity, and stability factors according to ISO GUM Guide (JCGM 100.2008) and ISO Guide 35 as given in Table 1. Figure 1 shows the limestone, raw meal, clinkers, and composite cement BNDs. Figure 2 shows the instrument used for making and characterizing the cement BNDs.

Loss of ignition is the process of measuring the weight change of a sample after it has been heated to a high temperature causing some of its content to burn

Table 1 Certified values and associated measurement uncertainties of chemical parameters of limestone, raw meal, clinkers, and composite cement, respectively

	Lime stone		Raw meal		Clinkers		Composite cement		Portland Pozzolana Cement	
Chemical constituents	Certified values (Wt. %)	Expanded uncertainty, $k = 2$	Certified values (Wt. %)	Expanded uncertainty, $k = 2$	Certified values (Wt. %)	Expanded uncertainty, $k = 2$	Certified values (Wt. %)	Expanded uncertainty, $k = 2$	Certified values (Wt. %)	Expanded uncertainty, $k = 2$

or to volatilize. The cement industry utilizes the LOI method to determine the cement's water content and/or carbonation as these reduce the quality. These tests are carried out at high temperatures (900–1000 °C) using the muffle furnace. The EDTA titration method determines parameters such as CaO, MgO, Al_2O_3, and Fe_2O_3. Alkalies are estimated using flame photometry or by Atomic Absorption spectrophotometer. TiO_2, MnO_2, and P_2O_5 are determined using UV-Vis spectroscopy.

Physical Parameters

The development of composite cement is illustrated (BND 5006) on physical parameters such as Blaine fineness as an example. The development of said certified reference material is followed as per the guideline of ISO 17034 and guide 35. The process covers material selection and verification, material processing (blending/grinding), Homogeneity, characterization, stability, packaging and certification, etc.

A systematic approach is presented below:

Material Selection and Verification

A similar matrix of a new lot of the material (Composite Cement Brand) for preparing CRM is sourced from the industry. The material is checked for compliance with product specifications laid down by BIS as per IS 16415:2015.

Material Processing

The material is sieved to eliminate any foreign particles and further blended and ground in a laboratory ball mill to ensure the proper sample homogeneity.

Fig. 2 Instruments used for making and characterizing the cement BNDs

Packaging

After proper homogenization, the sample is packed in an airtight bag to avoid the hydration of cement during storage prior to preparation and packaging. Then each bag is packed into different vials and capped, then packed in a box. Approx. 600 vials were produced, each containing approximately 10 g of cement. The vials are randomly selected (randomly block design) and sent to the subcontracted laboratories for measurements: homogeneity, characterization, stability, etc. After analyzing the results, the vials are packaged in small boxes containing four vials each.

Homogeneity

After the material is packed, the material is tested for homogeneity check to determine whether the material in different vials is the same. Minimum number of samples (ten nos) as per ISO GUIDE 35:2017 is drawn from the homogenized sample (randomize block design) for statistical check of homogeneity. The criterion for acceptance is decided before the assignment of property value.

Minimum number of units Nmin for a homogeneity study of materials characterized for a quantitative property given by:

$$\text{Nmin} = \max\left(10, 3\sqrt{\text{NProd}}\right) \tag{1}$$

where max (. . . , . . .) indicates the maximum of the terms within the parentheses. The maximum number of units for assessment of homogeneity is limited to not more than 30 units.

The laboratory is asked to measure triplicate samples from each vial. The received data is analyzed and evaluated through statistical analysis through the ANOVA method (ANOVA two factor without replication) to validate the homogeneous nature of the sample.

Characterization

To process the characterization of the material, an operationally defined measurand using a network of competent laboratories method is followed as per ISO GUIDE 35:2017. The analytical/testing work for characterization is done in sub-contracted laboratories accredited as per ISO 17025 and following IS test method. Composite Cement vials (total 24 nos) is sent to the subcontracted laboratories for fineness determination. The laboratories are asked to measure duplicate samples from each vial. The received data is analyzed and evaluated through statistical analysis. For determination of the property value of composite cement, a robust statistic calculation along with a Guide to the Uncertainty of Measurement (GUM) is considered for evaluation of the results.

Description of Method for Determining Blaine Fineness

The Blaine measurement is described in IS 4031(Part 2):1999. The principle of operation is that the permeability of a bed of fine particles is proportional to the fineness of the particles. Therefore, the test measures the flow rate of air through a bed of cement particles. Figure 3 shows the air permeability apparatus.

In brief, the test is carried out by packing the cement to be measured in a cell of known volume and placing it on top of a U-tube manometer that contains a non-hygroscopic liquid of low viscosity and density, e.g., dibutyl phthalate. The cell is placed on the U-tube so that a tight seal is created and a vacuum is created under the cement cell so that the liquid in the manometer is higher toward the cell. Then, the air is allowed to flow back only through the cement sample. The time for the liquid in the manometer to descend a set distance is measured. This time is used to calculate the fineness quantified by the surface area (S) of the cement defined using the following formula:

Fig. 3 Air permeability apparatus

The volume of cell = 1.6778
Bed weight (W) = Volume of cell × specific gravity × porosity (1 − e)

$$S = \frac{\rho_0}{\rho} \times \frac{(1 - e_0)}{(1 - e)} \times \frac{\sqrt{e^3}}{\sqrt{e_0^3}} \times \frac{\sqrt{t}}{\sqrt{t_0}} S_0 \tag{2}$$

S_0 is the specific surface of the reference cement (cm^2/g).
e is the porosity of the bed of cement under test.
e_0 is the porosity of the bed of reference cement.
t is the measured time for the cement under tests(s).
t_0 is the mean of the three times measured on the reference cement(s).
ρ is the density of the cement under test (g/cm^3).
ρ_o is the density of the reference cement (g/cm^3).

Stability

Minimum number of Samples as per ISO GUIDE 35:2017 is drawn from the composite cement lot for statistical stability check.

$$|XCRM - Xmon| \leq k\sqrt{(u2CRM + u2mon)} \tag{3}$$

XCRM = Certified value
Xmon = Monitoring value
uCRM = Standard uncertainties of the certified value
umon = Standard uncertainties of monitoring value
k = coverage factor at confidence level of 95%

Table 2 Certified values and associated measurement uncertainties of physical parameters of composite cement

Measurand	Estimation method	Certified value and expanded uncertainty
Specific surface area (Blaine)	IS 4031 (Part 2):1999	360 ± 8.2 m^2/kg

The certified value has been standardized with a specific gravity of 2.85

Fig. 4 Composite cement (Blaine fineness)

Certification

As the CRM of composite cement is developed, the CSIR-NPL team witnessed the test results to ensure the results validation and further certification for Bharatiya Nirdeshak Dravya (BND) through NMI of India. The certified value of the CRM is mentioned in Table 2 and the CRM specimen of composite cement is shown in Fig. 4.

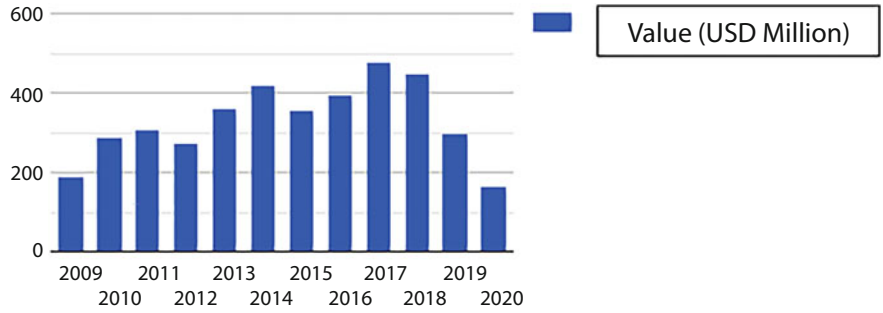

Fig. 5 Historical export analysis of cement from India (https://connect2india.com/global/export-Cement-from-india)

Impact on Import/Export

Cement manufactured in India is traded all over the world. Almost 176 countries and territories like the USA, United Arab Emirates, Sri Lanka, Nepal, Bangladesh, etc., actively import cement from India. The combined value of total export is 164.01 USD million for the year 2020. Historical export analysis of cement from India is given in Fig. 5 (https://connect2india.com/global/export-Cement-from-india).

Historical export analysis of cement from India shows that the cement export is increasing consistently from 2009 onwards except for 2019 and 2020 due to the Covid-19 pandemic. It shows that the acceptability of cement manufactured in India further increased among the countries due to precise measurement contribution after the development of BNDs in India.

CRMs are being produced at a very high cost; India is importing CRMs worth INR 1000 crores/annum (BND Coffee Table Book, NPL). It emphasizes a need for indigenous development of CRMs which will contribute to saving the import cost and also support the "Make in India" and "Self-reliance" pledge of Govt. of India.

In view, the Government of India decided to develop its standard material as Bharatiya Nirdeshak Dravya (BNDs), i.e., Indian Certified Reference Materials, through National Physical Laboratory (NPL), India, in the year 2018. CSIR-NPL and NCB have been working together to provide traceability for the reference materials in cementitious products for making such CRMs that are traceable to SI units. So far, 16 BNDs have been developed in Cement and Building materials and more number of BNDs are in the development phase. The list of available BNDs and their application is given in Table 3.

Requirement of New CRMS

Sustainable development has led to the necessity to implement changes toward balancing all the areas of human activity, including the construction sector. As the cement and construction industry is moving toward sustainability, there is a demand

Table 3 BNDs and their application

Sl. no.	Name of BND	Purpose/intended use
1.	Ordinary Portland Cement (OPC)-Blaine fineness **(BND 5001)** – range: 250–300 m^2/kg	Calibration of Blaine air permeability apparatus
2.	Ordinary Portland Cement (OPC)-Blaine fineness **(BND 5021)** – range: 320–360 m^2/kg	Calibration of Blaine air permeability apparatus
3.	Ordinary Portland Cement (OPC)-Blaine fineness (**BND 5011)** – range: 400–450 m^2/kg	Calibration of Blaine air permeability apparatus
4.	Fly ash-Blaine fineness **(BND 5004)**	Calibration of Blaine air permeability apparatus
5.	White Portland Cement (WPC)-Blaine fineness **(BND 5007)**	Calibration of Blaine air permeability apparatus
6.	Portland Pozzolana Cement (PPC)-Blaine fineness **(BND 5002)**	Calibration of Blaine air permeability apparatus
7.	Portland Slag Cement (PSC)-Blaine fineness **(BND 5003)**	Calibration of Blaine air permeability apparatus
8.	Composite Cement-Blaine fineness **(BND 5006)**	Calibration of Blaine air permeability apparatus
9.	Limestone-Chemical parameter **(BND 5056)**	Calibration of instrument (UV-Vis spectroscopy, flame photometer) and validation of method for characterization of the measurand for analysis of limestone
10.	Ordinary Portland Cement (OPC)-Chemical parameter **(BND 5051)**	Calibration of instrument (UV-Vis spectroscopy, flame photometer) and validation of method for characterization of the measurand for analysis of OPC
11.	Clinker-Chemical parameter **(BND 5058)**	Calibration of instrument (UV-Vis spectroscopy, flame photometer) and validation of method for characterization of the measurand for analysis of clinker
12.	Portland Pozzolana Cement (PPC)-Chemical parameter **(BND 5052)**	Calibration of instrument (UV-Vis spectroscopy, flame photometer) and validation of method for characterization of the measurand for analysis of PPC
13.	Raw Meal-Chemical parameter **(BND 5057)**	Calibration of instrument (UV-Vis spectroscopy, flame photometer) and validation of method for characterization of the measurand for analysis of raw meal
14.	Fly ash-Chemical parameter **(BND 5054)**	Calibration of instrument (UV-Vis spectroscopy, flame photometer) and validation of method for characterization of the measurand for analysis of Fly ash
15.	Coal-Chemical parameter **(BND 5091)**	Calibration of instrument (Bomb Calorimeter) and validation of method for characterization of the measurand for analysis of coal

(continued)

Table 3 (continued)

Sl. no.	Name of BND	Purpose/intended use
16.	Composite Cement-Chemical parameter **(BND 5055)**	Calibration of instrument (UV-Vis spectroscopy, flame photometer) and validation of method for characterization of the measurand for analysis of composite cement

for more CRMs in cement and building materials. NCB has produced 18 BNDs, including solid fuel (Coal). In addition, NCB is also producing other Reference Materials(RMs) viz. Granulated Glass Blast Furnace Slag- Blaine fineness, Calcined clay, pet-coke, silica fume, Iron ore, Red ochre, sand, Bauxite, White Portland Cement- chemical, Oil well cement-chemical, etc. Nevertheless, other CRMs available in the global market like Flue Gas Desulfurization Gypsum, phospho gypsum, Refractories (powder form), clinker phases for XRD calibration, etc.

In cement manufacturing, XRF/XRD is a state-of-the-art instrument that can provide complete quality control of clinker and cement. The X-ray fluorescence technique (XRF) is used to perform chemical elemental analysis on cement-making materials and X-ray diffractometry (XRD) equipment is typically required to determine the phase content in clinker or cement. On the other hand, the (XRD) system has the capability of measuring *quartz in raw meal*, *free lime* (CaO), and clinker phases, as well as calcite ($CaCO_3$) in cement. NCB has been developing secondary standard materials for XRF/XRD calibration for the specific cement plant product in the last two decades to improve its quality system.

In view of the above, the existing RMs is needed to be transformed into BNDs shortly and further development of the new BNDs like XRD for clinker phases, FGD gypsum, etc. meet the global gradient.

Future Goals

Research and Innovation play a pivotal role for any organization to remain competitive and keep pace with the demand and growth of society and the country. National Council for Cement and Building Materials (NCB), a premier Research, Development and Innovation institution, is equipped with multi-disciplinary expertise and state-of-the-art testing and evaluation facilities. Keeping in view the growing importance of CRMs/BNDs of cement and cementitious materials in India and Global, NCB and CSIR-NPL are aiming to develop more no. of Indian Certified Reference Materials in the areas of Cement and Building products to meet the National and Global demand. Our mission is always to provide our stakeholders with the best innovative solutions and quality products based on top-level advanced techniques.

Role in Indian Economy/GDP

Honorable Prime Minister of India, Narendra Modi Ji, dreams of making India a USD 5 trillion economy (https://pib.gov.in/) and a vision of "Atmanirbhar Bharat" or **self-reliant India**. CSIR-NPL has started a great initiative toward Atmanirbhar Bharat and Make in India through the BND program. These BND products will substitute imports and create a market capitalization for overseas industries and laboratories. The increasing supply of BNDs to domestic and international markets will contribute to the country's GDP and boost India's economy.

Conclusion

Certified Reference Materials (CRMs) of cement and 60 cementitious products are regularly used in the cement and concrete industry. CRMs are an important tool in realizing several aspects of measurement quality and are used for calibration of online and offline X-ray analyzers, validation of test methods, establishing purity of materials, and studying microstructural and phase compositions. The development of said certified reference material is followed as per the guideline of ISO 17034 and guide 35. The process covers material selection and verification, material processing (blending/ grinding), homogeneity, characterization, stability, packaging, and certification. As the CRM of composite cement is developed, the CSIR-NPL team witnessed the test results to ensure the results validation and further certification for Bharatiya Nirdeshak Dravya (BND) through NMI of India.

Abstract

India is the second-largest refiner in Asia and the fourth largest globally. Its crude oil import was US dollars 101.4 billion in 2019–2020. The economic progress of India is closely linked to its energy demand. Therefore, the need for oil and gas is expected to grow more, making the oil sector more attractive for investment. It makes it indispensable to have a stringent check on the quality of imports and exports of petroleum products. The results from lab tests play a significant role in ascertaining the quality of petroleum products. Using BNDs ensures that laboratory instruments perform to the standard of predefined value, thus assuring laboratory tests' accuracy. With the nonavailability of indigenous certified reference materials, domestic refiners have been importing the materials from other economies. CSIR-NPL has partnered with HPCL and BPCL to produce 28 BNDs, and the list is growing continuously. The petroleum BNDs are expected to save foreign exchange and time, avoiding delays in receiving imported reference materials. Also, with the availability of BNDs to the Middle East, the African continent will love to grow our business. The petroleum BNDs include BNDs for the various concentration of sulfur, flash point (PMCC and Abel), smoke point, distillation standards, pour point, color saybolt, color ASTM, total base number, total acid number, FIA aromatics, olefins, saturates, density, kinematic viscosity at different temperatures, freezing point, etc.

Introduction

Certified reference materials (CRMs) are essential for ensuring the quality infrastructure of any economy through testing and calibration with accurate and precise measurements traceable to standard units (Aswal 2020). Reference materials are needed due to rapid industrialization in various industries, including the environment, food and agriculture, petroleum products, etc. (Clapp 1998). The primary standard that guarantees the accuracy and comparability of the measurements as a baseline for the quality assurance attained through global networking is Bharatiya Nirdeshak Dravya (BND) (Neyezhmakov and Prokopov 2014). Many academic institutions and enterprises are made economically feasible by the BNDs produced at CSIR-NPL, which acts as an import substitute.

Accurate analytical results are the foundation for many essential conclusions on trade, business, legal matters, and resolving disputes (Gundlach and Murphy 1993). Accurate analytical results entail using certified reference materials, validated procedures, trained personnel, and CRMs (Maier 1991). Numerous international, national, and professional organizations have formed and strongly advocated using CRMs in analytical chemistry for quality control objectives (Charantimath 2017). It is essential to characterize samples together with CRMs to sustain the measurement procedure's long-term reliability (Kestens and Koeber 2022). Introducing petroleum CRMs facilitates quick access to petroleum-based laboratories and aid in the production of high-quality petroleum data (Pant et al. 2020).

CSIR-National Physical Laboratory (NMI of India) produced 10 BND®s in 2018 for chemical properties in petroleum products as per ISO 17034:2016 and ISO Guide 35 accreditation and legal metrology alignment with NMI. To produce BNDs on a broad scale, coherence between these bodies and NMIs must be planned. Now more than ever, NMIs must expand their skills to create various CRMs and BNDs in response to market needs. CSIR-NPL has taken the lead in this area by establishing MoUs with numerous RMPs to meet national and international demand.

Significance of Reference Standard and International Network

From the Bharat Stage (BS) VI emission standards and air quality perspective, the most important parameter defined in the fuel quality specifications is the maximum sulfur content of gasoline and diesel fuels in both cases; sulfur content is limited to a maximum of 10 ppm in the proposed BS VI regulation, which matches global best practices (Bharj et al. 2019). In BS-VI fuels, sulfur content is one of the critical parameters; it helps to meet BS VI emission norms and to decrease environmental pollution, low carbon footprint, and significant improvement in human health (Borkhade et al. 2022). The quality of many petroleum products is related to the mass fraction of sulfur present (Orr and Sinninghe Damsté 1990). There are also regulations promulgated in international, national, state, and local agencies that restrict the amount of sulfur present in some fuels, which causes a release of harmful sulfur oxides into the atmosphere (Engdahl 1973).

To date, internationally known sulfur standards are available, viz., SRMs were produced by NIST (National institute of standards and technology, USA) and a few other global ISO 17034:2016 accredited RMPs. All users had to procure these imported standards at very high prices and with long lead times for receipt (Martin et al. 2000).

There were no established reference material producers in India to cater to requirements. HPCL (ISO 17034:2016 accredited reference material producer) and CSIR-National Physical Laboratory (NMI of India) came forward to address the need in the year 2018; a total of 29 BND®s were launched jointly, and 10 sulfur BND®s are also part of the same.

Significance of Indian Reference Standard

The use of petroleum-based BNDs/IRMs for metrological perspectives such as testing, calibration, method validation, repeatability, reproducibility studies, control chart preparation, inter-laboratory comparison, quality control, and quality assurance has been discussed (Vempatapu and Kanaujia 2017). A detailed production/development process starting from planning the intention to produce the parameter with matrix to preliminary studies of homogeneity, stability, validation, assignment of property value with its associated uncertainty, and complete certification process of petroleum-based BNDs/IRMs is described. It is also discussed how the BND/IRM Division supports the reference material producers (RMPs) and various commodities

to produce BNDs, in which the traceability is established by NPL(I). Through dissemination of BNDs and rendering services to the Accreditation Body and Bureau of Indian Standard (BIS), the quality infrastructure of India can be strengthened. The impact of BNDs in the formulation in trade is narrated along with the conclusions and future perspectives. Further, it is planned to produce a series of petroleum-based BNDs starting from quantum standard, thermoelectric metrology, nanometrology, etc., which will be the future avenue of metrological activities. BNDs are Indian reference standards developed by Indian NMI CSIR – National Physical Laboratory and other Indian reference material producers.

Significance of NMI of India in Petroleum-Based BNDs

To establish national standards and disseminate traceability throughout the nation, the National Metrology Institute (NMI) plays a significant and vital role (Aswal 2020). NMI is responsible for maintaining national standards and approved reference materials (Kumari et al. 2021). As the NMI of India, the CSIR-NPL not only took part in and contributed to the BIPM and APMP but also achieved many CMCs for the nation. Various county stakeholders are informed of the metrological traceability, directly or through legal metrology, and NABL-approved laboratories.

Petroleum Products (BNDs)

Petroleum BNDs are helpful in:

1. Bringing traceability of measurement to Indian National Standard.
2. Reduce dependence on imported reference materials.
3. Calibration and performance evaluation of measuring equipment.
4. Method (measurement procedure) validation.
5. Comparison of different measurement procedures, etc.

Stakeholders:
1. Govt. of India “Maharatna” CPSE, Forbes 2000 Company.
2. Refining and marketing of petroleum products.
3. Listed on BSE and NSE.
4. Owns two refineries (Mumbai and Visakhapatnam).
5. Stake in HMEL and MRPL.
6. Retail outlets – 20,025, LPG Dealerships – 6243.
7. Locations: 140, ASF-47, pipeline length: 3775 KM.

CSIR–NPL achieved a significant milestone by releasing 28 petroleum BNDs in association with HPCL (Pant et al. 2020). The 28 petroleum BNDs jointly developed by HPCL and CSIR-NPL will provide traceability for all vital parameters of petroleum products testing and certification, comprising 12 physical properties,

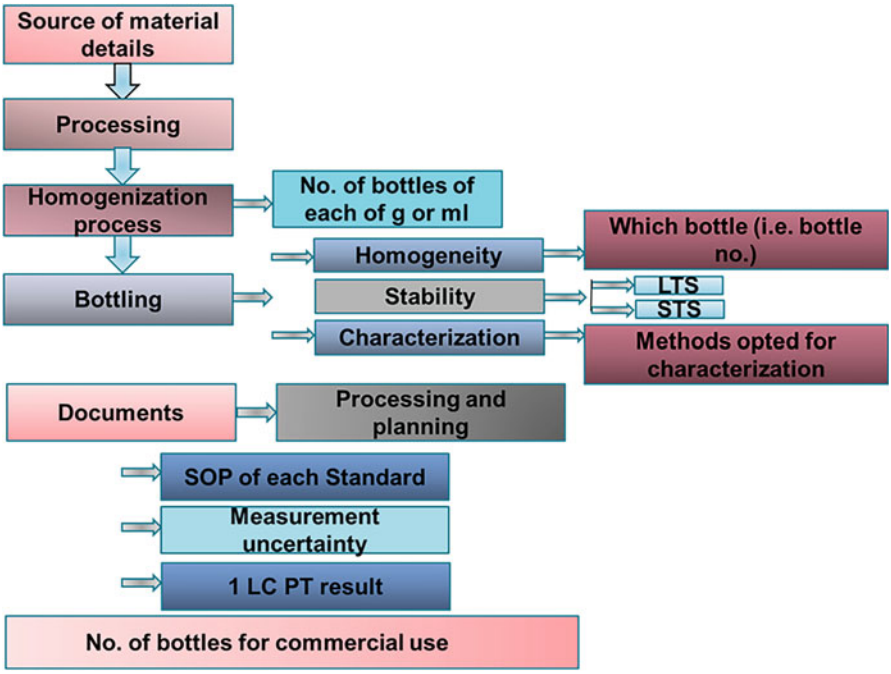

Fig. 1 Process of development of petroleum BNDs

3 physicochemical properties, and 13 chemical properties, including BND for sulfur content measurement at lower concentrations which will be of immense use for BS-VI fuels (Pant et al. 2020). The initiative will save vital foreign exchange through import substitution for certified reference materials (CRMs: BNDs). This unique initiative will be a milestone in ensuring our country's quality assurance of petroleum products. Figure 1 shows the protocols described as per ISO guidelines used for developing petroleum-based BNDs. Figure 2a and b shows honorable PSA to Govt. of India, R Chidambaram, DG-CSIR Dr. Shekhar C Mande, and other dignitaries releasing petroleum BNDs and petroleum BNDs by BPCL.

Physical, Chemical, and Physicochemical Parameter-Based BNDs

The physical properties-based petroleum BNDs have been developed and traceability for all vital parameters of petroleum products has been provided for testing and certification comprising 12 physical, 13 chemical, and 3 physicochemical properties. The flowchart shows the chemical and physical-chemical parameters of petroleum BNDs. The reference material producers are working in true spirit towards making India **"Aatmanirbhar Bharat"** as well as producing indigenous reference materials addressing in-line with **"Vocal for Local"** concept and thus contributing in response to the call of our Hon'ble Prime Minister Shri Narendra Modi towards making a

Fig. 2 (**a**) Releasing of petroleum BNDs by honorable PSA to Govt. of India, R. Chidambaram, DG-CSIR, Dr. Shekhar C. Mande, and other dignitaries and (**b**) petroleum BNDs by BPCL

"self-reliant India" (Paroda et al. 2020). In a step forward, HPCL started the development of BNDs in 2018–2019 in a tie-up with CSIR–NPL. Currently, 28 petroleum BNDs have been jointly developed by HPCL and CSIR–NPL. A few other petroleum-related BNDs are under development.

HPCL collaborated with CSIR-National Physical Laboratory (NMI of India) and produced 16 BND®s in 2018 for physical properties in petroleum products as per ISO 17034:2016 and ISO Guide 35, as represented in Tables 1 and 2. Lubricating oils are used in almost all industries for the maintenance of plant machinery, vehicles, engines, etc. (Holmberg et al. 2017). Total acid number (TAN) and total base number (TBN) standards help manufacturers to accurately dope the correct amount of additives in fuels/lubricants which will help prevent corrosion and related damage to engines and machinery components (Shahabuddin et al. 2012), which arises due to the formation of acidic/basic components (SOx and NOx) during the combustion process or the use of machinery. TAN/TBN is used as a guide in the quality control of lubricating oil formulations (Chamberlin et al. 1996). It is also sometimes used as a measure of lubricant degradation in service. TAN/TBN measured values can give information about the fitness of oil and balance useful life as shown in Table 3.

Table 1 List of chemical parameters of petroleum BNDs including diesel, gasoline, and kerosene

Sr. No.	BND	BND Details
1	BND® 7001	Sulfur Reference Standard in Diesel (mass fraction 2.5 ± 0.75 mg/kg)
2	BND® 7002	Sulfur Reference Standard in Diesel (mass fraction 5.0 ± 1.5 mg/kg)
3	BND® 7003	Sulfur Reference Standard in Diesel (mass fraction 10.0 ± 1.5 mg/kg)
4	BND® 7004	Sulfur Reference Standard in Gasoline (mass fraction 25.0 ± 2.5 mg/kg)
5	BND® 7005	Sulfur Reference Standard in Diesel (mass fraction 50.0 ± 2.5 mg/kg)
6	BND® 7006	Sulfur Reference Standard in Gasoline (mass fraction 50.0 ± 2.5 mg/kg)
7	BND® 7007	Sulfur Reference Standard in Kerosene (mass fraction 1000.0 ± 20.0 mg/kg)
8	BND® 7026	Sulfur Reference Standard in Gasoline (mass fraction 2.5 ± 0.75 mg/kg)
9	BND® 7027	Sulfur Reference Standard in Gasoline (mass fraction 5.0 ± 1.5 mg/kg)
10	BND® 7028	Sulfur Reference Standard in Gasoline (mass fraction 10.0 ± 1.5 mg/kg)

Table 2 List of physical parameters of petroleum BNDs including petroleum oils and mineral oils

Sr. No.	BND	BND details
1	BND® 7008	Density Reference Standard in Petroleum Oils
2	BND® 7009	Kinematic Viscosity at 40.0 °C Reference Standard in Petroleum Oils (Heavy Distillates)
3	BND® 7010	Kinematic Viscosity at 50.0 °C Reference Standard in Mineral Oils
4	BND® 7011	Kinematic Viscosity at 100.0 °C Reference Standard in Mineral Oils
5	BND® 7012	Kinematic Viscosity at (−)20.0 °C Reference Standard in Petroleum Oils/(Jet A1)
6	BND® 7013	Freezing Point Reference Standard in Petroleum Oils/Middle Distillates
7	BND® 7014	Flash Point-Abel Reference in Petroleum Oils/Middle Distillates
8	BND® 7015	Flash Point-PMCC Reference Standard In Mineral Oils
9	BND® 7016	Flash Point-COC (Cleveland Open Cup) Reference Standard in Mineral Oils
10	BND® 7017	Smoke Point Reference Standard for Petroleum Oils
11	BND® 7018	Distillation Properties Reference Standard of Petroleum Oils
12	BND® 7019	Distillation Properties Reference Standard of petroleum Oils
13	BND® 7020	Pour Point Reference Standard of Petroleum Oils, Lube, or Mineral Oils
14	BND® 7021	Color Saybolt Reference Standard of Petroleum Oils, Mineral Oils
15	BND® 7022	ASTM Color Reference Standard of Petroleum Oils, Lube, or Mineral Oils
16	BND® 7025	Aromatic, Olefins and Saturates content Reference Standard in Petroleum Oils

The quality of petroleum products depends on many physical properties measured values such as density, kinematic viscosity, distillation, pour point, color, and flashpoint (Al-Besharah 1989). Measurement of these physical properties plays a vital role in international trade, crude refining process, storage and transportation of

Table 4 Chemical and physicochemical parameters of petroleum BND

S. No.	Measurand	Certified value and uncertainty
1	Color ASTM	4 ± 1 color ASTM unit
2	Color saybolt	24 ± 1 color saybolt unit
3	Flash point	40.5 ± 1.5 °C
4	Viscosity at 100 °C	10.64 ± 0.04 cSt
5	Density (kg/m^3)	799.8 ± 3.2
6	Viscosity at 40 °C	2.917 ± 0.02 cSt
7	Viscosity at 50 °C	170.2 ± 0.6 cSt
8	Viscosity at −20 °C	3.171 ± 0.022 cSt
9	Freezing point	−57.50° ± 1.5° C
10	Flash point PMCC	74.5 ± 3.5° C
11	Flash point COC	212 ± 15° C
12	Pour point	−6.00 ± 3.0° C

various petroleum products, and calibration and a performance check for measuring equipment (Wauquier 1995). There are also regulations and specifications promulgated by international, national, state, and local agencies that restrict the limits of these physical properties to address basic requirements, viz., environmental aspects, fuel economy, and technological advancement in the automobile sector. In recent, internationally known standards were available viz. SRMs were produced in NIST (National Institute of Standards and Technology, USA) and a few other global ISO 17034:2016 accredited RMPs. All users had to procure these imported standards at very high prices and with long lead times for receipt. Table 4 represents the chemical and physicochemical parameters of petroleum BNDs.

Density

Density is crucial to the performance of both machines and lubricants (Gropper et al. 2016). The mass per unit volume of a substance determines its density. For example, an object constructed of steel or iron will have less volume than an identical object made of a variety of less dense materials (e.g., water, petroleum ether, etc.). A substance's density varies with pressure and temperature. For solids and liquids, this variation is small; however, for gases, it is significantly more. Since most systems are made to pump a fluid with a given density, their efficiency changes when the fluid's density changes (Mwesigye and Yılmaz 2020). The main technique for establishing the traceability of reference hydrometers is the hydrostatic weighing

Table 5 Industry/market demand of various fluid

method (also known as the Cuckow's method) (Kumar et al. 2013). This method uses a balance and the Archimedes principle to measure the actual masses of a hydrometer in air and liquid at a specified stem point scale. When using hydrometers in the lower range, a sinker with known mass and volume is employed for Hydrometer calibration by hydrostatic weighing with automated liquid surface positioning (Aguilera et al. 2007). The primary solid density standard, the silicon sphere, can be used to calculate density (mass/volume) and is traceable to mass and length standards (for volume) (Gupta 2002). Due to silicon's low density and low thermal expansion coefficient, the need for air buoyancy correction is limited (Mizushima et al. 2004). Liquid is chosen according to the required stem scale point, and its density is evaluated using a silicon sphere (Mizushima et al. 2004).

Density Certified Reference Materials are used to verify laboratory equipment used to test petroleum and derivative products for density in accordance with methodologies including, but not limited to, ASTM D4052, IP 365, and other comparable international methodologies (Zanão et al. 2018). Kilogram per cubic meter (kg/m^3) is the SI unit of density (Table 5).

Viscosity

A fluid's viscosity is a gauge of how difficult it is for it to flow. It refers to the internal friction of a fluid in motion. Because of the high internal friction caused by its molecular structure, a fluid with high viscosity opposes flow (Thorpe et al. 1894). A fluid with lower viscosity, on the other hand, flows smoothly because of its molecular structure, which produces very little friction when it is in motion. The step-up approach is used to establish standard viscometers and standard viscosity oils using distilled water as the primary standard and water's kinematic viscosity (Fakhrabadi 2021). First, two master viscometers are calibrated using water at 20 °C and

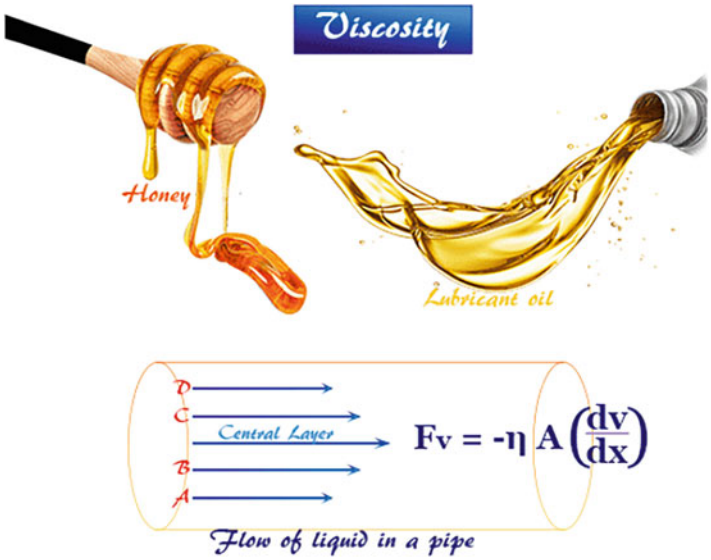

Fig. 3 Viscosity explanation with the help of fluid flowing through the pipe (https://www.priyamstudycentre.com/2020/11/viscosity.html)

calibration constants between (0.001–0.003) mm^2/s^2. These two master viscometers evaluate the kinematic viscosity of two standard oils at 40 °C. The appropriate corrections are performed for surface tension, temperature, and buoyancy.

In Fig. 3, the fluid is flowing in a pipe. The fluid does not move at the same speed throughout the pipe as it is flowing. Almost stationary is a thin layer that is in direct touch with the pipe wall. The core layer's velocity increases as you move away from the pipe's wall and stays at its highest level. As a result, the velocity of the flowing liquid has a gradient (dv/dx). The internal friction of the two layers causes each layer of the liquid surface that is flowing at a higher velocity to have a retarding effect. Viscosity is the amount of resistance a fluid offers to another fluid part moving at a different speed than it does to a portion moving at its own speed (Vogel 2020).

Flash Point

The lowest temperature at which a liquid (often a petroleum product) will produce a vapor in the atmosphere at its surface that will "flash," when in contact with an open flame (Stachowiak and Batchelor 2013). The flash point is a broad indicator of a liquid's combustibility (Glassman and Dryer 1981). There is not enough vapor present below the flash point to support combustion. Flash points are determined by carefully controlling the heat of a liquid to a range of temperatures, then applying a flame to the vapor rising to the liquid's surface. Either a "open cup" or a "closed cup" device is used for the test (Lance et al. 1979). The sample is placed into a test cup that is totally open at the top for the open cup test. Before the sample is heated, a thermometer is placed inside it. Every time the sample temperature rises by 2 °C, the test flame is passed over the cup. The flash point is attained when the sample vapors temporarily catch fire. The ASTM D92 Cleveland Open Cup (COC) test is the most widely utilized

Fig. 4 Picture of flash point process (https://www.bcl.co.za/news/q8oils-and-blue-chip-sign-lubricant-agreement-for-s-a-market/)

test procedure (Phillips and Totten 2003). In the closed cup testing, the sample is put into a test cup with a lid that is sealed and opened when a flame is applied as the source of ignition. As opposed to the open cup approach, when the vapors are exposed to the atmosphere, the closed cup technique captures all of the vapors produced during the heating of the sample. The fact that the closed cup test produces fewer flash points than the open cup test is therefore not surprising. Closed cup flash points are often calculated using the ASTM D93 Pensky-Martens Closed Cup (PMCC) test (Catoire and Naudet 2004). Flash point process picture is shown in Fig. 4.

Distillation

The term "refining of petroleum" refers to the process of separating the different components of petroleum from one other (Meyers 2016). This is accomplished by a procedure known as **fractional distillation**, which is premised on the observation that the various petroleum constituents have distinctively different boiling points (Shishkin 2006). Crude petroleum is heated in a furnace to a temperature of around 400 °C or somewhat higher during fractional distillation. The three most significant petroleum fractions that result from refining are as follows: gasoline, kerosene, and petroleum gas. Apart from these, diesel, lubricating oil, paraffin wax, and bitumen are the constituents of petroleum as shown in Fig. 5.

Pour Point

The pour point, which determines the temperature below which crude oil turns plastic and ceases to flow, is crucial for recovery and transportation (Ilyin and Strelets 2018). The range of pour points is from 32 °C to below −57 °C. Standard Test Procedure for Pour Point of Crude Oils is ASTM D97 (Venkatesan et al. 2002). For the purpose of promoting the growth of paraffin wax crystals, the specimen is cooled inside a cooling bath. The test jar is removed and inverted to look for surface movement at around 9 °C above the anticipated pour point and then every 3 °C after that. The jar is maintained horizontally for 5 s when the specimen does not flow when tilted. The pour point temperature is calculated by adding 3 °C to the

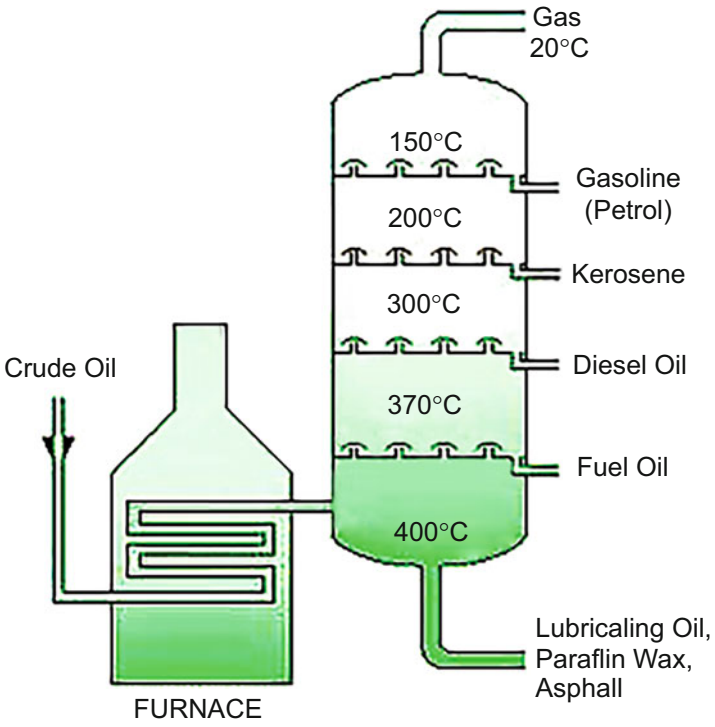

Fig. 5 Schematic of refining process and constituents of petroleum (https://www.geeksforgeeks.org/fractional-distillation-of-petroleum/)

equivalent temperature if it does not flow. It is also important to keep in mind that failure to flow at the pour point could potentially be brought on by viscosity or the specimen's previous thermal history (Donaldson et al. 1985). As a result, the pour point could provide a misleading impression of the oil's handling properties. The conduct of additional fluidity tests is also possible. The upper and lower pour points of the specimen can be used to determine an approximate range of pour points. An alternative to the manual test process is ASTM D5949, Standard Test Method for Pour Point of Petroleum Products (Automatic Pressure Pulsing Method) (Nadkarni and Nadkarni 2007). When reporting at a 3 °C temperature, it employs automatic equipment and produces pour point values in a format identical to the manual method (ASTM D97) (Standard 2001).

Dynamic Viscosity BND™ and BND® of Non-Newtonian Fluids Using Magneto-Rheometer and their Instrumentation

The CSIR-National Physical Laboratory, India (NPLI) develops Indian Certified Reference Materials (BND™) for research into accurate measurement methods, calibrating instruments, and providing quality control. NPLI certifies the BND for

rheological properties of non-Newtonian fluids, which show shear rate dependence of viscosity. Accurate measurements of these material properties are critical for predicting the behavior of these fluids in the complex flows they experience during processing and use. The development of this new BND is based on a multiphase approach. A round robin test of the BNDs is also planned, involving instrument manufacturers and users in industry and at universities. The round robin will assess the lab-to-lab variability in these measurements.

This BND (IRM) is intended for use in the calibration of the rheometer for the measurement of the rheological properties of non-Newtonian fluids. This consists of a nanofluid (10 ml $\pm$ 0.01 ml) with the dispersion of Fe_3O_4 nanoparticles (with a particle size distribution of 8–10 nm) in kerosene.

Absolute viscosity (also known as dynamic viscosity) is the measurement of the fluid's internal resistance to flow (Špeťuch et al. 2015). It is the ratio between the applied shear stress and the rate of shear of a liquid.

NPLI develops the BND for rheological properties of non-Newtonian fluids, which show shear-rate dependence of viscosity. Accurate measurements of these material properties are critical for predicting the behavior of these fluids in the complex flows they experience during processing and use. Figure 6 shows parallel plate geometry for dynamic viscosity measurements.

The measurement of non-Newtonian liquids is only possible with the rotational viscometer (ISO 3218.2) (Yu et al. 2022). In this type of rheometer, the tested fluid is sheared between two parallel surfaces, one of which is rotating. Each determination of viscosity must be accompanied by the temperature (with a constancy of $\pm$ 0.2 °C) at which the measurement was made. Usually, the angular velocity is imposed and the response of the material is monitored by the measurement of the torque. The range of this viscometer is 10 mPa-s to 10^9 mPa-s. The manufacturers recommend the use of standard oil of known viscosity to verify that the instrument is operating correctly. For non-Newtonian fluids, the results obtained are preferred in the form of flow curves which must be interpreted, assuming the validity of various laws of flow (Coleman et al. 2012). One very important aspect of providing certified data for a BND is to include estimates of uncertainties in the data as well as in any quantified

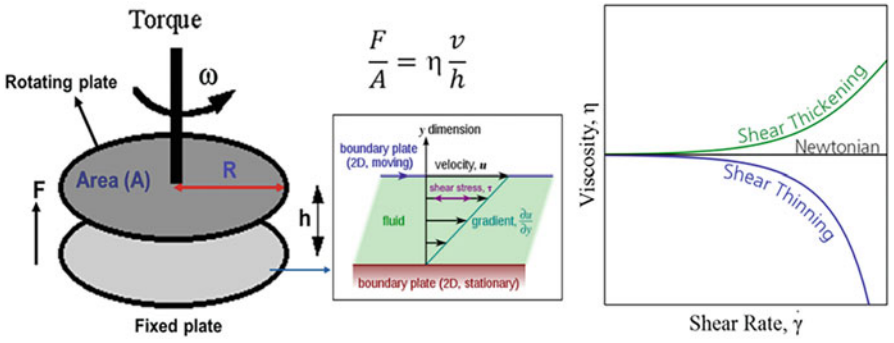

Fig. 6 Parallel plate geometry for dynamic viscosity measurements

parameters. The test report is to be drafted in accordance with the specifications in the standards. It includes individual and mean values at each temperature.

Dynamic Viscosity BND® of Newtonian Fluids (Silicon Oils)

Almost every industry that deals with liquids or semiliquids relies heavily on Newtonian fluids, particularly silicone oils, because of their unique properties and behavior (Lansdown 2004). The primary criterion for determining a fluid's viscosity to ensure high-quality goods is dynamic viscosity (η) (Chhabra 2010).

A fluid's dynamic viscosity, which measures the flow-resisting force a fluid exerts, is defined for a Newtonian fluid as

$$\eta = \tau/(dv/dn)$$

where τ is the shear stress, v is velocity of fluid in the shear-stress direction, and dv/dn is gradient for v in the direction perpendicular to flow direction. Concentric (or coaxial) cylinder systems (DIN EN ISO 3219 and DIN 53019) are an effective instrument for assessing dynamic viscosity, which measure the dynamic viscosity. With the help of rheometer, shear rate and shear stress are calculated with precision using bob and cup geometry to calculate the dynamic viscosity as shown in Fig. 7a–c.

From concentric cylinder geometry, the shear rate is (Pant et al. 2020)

$$\gamma = 2 \times \omega RC/(RC)2 - (Rb)2,$$

and shear stress is (Pant et al. 2020)

$$\tau = M/2\pi(Rb)2$$

These equations describe how the measured torque, the bob's radius, and its length affect the shear stress on the surface of the bob. Newton's law uses the shear

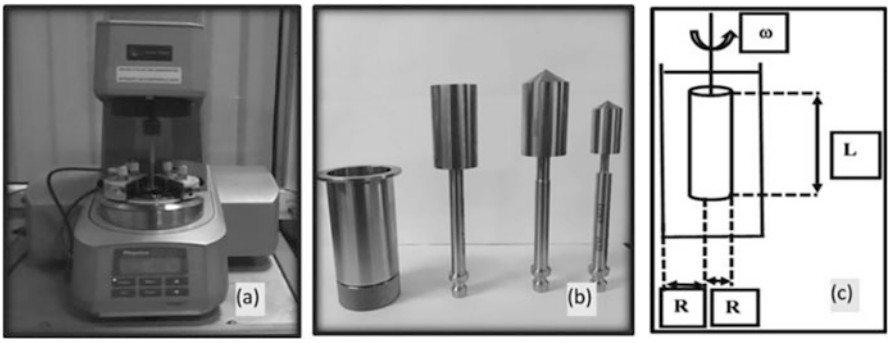

Fig. 7 (**a**) Magneto-rheometer; (**b**–**c**) cup and bobs of concentric cylinder geometry

rate (γ) and shear stress (τ) factors to calculate a Newtonian fluid's dynamic viscosity (η). For silicon oil, measurements are performed in the temperature range of −20 to 100 °C and a dynamic viscosity range of 1 Cp to 105 Cp.

Multi-Way Principal Components Analysis (MPCA)

Decreasing the number of dimensions of a complex data can be done by marking the greatest variances' direction. This method is called principal components analysis (PCA) (Rao 1964). One of the popular methods for algorithms is to decompose a matrix that is being observed, say X, into a set of scores T and loadings W while maintaining the form T = XW; this is singular value decomposition (Höskuldsson 1995). Each constituent of the loading's matrix W will be able to define one component of the low-dimensional subspace which will be interpreted, e.g., a chromatogram. The dimension is decreased by maintaining only the L constituents of W that define more than a threshold variance in the data, where L < the rank of X. So, this requires the complex data to be arranged in form of a matrix, a two-way array to be precise. We can use this method for higher orders also, then it becomes a multi-way array. In the case of a three-way array, the matrix X must have some I × J × K dimensions, which should be arranged into a two-way array X' of dimensions I × JK. One very good example of a multi-way array is the arrangement of GC-MS, because this three-way array is in such a way that each way represents different profiling, mass spectra, and elution times. Now the two-array equivalent will have different profiling and the mass spectra along with the chromatograms (de Carvalho Rocha et al. 2017).

The use of the MPCA approach in Elektrociepłownia Białystok is made to find leaks in a steam boiler's piping system before they cause any leak (Indrawan et al. 2021). When a leak first appears in a pipeline or when it enlarges to the point where the operational staff can clearly identify failure signs, it can be quite difficult to pinpoint exactly when it occurs in an industrial steam boiler. The length of a boiler's pipeline section is several dozens of meters, and cracks might occur anywhere along it. As a result, the development of these faults often varies over time and has a very diverse impact on process variables. In many cases, a single leak results in cracks in nearby tubes, a process known as failure propagation and multiplication (Davoodi and Mostafapour 2014). Measurements of a number of process variables must be used in the tube leak detection method, and they must be correlated with common defect patterns (Swiercz and Mroczkowska 2020).

Parallel Factor Analysis (PARAFAC)

Now we can develop our solution into a multidimensional one, in other words, a multidimensional equivalent of principal component analysis, which is named as parallel factor analysis (PARAFAC) (Harshman and Lundy 1994). In this method, the observational matrix X will be divided into scores matrices A, B, and C such that its dimensions are I × F; J × F; K × F, respectively, here F represents a number of factors, an analogue of number of components (L) in the MPCA method. This

analogue makes it clear that the value of F is always less than the rank of the matrix X. If we can make it so that all the A, B, and C matrices are positive at all the time, then we can solve PARAFAC using a nonlinear optimizer like alternating least squares (Paatero 1997).

Kohonen's Self-Organizing Map (SOM)

Kohonen's self-organizing map is one method in which the data is projected in a 2D space as close as possible to the interpretation (Su and Chang 2001). We can say it is a neural network. It takes the manipulation of the data required to map the 2D space and location of the data space to project, corresponding to a particular node. As each iteration runs, the data in each node comes closer and closer to the original sample data. There should be more nodes in the set than the number of sample data so that a particular data can be associated to its neighboring nodes in the neural map. The more similar the sample data, the closer they are in the neural map; so, this can analyze the nonlinear relationships within the sample database. For example, a straight line means a convolute and a nonlinear path. The nodes in the neural map can be mapped in terms of a L × N grid. We can describe it into a three-way array M with dimensions L × N × S. There are two types of distances between nodes. The distance between two nodes M_{ln} and M_{op} in the data set is the Hellinger distance D_h. The distance between the same two nodes in the map is the Euclidian distance D_E. This is given by the equations below.

$$D_H^2(M_{LN}, M_{OP}) = 1 - \Sigma_s(M_{LNS}M_{OPS})^{\frac{1}{2}}$$

$$D_E^2(M_{LN}, M_{OP}) = (L - O)^2 + (N - P)^2$$

Conclusion

CSIR-NPL has launched the mission mode program on the development of BNDs in diverse sectors with consideration for the increasing importance of reference materials in the worldwide market. This chapter focuses on the production of petroleum-based BNDs. CSIR-NPL has produced 29 BNDs in collaboration with HPCL and BPCL, and the list is continually rising. Numerous physical properties, including density, viscosity, distillation, pour point, and flashpoint, are assessed to determine the quality of petroleum products.

Abstract

Metrology, in a broad term, is defined as the science of measurement or the study of measurement. The term metrology is the combination of Greek terminologies "metron" and "logos," which refers to the study of measurement, including both experimental and theoretical. In the present era of globalization, it is an imperative element in many fields, including manufacturing, engineering, science, and technology. It is used in diversified applications, including characterization and structural analysis in engineering; construction of different products in aerospace; process and quality controls in manufacturing; energy generation, transmission, and distribution in energy; and the development of medical products, devices, safety standards, diagnostic, monitoring, control, and therapeutic purpose in healthcare. The list of applications is endless, and only a few are mentioned. Metrology is applied to corroborate and confirm already defined specifications and standards in these applications. The metrological traceability of the standards is often established by calibrating, testing, and verifying them against better standard(s), supported through a well-recognized quality system implemented in the certified, accredited laboratories authorized by certification bodies. A fleeting investigation of the metrological practices being followed is presented in this chapter, enabling an understanding emphasizing the evolution of industrial revolutions, some of the application-oriented trends in industrial metrology, the contribution of metrology in achieving Sustainable Development Goals (SDGs) set by United Nations Organisation (UNO), and the role of industrial metrological measurements in the national quality infrastructure. It is hoped that the chapter will provide a good resource material in a single window for the readers following and working in the field of industrial metrology.

Introduction

Life began in this universe more than a million years ago. Humans started living as a part of nature, finding food articles and water sources for survival and searching dwellings and shelters in forests, plains, rivers, caves, mountains, etc. Survival mainly depended upon the convenience of available resources based on plants, creatures, and animals within their reach in nearby places with a workable distance and their ability to collect and catch them. No one might have thought of any need for measurement in these ancient communities. However, they might be using some measurement assessment like the food is heavy or light, good or bad, far or near, adequate or inadequate, etc. However, in all walks of human life, humanity tends to explore and evaluate qualitatively and quantitatively various things around, say objects, elements, phenomena, and processes. The only way to acquire objective evidence and data is to perform measurements. Lord Kelvin has rightly said that "When you can measure what you are speaking about and express it in numbers, you know something about it; but when you

cannot express it in numbers, your knowledge is of a meager and unsatisfactory kind; it may be the beginning of knowledge, but you have scarcely, in your thoughts, advanced to the stage of science, whatever the matter may be." Of course, our knowledge and expertise are highly dependent upon the measurements. Measurement is thus the heart of all our activities in the material world, in industry, academia, legal, trade and commerce, space, defense, etc. Measurements are characterized as scientific and metrological measurements (Aswal 2020a, b; Rab et al. 2020; Peiser et al. 1979; Fanton 2019; Yadav et al. 2020a, b; Chakrabarti et al. 2008; Gupta 2009; Javaid et al. 2021; Garner and Vogel 2006; Kumar and Albashrawi 2022; Zafer et al. 2019).

Scientific measurements are performed to provide exact and comprehensive information about the phenomena extracted from interfering convolutions in terms of characteristic principles and theories of nature. The metrologist is the trained expert to perform such metrological experiments and compare them quantitatively with an established base for validation because only measurements are not adequate to fulfill the objectives of science. It is the duty and responsibility of metrologists to make descriptive, comprehensive, and valid interpretations of the measurements made, compared, and validated in his/her evolutionary ability to forecast and correlate with unexplored natural phenomena. Such investigations, results, and insights are well recognized and receive appreciation from the scientific community. With continuously improved precision and accuracy, metrologists are now able to design experiments and perform measurements to meet societal needs (Peiser et al. 1979; Fanton 2019; Yadav et al. 2020a; Bailey 2017; Lean 2015; Rab et al. 2021a; Yadav and Aswal 2020; Mari and Wilson 2014).

Industrial metrology basically deals with the application of measurement science in industrial manufacturing, processes, quality controls, monitoring, recording, and their use in life, health, trade, and society for ensuring the appropriateness of measuring instruments/devices, their traceability, and quality control. Metrology is categorized into three subareas (Fig. 1) as (i) scientific or fundamental metrology, (ii) applied or industrial metrology, and (iii) legal metrology. Fundamental metrology deals with the realization of SI units, unit, and quantity systems, establishing primary and secondary standards, and developing need-based new measurement methods and techniques. Applied metrology deals with disseminating measurement standards to users calibrating, testing, and verifying their instruments, maintaining secondary and working standards, and quality control of measuring instruments used in the industry. Legal metrology deals with the regulatory framework and regulatory aspects of measurement and measuring devices (Aswal 2020a; Rab et al. 2020; Peiser et al. 1979; Fanton 2019; Yadav et al. 2020a).

Industrial Revolution

Historically, the transformation of the economy from ancient handmade goods and handicrafts to machine-made or industrial processing manufacturing started in the eighteenth century in Europe and especially Britain with the introduction of innovative methods, techniques, and ways of doing things. Accordingly, society's living status also changed enormously, later spreading globally. Arnold Toynbee (1852–1883), the

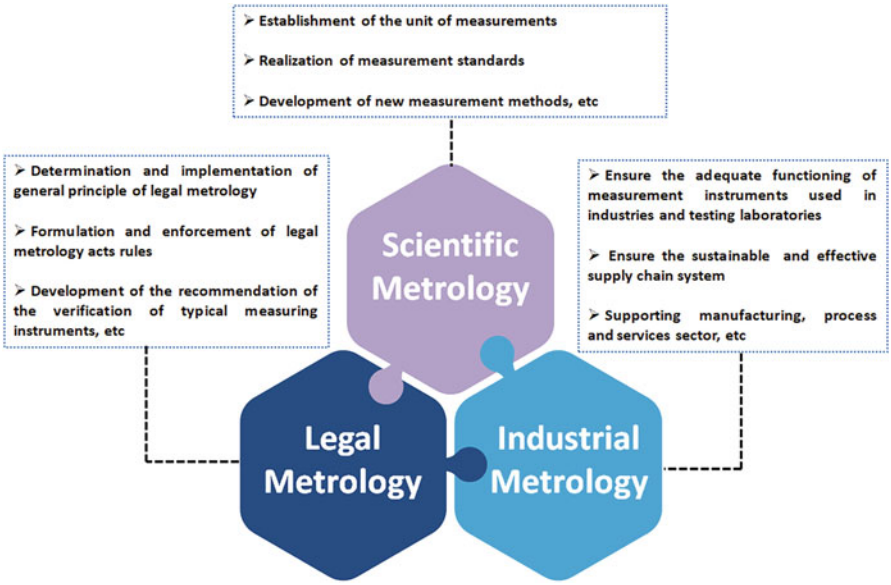

Fig. 1 Subareas of metrology

famous historian and writer, introduced the terminology for changes during the industrial revolution. However, such changes of the industrial revolution could not enter India and China until the twentieth century, while it entered the USA and Western Europe by the nineteenth century. The industrial revolution certainly revolutionized all walks of human life. This visibly transformed the social, economic, technological, and cultural status. The people started using iron, steel, new sources of energy like fuels and mechanical power, coal, steam, petroproducts, electric power, thermal energy, spinning wheels, power loom, manufacturing units, factories, various transport, and communication means like the steam engine and ships, automobiles, aviation, telephone, telegraph, radio and later on TVs, frequent and increased application of science to industry utilizing natural resources, and the large-scale production of manufacturing articles and goods (Popkova et al. 2019; Pozdnyakova et al. 2019; Koc and Teker 2019).

Further emphasis was simultaneously placed on the development of nonindustrial sectors to cater the raw material demands, mainly improvement for the agricultural and farming sectors, improving wider distribution network; cooperation for international trade, regulations, and policies to help and assist in fulfilling needs of the industrialized society; and edifying renovations placing focused attention on imparting training and enhancing skills of the workers to enable them to utilize machines, tools, devices, instruments in factories, plants, and manufacturing hubs (Varshney et al. 2021; Rab et al. 2022a).

As mentioned above, the ***First Industrial Revolution*** started in the eighteenth century with the introduction and use of steam power and machine for manufacturing.

For example, the threads prepared using hand-driven spinning wheels were transformed into power-driven mechanized looms, increasing the production of thread manifolds and saving time. The introduction of the use of steam power in industrial units and transportation was the breakthrough of the era employing steam engines and steamships for many applications. The ***Second Industrial Revolution*** started with the invention of electricity during the nineteenth century. With the use of electricity, industries could exploit several natural resources that were not hitherto utilized, such as metals, rare earth materials, new compositions and alloys, and synthetic products, new energy sources. Newer machines, tools, and devices were developed and utilized for a number of industrial applications, which also gave rise to automatic factories. Although fewer factories were partly made automatic, complete automation could only begin in the early twentieth century with the introduction of computers. The third quarter of the twentieth century may be characterized as the beginning of the ***Third Industrial Revolution*** with the advancement in automation with the use of programmable memory chips, controls, and computers. This could result in the automation of the whole production line with minimal human interventions, for example, robot-driven assembly lines.

The ***Fourth Industrial Revolution,*** also known as ***Industry 4.0***, is said to be started at the beginning of the twenty-first century with the technological application of information and communication in the industry. The computer-assisted production lines are being expanded, modernizing high-speed network connections, using cloud computing and digital twins. Potentially strong, Industry 4.0 is now able to deliver some implausible innovations and advancements in the industrial manufacturing sector. Now, smart machines, as part of smart factories, can assess, identify, detect, and predict failures and initiate, trigger, and alarm maintenance processes automatically for the probable plan, act, carry out maintenance, and rectify errors amicably. The digitalization of the manufacturing process enables flexibility for acquiring and passing correct information to the appropriate staff at the right time. In a nutshell, Industry 4.0 has proven to be a game changer for industrial units. Digital manufacturing would probably change how we think and work and finally result in how products are manufactured, repaired, maintained, serviced, refined, and improved.

After passing less than a decade since the introduction of Industry 4.0 and the interaction of machines with humans, the next industrial revolution is already in sight called the Fifth ***Industrial Revolution 5.0 or Industry 5.0***. In this revolution, humans and machines interact extensively and work together to find and improve the ways and means for increasing production efficiency. It is very interesting to mention that Industry 4.0 and Industry 5.0 are both in the same era. It is a very complicated situation for those industries tuned and adopting Industry 4.0 and simultaneously feeling the need for Industry 5.0. Sometimes, it is funny and confusing for them to go for well-established Industry 4.0 or choose Industry 5.0, which is just at the introductory stage. The financial viability of the newer products is also an issue to be tackled as it is determined using costing software for the manufacturing industry. However, it could easily be inferred that Industry 4.0 is for today and Industry 5.0 is for tomorrow.

Until the introduction of the First Industrial Revolution, metrology was not recognized as an important activity because all the available products prior to the industrial revolution were handmade. The need for measurement was probably felt necessary and important when post handicraft era, the produced goods flowing out of the production line were similar/identical in safe, size, dimension, weight, volumes, etc. Such requirements in industrial production could give rise to the concepts of quality control, quality assurance, etc. These developments had an impact on measurement science and technology. Accordingly, for the first time, the man felt the need to have an international system of units for "all people all the time," and indeed it is now called the SI system of units. Figure 2 shows the different industrial revolution timelines and their major theme.

The recent COVID-19 outbreak and the use of digital and online technologies have changed the ways we used to work and created/opened new lines of research and means of utilization for effective, timely, customer-oriented, driven, and satisfying products and services. The visionaries have now visualized the concept of ***Industrial Revolution 6.0***. Virtual reality and artificial intelligence (VR/AI), the Internet of Things (IoT), and cybersecurity are the emerging technologies pushing for the Sixth Industrial Revolution. The main focus of the Sixth Industrial Revolution is on medical technology, infusing quick and accurate fully automatic medical diagnosis, adaptive manufacturing/printed controlled medicines, machine, and body parts, and assisting medical practitioners and critical administrative workers absolving their additional work burden to enable them to focus on many trivial and critical issues. Search and use of alternative energy sources, robotic cleaning, task-specific

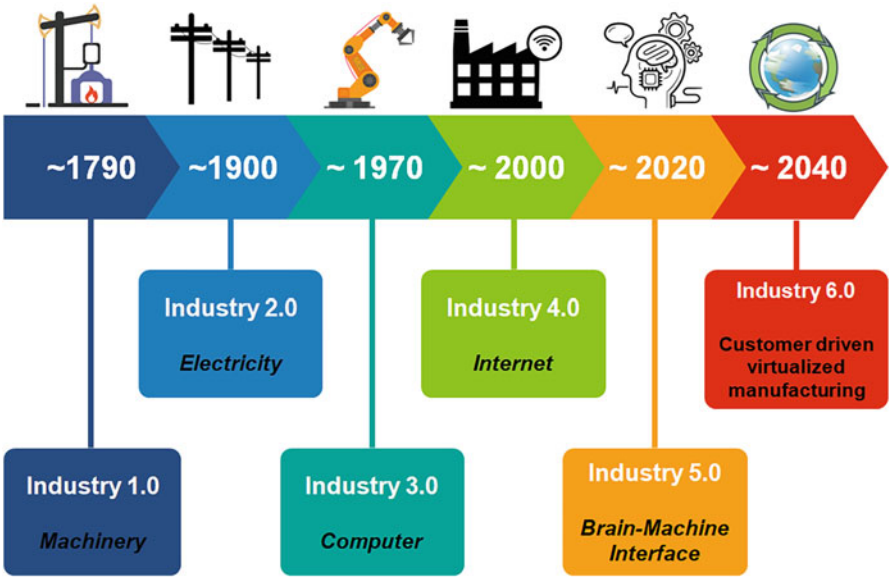

Fig. 2 Industrial revolution timeline

deployment, and fusion of novel and innovative ideas would lead the future in Industry 6.0 (Chourasia et al. 2022).

Some of the Application-Oriented Trends in Industrial Metrology

For the sake of the simplest example in dimensional quantities, i.e., the values of length and width of a component part, the exact measurement uncertainty in manufacturing such component parts is extremely important in the industrial sector. The noncompliance cost often surpasses the price of the manufactured product. Sometimes, even it results in the recalls of finished and marketable manufactured goods from the market. This not only tarnishes the image of the manufacturers but also results in heavy losses to customers as well as the company. Most of the time, outcome is legal proceedings and even incurs penalties, mental harassment, physical injuries, and violation of set regulations. From the customer's point of view, damage to a brand's name is seriously endangered due to the amount of noncompliance, besides keeping safety and health at risk. Further, noncompliance breaches confidence, a focal point and significant for establishing the brand name today. This is why most companies working in a globally competitive market have an effective quality control system backed by well-established metrological infrastructure (Wang et al. 2018; Bauer et al. 2015; Schmitt et al. 2016; Rab et al. 2021b).

Similarly, metrological processes and quality control are essential strides in the manufacturing industry. Actually, the quality control process is an investment in the long run. Few industries still avoid it as much as possible, bearing in mind that it is an additional cost to consumers. Even nowadays, in many developing nations leading to produce in bulk quantities, it is implemented to a bare minimum for avoiding slowing down the production line. This mindset has to be changed to keep pace with the brand establishment and recognition.

Nowadays, the core issue is not producing/manufacturing more but producing/manufacturing better and as per demand. Here lies the role of industrial metrology, which should help and support the production process via data collection to correct the process. If it is impossible to correct the process, at least it should be used to halt the process before it starts producing squandered morsel. The choice of appropriate measurement standard is mainly based on situation to situation, considering several issues like the measurement uncertainty needed, type and pace of measurement performed, and operational easiness and use.

Global metrological and technological advancements are approaching semi- or full automation, rapid, quick, and flexible measurement alternatives. Financial aids are easily available for viable projects and measuring solutions, which were not accessible due to high cost, are now available. It is very difficult to judge which is the top-class measuring instrument or the best measurement process control device. It all depends upon the precision, accuracy, and wholeness of the operational functions. For example, a measuring device should have process requirements of faster results, no environmental hazards, and compliance with safety standards. Normally in the automation process, ease of operation and mounting are highly important.

The applications related to measurements in manufacturing, manufacturing control, monitoring, and recording processes for use in society, for judging the operational integrity and ensuring the suitability of measuring instruments/devices, their calibration, testing, inspection, verification, and quality control fall under the category on industrial metrology. The last two decades have witnessed enormous technological advancements in industrial metrology. In order to complete a metrological or process task, quickly, precisely, reliably, and accurately, a single setup or a combination of multiple systems is required. One such beautiful example is the use of computer tomography (CT). CT was first invented and used in health science during the year 1972. Since then, many advancements have been carried out in CT scanning to examine optically, measure, and control the different component parts and methodologies. It is a wonderful technology to describe the number of metrological steps in a complete process, i.e., multiple inspection systems and techniques: (i) electromagnetic testing involving a measure of electric current or magnetic field; (ii) liquid penetrant testing having low viscosity fluids for the material under test, which dribbles through defects/cracks/pores and then controlled using a developer to bring it upward to assess the proper flaw; (iii) destructive testing, allowing damage of physical part for the inspection of internal parts; and (iv) visual inspection involving the operator to continuously monitor/gauge the test part using magnifier or computer (De Chiffre et al. 2014; Carmignato et al. 2012; Rab et al. 2022b).

Industrial metrological requirements like precision and accuracy are extremely important in health science, especially medical parts. The speed of manufacturing, testing, and supply at the proper locations of the essential items is another contemporary example, citing the special case of scientists, medical experts, and other staff working toward the COVID-19 vaccine to ensure its safe rollout across the globe. This could only be possible through metrology. A CT can efficiently scan multiple images of the same part or multiple parts (sometimes in hundreds) and reject the defective parts if not as per specification. The ultrasound-based detection, analytical, therapeutical, and characterization techniques, tools, and data are widely used and utilized in a number of industrial metrological applications. The data and results about ultrasonic velocity in samples, attenuation, refraction, reflection, bulk tissue properties, quantitative distance, Doppler measurements, and tissue elasticity of the organs thus generated are complex but become reliable and appropriate if the techniques used are properly made traceable through calibration and standardization. The imaging methods providing information about the present nature and amount of matter can be considered biomarkers and are conceptually similar to laboratory assays. Quantitative imaging includes developing, standardizing, and optimizing anatomical, functional, and molecular imaging acquisition protocols, data analyses, display methods, and reporting structures. Thus, such metrological measurements save a lot of time, money, and manpower (Sullivan et al. 2015; Rab and Yadav 2022; Javaid et al. 2022).

As per an estimate by CAGR, the industrial metrology market is expected to grow at 6.0% per annum from 2021 to 2026. A huge demand from the manufacturing industry for inspection, verification, testing, calibrations services, tools, instruments, quality control, etc. and big data analytics are the major sources for the growth in the industrial metrology sector. The major industry tycoons like Reliance, BHEL, GAIL,

Faro, Carl Zeiss, Nikon, Mitutoyo, etc., are developing and supplying several data analytics, control, process, management, security software tools, applications, and metrological solutions for the industrial metrology stakeholders (Aswal 2020a; Global Newswire 2022; Kuster 2020; Meškuotienė et al. 2022).

The demand for the development, installation, commissioning, use, and applications of energy-saving and efficient devices and lightweight materials in all walks of human life, especially automation, health, aviation, space, automobile, etc., is increasing exponentially. This has created a huge demand for metrological tools/solutions. Automotive, electronics, and power generation industries need precisely designed and fabricated components/parts with improved tolerances. The 3D measurement and manufacturing, portable CMMs, robotics-dependent CMM scanners, cloud computing platforms, and several forms of geometrical metrology solutions have fueled the growth in industrial metrology. As mentioned above, the utilization of cloud-based metrology solutions, form and geometrical dimensioning and tolerances, robotic-assisted metrology, laser scanning, automation, and installation of multisensory metrology software are contributing to increase the growth further (Chua et al. 2017; Emmer et al. 2017; Tsukahara 2007).

The humongous outbreak of COVID-19 situation recently has probably changed the perspective of working behaviors and environments. The special arrangements were made/being made involving minimum human resources in less time in a collaborative and cohesive way, keeping physical-distancing norms in mind. The global impact of COVID-19 has pushed all to move to alternative arrangements of virtual and online platforms, which is again fueling the growth in digital metrological tools and solutions. Measurement standards and metrological activities provide scientific and metrological infrastructure to the country. For industrial and scientific developments in any country, the role of national metrology institutes (NMIs) is significant and irreplaceable in the advancement of the field and its related technologies. It is the responsibility of all the stakeholders involved in metrology, be it manufacturers, standard and conformity bodies, NMIs and accredited laboratories, regulators, and users, to ensure that the instruments, devices, tools, and software solutions used are functioning properly, as per regulatory framework, and traceable to metrological standards (Rab et al. 2022a; Tzalenchuk et al. 2022; Davis 2018; Mustapää et al. 2020; Thiel 2018).

Considering the demands for futuristic metrological requirements, industries, administration, policymakers, and regulators are also swapping to automated and paperless digital systems as far as possible. As an example, there are more than 100 million electricity, gas, water, or heat legal meters in use in Germany. Additionally, a lot of metrological and other measuring devices are in use in laboratories, petrol pumps, weighing balances, and scales in the food sector. If all these instruments and devices are automated and digitally traced, the operator or the service users would not require the accuracy check. Automation of the inspection task and traceability would help industries, manufacturers, and laboratories to get the benefits of frequent inspection and rapid processing.

It is also extremely important for government agencies to work toward automated legal metrology solutions and reliable and accurate measuring systems to ensure

users get the correct commodities timely and quantitatively. The safeguarding of consumer rights is also highly critical ensuring the publication of mandatory requirements on packaged goods. Priority is also required from government agencies to formulate and execute legal regulations for medical devices, automotive, and software industries providing automated metrological solutions for consumer safety. Government, industrial functionaries, and all other stakeholders have to keep pace with the digital transformation, metrological solutions, emergence, and introduction of a number of emerging technologies. The number of such measuring instruments and technologies is countless, and they are being used or intended to be used for generating huge data banks. These instruments are required to be inspected, tested, verified, and calibrated at various stages for the grant of model/pattern approval, surveillance audits, and manufacturers' services. Big data analytics are required to maintain and manage this huge data bank. Another interesting and key area is 3D metrology, which utilizes 3D optical scanners capable of providing useful data on malfunctioning products.

In the global industrial metrology growth, the share of Asia-Pacific is comparatively higher than the other regions, and it is further expected to grow in the coming decade. The growing demand from automotive, aerospace, health, and manufacturing would lead the growth in the region. Moreover, Asia-Pacific nations are contributing aggressively to R&D and funding extensively, including India, China, Thailand, South Korea, Vietnam, and Japan, in the industrial metrology market in the region. Process assurance and product inspection are becoming much more pronounced areas of metrology in companies. The safeguarding of processes takes place on the line; here, the requirement for speed predominates; the inspection of dimensions, shape, and position remains in the measuring rooms; here, the requirement for accuracy predominates.

Emphasis is placed on making metrology simpler for manufacturing users, especially those unaware of and who are experts in metrology. Weight is being placed behind on operational easiness and lucidity of the results. Newer interfaces, conceptually simpler approaches, fast and quick execution and results, avoiding unnecessary repetitions, and concentrating on essentials are the special features being focused on for users in manufacturing. Another feature being added is the direct feedback and alert system to the processing machine to address and rectify the issue, amicably an error/problem if noticed/detected. Artificial intelligence is being used/applied to make extrapolation solutions through projections and trends to minimize production runouts.

Contribution of Metrology for Achieving Sustainable Development Goals (SDGs)

Metrology is a focused key area that contributed immensely to achieving the SDGs because it is crucial and indispensable to shield the planet, to ensure the exalted and improved lives for all individuals, and to accomplish inclusive economic growth and prosperity. It is extremely crucial and vital for trade, scientific comparison,

innovative and incipient technologies, mutual scientific cooperation, or even simple exchange of ideas and information. In the fast-changing, technologically advanced world, measurements are also getting more and more precise, accurate, and sophisticated. Consequently, measuring methods, devices and instruments are also becoming technologically advanced rapidly. Therefore, there are demands for improved measurement standards, adoption, and introduction of new and novel metrological concepts in newer fields, viz., nanotechnology, biotechnology and healthcare, food, clean water, clean and green environment, and energy sources, which are going even at a much faster speed. These are some of the important SDGs for the country to achieve. The role of national metrology institutes (NMIs) and the CSIR-National Physical Laboratory (CSIR-NPL), in the case of India, is paramount, not only for scientific and metrological developments in the country but also achieving SDGs (Yadav et al. 2020b; Fisher Jr et al. 2019; da Cruz et al. 2019; Grek 2020; Galimullina et al. 2020; Lazzari et al. 2017). Figure 3 shows the SDGs set by the UN.

The accurate and precise measurements through strong metrological infrastructure are essentially required for/help for achieving the different SDGs due to the following objectives:

(i) To ensure that all stakeholders (producers and manufacturers, farmers, etc.) get the correct payments for their products and that all consumers get the correct amount of goods.
(ii) To design, develop, fabricate, manufacture, and deploy suitable metrological techniques, methodologies, instruments, devices for industry, and manufacturers for helping product innovation, process improvement, and quality assurance.
(iii) To make sure that the component parts and finished goods comply with the regulatory requirements, documentary standards, and product specifications.

Fig. 3 The United Nations' 17 Sustainable Development Goals (courtesy of UN/SDG)

(iv) To ensure that quality expectations like product cost, durability, and reliability of the stakeholders (consumers) are met.
(v) To ensure that the control of prepacked goods/commodities is actually supporting/reducing market fraud.
(vi) To ensure the correct measurements of raw materials exported in bulk, which enable them to pay the correct price. It also helps governments to collect correct taxes on exports.
(vii) To also help improve the economic conditions for all concerned and assist in poverty reduction through metrological controls.
(viii) To remove technical barriers to trade through global acceptability of measurements and test results.
(ix) To facilitate international trade and contributes to inclusive economic growth, access to opportunities for small- and medium-sized enterprises (SMEs), and a level playing field for developing economies.

The cohesive metrological and documentary standards, varying calibration, testing, and certification systems help improve product quality, remove trade barriers, and reduce costs, time, and market uncertainties. Though metrology provides the impetus for growth in each of the SDGs, but major contributions can be listed as follows.

Metrology and the SDGs for Good Health and Well-Being for People (Goal 3): "Ensure Healthy Lives and Promote Well-Being for All at All Ages"

The innovations in medical electronics have strengthened the existing healthcare infrastructure in diverse dimensions, such as digitizing medical tests and diagnostic and therapeutic procedures. Recently, the central government made regulations for medical devices, under Section 33 of the Drugs and Cosmetics Act, 1940, called the "Medical Device Rules 2017" (https://cdsco.gov.in/opencms/export/sites/CDSCO_WEB/Pdf-documents/medical-device/Classificationg1.pdf. Accessed 31 Oct 2022), which came into force on January 1, 2018. CSIR-NPL has also initiated a major program on biomedical metrology to achieve the following objectives as part of SDG (Goal 3), reproduced from (https://www.bipm.org/documents/20126/43974911/Presentation-CGPM26-Sarmiento-SDG.pdf/c2dacbcf-8e92-ea6f-56e0-7253ff777769?):

- Medical measurements are fundamental to preventing, diagnosing, and treating diseases and other medical conditions. Getting measurements right improves patient outcomes, saves time, and reduces costs.
- Internationally recognized and accepted equivalence of measurements in laboratory medicine and traceability to appropriate measurement standards will lead to:
  - Improvement in the quality of healthcare of patients
  - Reduction of false-positive and false-negative test results
  - Reduction in costs for government and healthcare insurers

- Improvement of efficiency of healthcare
- Global acceptability of measurements and tests, which removes technical barriers to trade

Most of the NMIs are already providing calibration, testing, and consultancy services and conducting training programs for users and industries in various medical devices, i.e., blood pressure measuring instruments, clinical thermometers, medical weighing balances, infusion pumps, ultrasonic power measurements, and defibrillator analyzers, apart from various process parameters. The services for more medical devices are being introduced as per requirement. The CSIR-NPL, being the NMI of India, has also taken the noticeable initiative to "Ensure healthy lives and promote well-being for all at all ages."

Metrology and the SDGs for Ensuring Access to Affordable, Reliable, Sustainable, and Modern Energy for All (Goal 7)

As per the target set by 2030, using renewable energy and alternative energy sources would certainly reduce carbon dioxide emissions (Mission 500 GW by 2030). Such initiatives supported by directives and regulations would address all the aspects of the energy supply chain and measures to reduce energy consumption at the point of use. This strategy focuses efforts on sustainable and secure energy supplies (generation, transmission, and consumption), methods to reduce greenhouse gas emissions, and increasing competitiveness. CSIR-NPL is also working toward establishing primary standards for the calibration and testing of solar cells with comparable measurement uncertainty across the globe (Aswal 2020a; Yadav et al. 2021). This would be a unique facility as this is a gray area in the country, and no existing infrastructure is available for the calibration of solar photovoltaic devices. After establishing these measurement standards and facilities, CSIR-NPL is committed to dedicating them to national services and providing metrological traceability to users, academic institutes, and PV industries/testing agencies. It would finally help to achieve the national mission of self-sustainable India by providing quality measurements in the country. It would also help in a clean and green environment. Such efforts and initiatives would certainly play a major role in achieving SDG (Goal 7) for ensuring access to affordable, reliable, sustainable, and modern energy for all and SDG (Goal 13) for climate actions.

Metrology and the SDGs for Industry, Innovation, and Infrastructure (Goal 9): "Build Resilient Infrastructure, Promote Inclusive and Sustainable Industrialization, and Foster Innovation"

The main contribution of metrology in achieving SDGs is for industry, innovation, and infrastructure (Goal 9). The following important objectives are the key to any country's industrial revolution and growth:

- To manufacture and trade precisely made and tested products and components that trading partners accept for the economic success of a country.
- To control manufacturing processes and guarantee the quality of products, there is a need to align instruments to reference standards and ensure measurement traceability.
- To develop and deploy appropriate metrological methods being key for the industry and supporting product innovation, process improvement, and quality assurance.
- To ensure that components and finished products meet regulatory requirements, documentary standards, and specifications.
- To ensure that consumer and industrial quality expectations are met, including product value/price and reliability.

Right from its inception in 1950, the CSIR-NPL is fulfilling its primary charter of being the custodian of national measurement standards and providing various services to all the stakeholders to outshine in their efforts of quality products and suitably compete in international trade (Aswal 2020a; https://www.bipm.org/documents/20126/43974911/Presentation-CGPM26-Sarmiento-SDG.pdf/c2dacbcf-8e92-ea6f-56e0-7253ff777769?; Mission 500 GW by 2030; Yadav et al. 2021; Sanjay et al. 2020a, b, c, d; Yadav et al. 2018). It is also responsible for formulating and advising the country's policies, guidelines, and recommendations on evolving advanced metrology programs for government organizations, institutions, regulators, industries, and other stakeholders. The industrial system based on process, electrical and electronic parameters, sensors, and transducers with high-precision metrology is the backbone of Industry 4.0. After the historic decision taken by CGPM to redefine SI base units based on quantum standards/fundamental constants on November 16, 2018, and implemented from May 20, 2019, the role of CSIR-NPL is further increased manifold, not only to link and establish all SI units to fundamental constants but also educate all the stakeholders, regulators, administrators, policymakers, academic institutions, industries and users about the new changes and their implications in industry, innovation, and national metrological infrastructure.

As a continued and sustained effort, CSIR-NPL provides traceability services to almost 2500 industries and user organizations, generating more than 3000 calibration and test reports annually. The major customers are from national- and state-level R&D institutions; calibration, testing, and R&D laboratories; various sectors like oil, petro-products, refineries, automobile, and lighting industry; electronic, electrical, power, civil supplies and aviation, defense, space, healthcare, medicine, and safety and it's standards, pollution controls, monitoring, process, and manufacturing industries; and SAARC NMIs (Sanjay et al. 2020a, b). To strengthen the ties between NMI and industries, government organizations, and other stakeholders, almost 20–30 awareness and training programs are organized per annum for R&D laboratory, NABL labs, legal metrology officers, industry participants, and SAARC NMIs. Need-based consultancy services are also extended to industries in most of the measurement parameters.

The recent COVID-19 pandemic has generated new insights among researchers to work toward developing new technologies for testing PPE and medical devices.

Rapid industrialization, increasing demand for more precise measurements, updated technologies having a combination of IoT, artificial intelligence, soft metrology, and highly skilled manpower have increased the strong role of CSIR-NPL in the national measurement system, quality infrastructure, as well as the need for more stringent metrological regulations and certifications in trade and commerce. Its pioneering works have made a significant contribution in several sectors, such as infrastructure, industries, healthcare, defense, energy, environment, space programs, academia, etc.

Therefore, the contribution of CSIR-NPL for achieving SDGs is not only important and crucial for industry, innovation, and infrastructure (Goal 9) but also for socioeconomic growth (Goal 8) for promoting sustained, inclusive, and sustainable economic growth, full and productive employment, and decent work for all. This would not only help foster innovation, quality, and competitiveness in product manufacturing and improve export, development of import substitutes, and industrial growth, which in turn translates to improve our GDP, but also generate expertise in metrology, translating finally into employment generation.

Metrology and the SDGs for Climate Action (Goal 13) to Take Urgent Action to Combat Climate Change and Its Impacts by Regulating Emissions and Promoting Developments in Renewable Energy

The role of metrology is crucial in achieving SDG (Goal 13) wherein the following listed points need to be considered before achieving objectives:

- Accurate measurement is central to understanding climatic changes by identifying long-term trends of small magnitude from data that can vary enormously over very short timescales.
- Millions of measurements are made every day covering several climatic parameters using different techniques all around the world.
- The accurate and high-quality air pollution data are helpful in proper policy formulation and devising better mitigation techniques.
- The data has to be consistent so that it is meaningful and can be combined, by making measurements that are fully traceable to SI units ensuring the stability of measurement over time.
- The emergence of emissions monitoring, carbon trading, and other technologies such as carbon capture and storage all bring down their own measurement challenges.

CSIR-NPL is serving the nation through environmental metrology services, which is a key requirement for the generation of precise and high-quality air pollution data. CSIR-NPL has taken a massive program and is working to develop a national certification program in this area to help various stakeholders like industries, researchers, and policymakers (Sharma et al. 2020). Recently, CSIR-NPL has been authorized by the act of parliament as the "Certification Agency for Air Pollution Monitoring Equipment" by the Ministry of Environment, Forest and

Climate Change (MoEFCC), Govt. of India. Now, CSIR-NPL has developed a certification scheme (NPL-ICS) for certification of air pollution monitoring equipment, including Continuous Ambient Air Quality Monitoring Systems (CAAQMS), Online Continuous Emission Monitoring Systems (OCEMS), and particulate matter samplers in the country, and has already been notified by the MoEFCC for adoption under the National Clean Air Programme (NCAP). These efforts themselves speak volumes of the contribution of CSIR-NPL in achieving SDGs for climate action (Goal 13) to take urgent action to combat climate change and its impacts by regulating emissions and promoting developments in renewable energy.

Metrological Industrial Measurements and Their Significance for Indian Infrastructure

Metrological measurements are essential and important in our daily life for preventing the underuse, overuse, and misuse of product quantity and services and to identify disparities in the delivery and outcomes. Measurements are used for quality improvement, benchmarking, and accountability. Scientifically accurate and valid measurements have the potential to significantly improve quality and efficiency. Measurements play a key role as an engine of the industrial revolution and the growth of any country. Measurement standards and related activities provide scientific and metrological infrastructure to the country. With the advent of better-quality products through metrological advancement, our industries can compete internationally and overcome trade barriers/constraints and finally achieve export targets. This finally translates into the growth of industries through rapid industrialization, economic growth, and societal upliftment. Therefore, it is fundamentally important in industry and trade, not only for the consumers but also for the manufacturers, because accuracy, quality, and reliability of the products and measurements are equally important for both (consumers and manufacturers). Metrological activities ensure that the measurements are stable, comparable, and coherent. Suppose such metrology is not part of the manufacturing; in that case, we will end up with substandard products, which will be very damaging to the Indian economy, especially in view of the thrust we are giving to local industries (Aswal 2020a; Rab et al. 2021a; Lazzari et al. 2017; https://cdsco.gov.in/opencms/export/sites/CDSCO_WEB/Pdf-documents/medical-device/Classificationg1.pdf. Accessed 31 Oct 2022; https://www.bipm.org/documents/20126/43974911/Presentation-CGPM26-Sarmiento-SDG.pdf/c2dacbcf-8e92-ea6f-56e0-7253ff777769?; Mission 500 GW by 2030; Yadav et al. 2021; Sanjay et al. 2020a, b; Ačko et al. 2020; Bhardwajan et al. 2021; Garg et al. 2021).

What Needs to Be Done to Ensure Good Quality Measurement

Metrological infrastructure is the foundation stone for the practical realization of the Hon'ble Prime Minister's call for AtmaNirbhar Bharat. For both Make in India and

AtmaNirbhar Bharat programs, a robust national QI (metrology, standards, and accreditation: all of them harmonized with respective international counterparts) is essential to ensure that all products are in compliance with regulatory requirements. Metrology is absolutely essential for making India, trade, innovation, and new technology developments, which in the national context are the pillars on which the "AtmaNirbhar Bharat" would grow. The five pillars of development, as put forward by our honorable Prime Minister, viz., economy, infrastructure, system, demography, and demand, can be achievable with precise measurements and their certification or product approval. Thus, the honorable Prime Minister's call for "Vocal for Local" leading to "AtmaNirbhar Bharat" is conceivable, and metrological traceability and reliability in measurements would play a big role culminating in indigenous products with global acceptance and quality, and it would finally result in a quantum jump in economic growth. Much coordinated and effective synergy between all the stakeholders is always required. The country needs to enhance its metrological capabilities at par with international metrological institutes, developing more primary standards traceable to seven base SI units, enhancing calibration and measurement capabilities (existing 236, in comparison to leading NMIs of the world having more than 1000), participation in international inter-comparisons of standards for compatibility and global visibility, and finally the stronger network system of unbroken chain to disseminate the measurement standards to users and clients to get their maximum benefits. As per an estimate, there are more than 400,000 testing, verification, and calibration laboratories in the country in organized and unorganized sectors. Most of these laboratories would require traceability in coming years as the awareness of AtmaNirbhar Bharat is rising to ensure quality in their measurements, process, products, and services.

How This Is Critical in the International Market Given the Standards Applicable

Documentary standards are used to facilitate measurement, manufacturing, communication, and commerce. Standards play an important role in the economy, enabling companies to comply with relevant laws and regulations; providing interoperability between new and existing products, services, and processes; speeding up the introduction of innovative products to market; and facilitating business interaction for mutual understanding. In the case of metrological standards, as science evolves, advanced technologies are developed that demand even more precise and accurate measurements. As a result, the need is felt to focus research efforts on metrology, realize all the seven SI base units in terms of fundamental constants at CSIR-NPL, and establish quantum-based primary standards, BNDs, and primary and secondary standards of allied parameters. To keep pace with global advancement in metrological technologies and also as a responsibility of custodian of measurement standards, CSIR-NPL requires support from all stakeholders to establish and develop new measurement standards based on quantum metrology; to maintain the existing measurement standards and calibration facilities to cater to the rapid industrial

demand; to participate in international comparisons to be at par with international NMIs and to upgrade, extend, and intend measurement ranges and improve upon measurement uncertainties of existing measurement standards and measurement facilities; to participate in BIPM and APMP meetings to maintain and upgrade existing CMCs. In a nutshell, standards help organizations in reducing costs by minimizing errors and redundancies; increasing productivity and efficiency; mitigating risks; maintaining consistency, customer confidence, and uniformity; and eliminating trade borders.

What Can Be Done by Department Heads/District Collectors in This Regard

Traceable measurements are the prerequisite for quality assurance. All economies have their own mechanism imposed through government organizations that are responsible for monitoring the measurement accuracy, demonstrating the importance of the integrity of measurement to a nation's economic growth and prosperity. In the Indian existing system and mechanism of monitoring, CSIR-NPL provides traceability to the Regional Reference Standard Laboratories (RRSLs) of weights and measures and the controllers and inspectors are responsible for implementation at the state levels and at the district levels, respectively. This mechanism needs to be strengthened further by local authorities.

Every department should make it a target to ensure that the manufacturing and services are done with a quality framework that can be traced to the reference standards provided by the National Physical Laboratory. Such calibration and referencing could be suitably incentivized and monitored to ensure quality. In districts, district collectors also can sensitize entrepreneurs about the necessity of products and services to match up to the standards internationally recognized.

Conclusion

An introduction to the fundamentals of industrial metrology is described in this chapter. The study is divided into four parts. The first section described how measurements fit into the industrial revolution. The introduction of important ideas such as application-oriented trends in industrial metrology follows. The contribution of metrology to achieving sustainable development goals is discussed. Finally, a detailed description of the industrial metrological measurements and their importance for Indian infrastructure is given. Since metrological applications impact all aspects of our daily lives, measuring, practicing, and following well-established measurement techniques, methods, and procedures are paramount and critically important. As per the applications and use, metrology is divided into three categories: scientific or fundamental metrology, industrial or applied metrology, and legal metrology, which are interconnected. Industrial metrology serves two purposes. First, it is crucial to specify potential measurement-based acceptance/rejection of goods and services and carry out functions for measuring,

monitoring, controlling, and recording operations to ensure that they adhere to the required standards. Second, it also enhances the likelihood that the measuring apparatus complies with any applicable technical or legal specifications for its intended usage, which is often application specific. Modern industries and all the advanced production systems are centered and dependent upon the ever-increasing intelligent, adaptable, and quick-learning metrology systems. These metrology solutions will accelerate the manufacturing more inventive, well-designed, and high-quality goods while significantly reducing downtime in networked factories. The metrological solutions currently available in the market can be utilized to improve the manufacturing efficiency at all levels, even though a lot of advances in this field will continue to enter the market.
