under serious threat. There is recognition of having good air quality and importance of its regular monitoring extensively. In industrialized countries particularly in the USA, Japan, and Germany, monitoring of industrial emissions has almost completely shifted to use of automatic continuous monitoring instruments based on some specific physicochemical or electrochemical properties of the pollutants. Such instruments require very specific sensors for each pollutant, calibration procedures needing calibration gases of exactly specified and known composition, and dust-free and air-conditioned environment. Such systems become almost unaffordable, from the capital cost point of view, for industrial units in developing countries, particularly for medium- and small-scale units. Even more difficult to tackle are problems of nonavailability of instrument spares and calibration gases in the local markets and also of competent manpower for proper operation and maintenance of these sophisticated systems. Experience in India shows that wherever such systems were installed, they remain inoperative almost from the very start.

The USEPA had developed simple concepts for monitoring of source emissions and also ambient air quality. These may have become obsolete in industrialized countries but still remain suitable for adaptation in developing countries. Even here, instruments manufactured in the USA, Japan, Germany, etc. often tend to make the instrument complex and costly, again creating problems of operation, maintenance, spares, etc., besides the significantly high costs. Instruments described here are based on simple USEPA concepts and are simple for use and maintain in field conditions of warm, tropical climate of developing countries. These instruments are also cost-effective.

Air pollution · Air quality · Appropriate instruments · Manual samplers

Introduction

Growing air pollution is a matter of big concern now. Combustion from vehicles and industries, mining, and construction activities are major sources of pollution and chiefly responsible for deteriorating air quality which is adversely impacting human health, plants and vegetation, agriculture, wildlife, materials, and all other components of our environment. Impacts of some pollutants are short-term and of others are long-term. Recent studies have established that some pollutants are also responsible for climate change and reduced visibility. People working in mining areas are exposed to heavy concentrations of pollutants and suffer from respiratory disorders, bronchitis, asthma, and other deadly diseases like silicosis. Our residences and offices are increasingly becoming air-conditioned and poorly ventilated leading to buildup of carbon dioxide levels as the day progresses. Extensive use of paints and laminates adds VOCs in the indoor air. Instances of "sick building syndromes" are increasingly being reported in cities. Due to increased vehicular mobility and use of

loud musical devices, ambience is becoming noisy and our hearing is getting impaired. Local meteorology also plays a great role in either buildup or dispersion of pollutants in ambient air. Thus, it is evident that good air is essential for survival of living organisms. Regulatory bodies in all countries have laid down limits for emissions from various polluting sources and also standards for good air quality to protect the health of all human beings. Therefore, regular monitoring of emissions from various sources and ambient air quality as well as indoor air, noise, and local meteorology is essential and a necessity. There is a need of appropriate instruments for monitoring air pollutants and air quality. This chapter shall describe such instruments in detail.

Monitoring Air Pollution and Air Quality

To assess pollution loads, one often needs to monitor the emissions into the atmosphere from various sources that are likely to influence air quality in the area. The emissions could broadly be categorized into two groups: (a) formal emissions or discharges from a stack or duct which can be reliably sampled and quantified and (b) fugitive emissions. Formal emission could again be either from stationary sources existing at various heights above ground level like stacks, ducts, vents, etc. or from mobile sources, e.g., vehicular exhausts. Emissions from stationery sources are sampled as per the stack sampling technique and modeled as "point sources" of pollution. Emissions from mobile sources are monitored by various methods briefly described herein after and modeled as "line sources." Fugitive emissions cannot be very exactly quantified and are only approximately assessed. These are modeled as "area sources of pollution." Emissions from a mobile source like a vehicle vary not only from vehicle to vehicle; its state of loading also depends on a number of factors like the speed of movement, slope of the road, condition of the road surface, condition of the tires, and even the speed and direction of wind, etc. Also the pollution caused by a moving vehicle should not include only the emissions from exhaust or tailpipe but also the dust lifted up from the road surface and tire-wear and tear and also vapors escaped from fuel tank, piping, crankcases, etc. Government's transport departments usually mandate the Pollution Under Control (PUC) certificate for the vehicles. The PUC test assesses the emission of a vehicle and checks whether it follows the standard pollution regulations or not.

Air pollution and air quality measurements can broadly be described under the following categories:

(i) Source emissions
(ii) Ambient air quality
(iii) Personal exposure and work zone air quality
(iv) Indoor air quality
(v) Local meteorology
(vi) Noise

There are different techniques and instruments to measure any given pollutant. One should examine the options to determine which techniques and instruments are most appropriate, taking into account the main uses of the monitoring data, initial investment costs for equipment, operating costs, ease of operations, and reliability of systems. Considering this we would study simple methods and instruments to measure these categories.

Source Emission Monitoring

Generally, two types of techniques are followed for monitoring of emissions from stationary sources or stacks: extractive type manual sampling and continuous emission monitoring.

Extractive Type Manual Sampling

In this technique primary methods of sampling and analysis are followed wherein a stack gas sample is extracted from the stack/duct and dust particles present in the stack gas are collected on a filter media, their quantities are measured gravimetrically from the weight of dust collected on the filter media and results are calculated after dividing the weight of dust collected by the volume of gas sampled. Gases present in stack emissions are monitored by absorbing the filtered stack gas in suitable chemical reagents and subsequently analyzing them in the laboratory using standard wet chemical methods to know their concentrations.

The most common and widely used method for stack emission monitoring world over is extractive or grab sampling technique. In this technique, instrument used for sample collection is not restricted to a specific pollutant, but a variety of pollutants can be sampled with the same instrument. A representative sample is drawn from different points selected across the entire cross-sectional area of the stack or duct. These points are called traverse points (US EPA 1994). A typical view of selection of traverse points inside a stack or duct is shown in Figs. 1 and 2.

Instruments based on the primary techniques are designed to be portable to allow collection of sample of emissions from multiple stacks. In some cases they require installation of a monorail system on the chimney at the monitoring location. Instruments installed on monorails are usually heavy as the gas-filtering media or particulate collection media is placed outside the chimney in a heated box which makes the sampler probe heavy and, therefore, needs a monorail. In portable instruments filtering media is kept inside the chimney during monitoring; it makes the handling of sampling probe easy and convenient. The following photographs show a sampler mounted on a monorail as per USEPA Method 5(US EPA e-CFR40 2020) and a portable sampler with in-stack filtration as per USEPA Method 17(US EPA e-CFR40 2017). The schematic diagrams of sampling trains for both techniques are shown in Figs. 3 and 4.

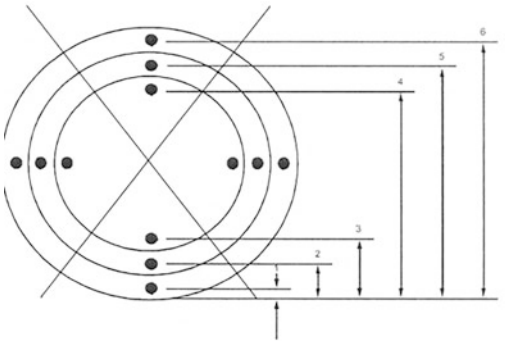

Fig. 1 Traverse points inside a stack

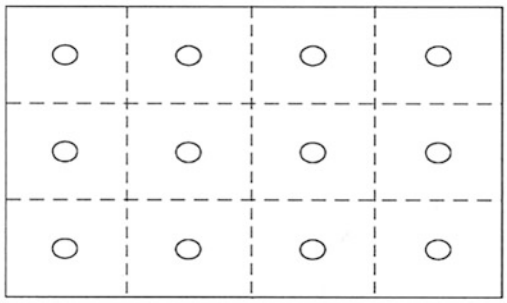

Fig. 2 Traverse points inside a duct

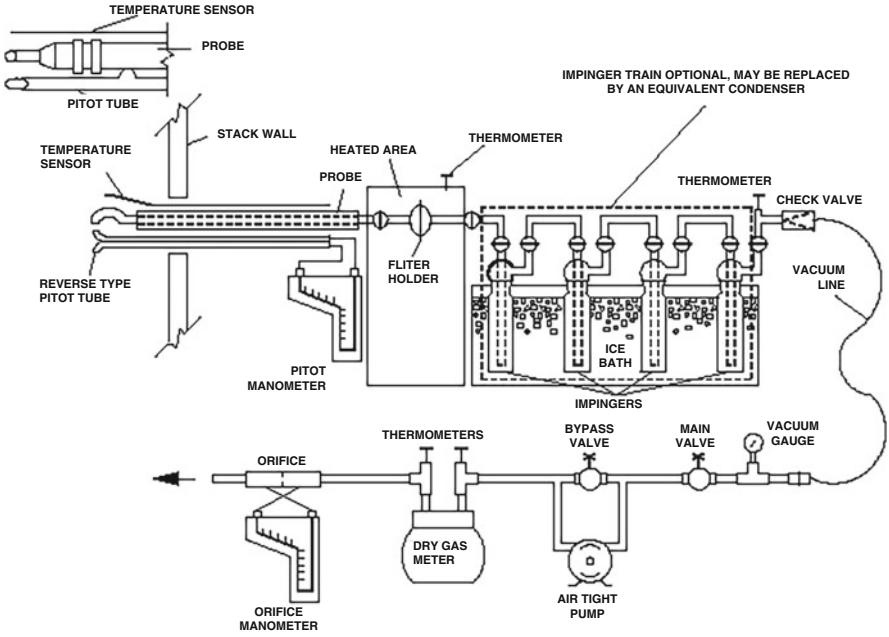

Fig. 3 Sampling train for EPA Method 5

Monitoring with a sampler installed on a monorail (as per USEPA Method 5)

Monitoring with a manual sampler as per USEPA Method 17 (in-stack filtration)

A conventional stack sampler consists of the following major components:

1. Pitot tube.
2. Thermocouple.
3. Probe set consisting of set of nozzles, thimble holder, probe pipes, and hoses.
4. Suction pump.
5. Instrument panel consisting of differential pressure meter, pyrometer, rotameters, stopwatch, and set of glass impingers mounted in a box with provision to keep ice.
6. Tripod stand and associated consumables like filtration thimbles, absorbing reagents, etc. A typical stack sampler is shown in Fig. 5.

Sampling Port Holes and Platform

Construction of a sampling port hole for drawing the stack gas sample and a platform for accommodating the stack sampler and the monitoring team on the stack are the

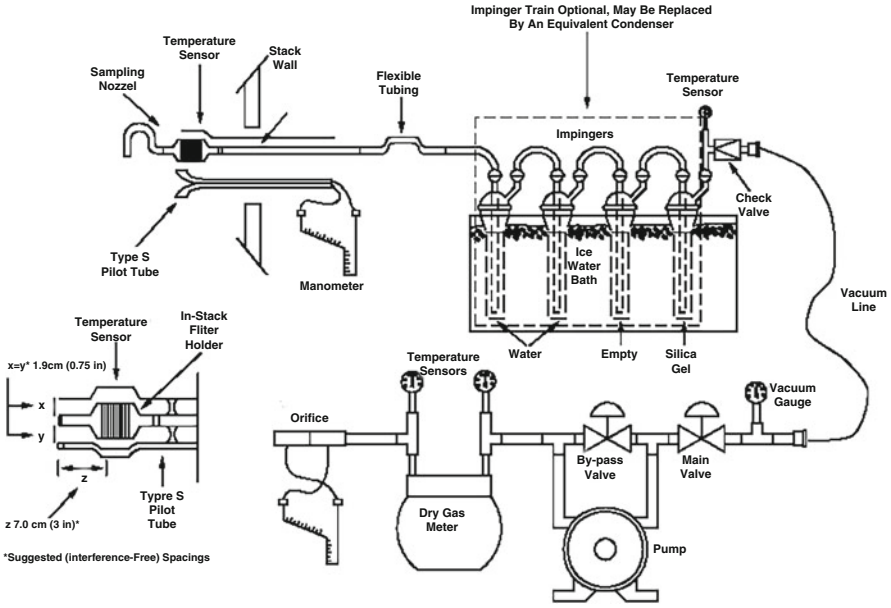

Fig. 4 Sampling train for EPA Method 17

Fig. 5 A stack sampler

prerequirements of the sampling. Sampling port hole of 100 mm internal diameter should be ideally located at more than 8 times of the stack diameter (8D) downstream from any merging point, bend or tapering and 2 times of stack diameter (2D) upstream from the exit point, bend, or any other flow disturbance

point (Guidelines on methodologies for source emission monitoring 2013–2014). Sampling platform should be about 1.5 m below the port hole, and a power supply point should be available for operation of monitoring instruments. A schematic diagram of the location of sampling port hole and the platform is shown in Fig. 6.

An important aspect of stack emission monitoring is that sampling for the particulate matter (PM) is carried out at isokinetic conditions, i.e., samples from the stacks or ducts are extracted at the same velocity which exists inside the stack or duct. And velocity across the entire cross-sectional area of a stack or duct may not be same; therefore, velocity is measured at various selected traverse points, and isokinetic flow rates are calculated at each traverse point. Samples are then drawn at each traverse point at the calculated flow rates. Stack temperature, stack pressure, stack gas moisture content, and the stack gas density are also measured and considered in calculating the isokinetic flow rates.

The first step in stack emission monitoring is to know the stack gas velocity. For this differential pressure is measured at selected traverse points across the cross-sectional area of the stack with the help of a pitot tube and a manometer available with the stack sampler. Stack gas temperature, stack pressure, stack gas density, and moisture content are also measured, and stack gas velocity is then calculated using the following equation (Emission Regulations 1985):

$$V = K\left(\frac{2 \times g \times \Delta P \times dm \times Ts}{da \times Ta}\right)^{1/2}$$

where

V = Stack gas velocity in m/s
K = Pitot calibration constant
g = Gravitational constant (9.81 m/s^2)
Δ P = Differential pressure across the stack in meters
dm = Density of water in Kg/m^3 (1000 kg/m^3)
da = Density of stack gas in Kg/m^3 (for air it is 1.25 kg/m^3 at 25 °C)
Ta = 273 + 25 in °K
Ts = Stack gas temperature in °K

During sampling, stack gas enters the sampler through the nozzle; therefore, the isokinetic flow rate through the nozzle needs to be set at the sampler which is calculated after multiplying the stack gas velocity with the cross-sectional area of the nozzle used. Usually a rotameter is used to set the flow rate on the stack sampler; therefore, isokinetic flow rate is derived after selection of a suitable nozzle so that the calculated flow rate falls within the measurement range of the rotameter of the sampler. Usually a set of 3–4 nozzles having different cross-sectional areas are available with the sampler. A schematic diagram of a nozzle, thimble holder, and sampling probe is shown in Fig. 7.

Temperature of the stack gas is measured with the help of a thermocouple and pyrometer available with the stack sampler. Moisture content in the stack gas is

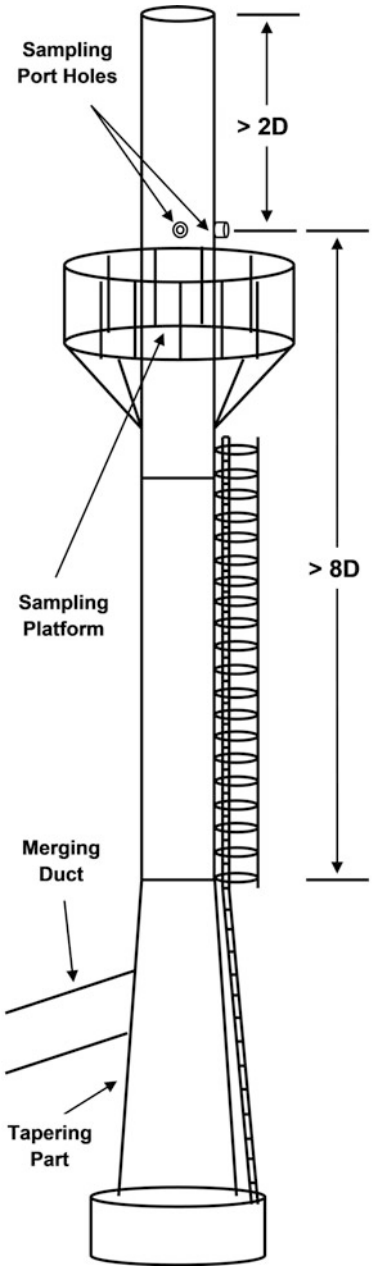

Fig. 6 Location of sampling port hole and platform

determined either by drawing a known volume of stack gas and condensing the water vapors present in the stack gas in an ice-cold water trap or by absorbing it in the activated silica gel bottle. To collect the moisture in ice-cold water trap, a known

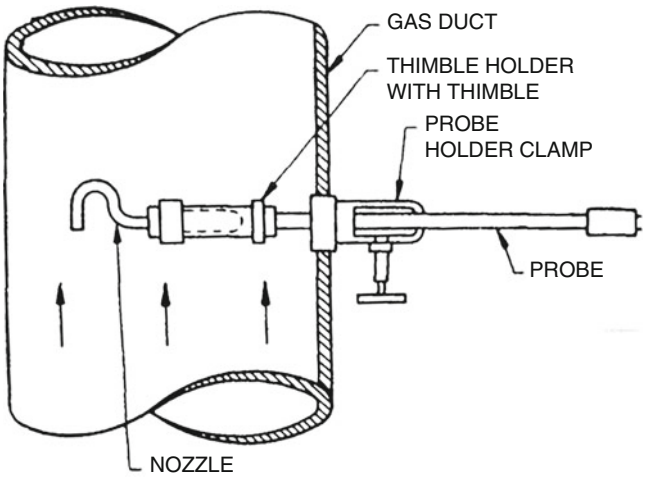

Fig. 7 Schematic diagram of a nozzle, thimble holder, and sampling probe

volume of ice-cold water is taken in a glass impinger maintained at low temperature by ice, and a known volume of gas is passed through it at a low flow rate. The water vapors present in the stack gas get condensed in the ice-cold water, and consequently, there is an increase in the volume of water from the initial volume of water taken in the impinger. Moisture content is then determined from the volume of water condensed and volume of gas passed through it. Another method for determination of moisture in stack gas is by absorbing stack gas moisture in activated silica gel. In this method, a known volume of stack gas is passed through the granular activated silica gel taken in a glass bottle. The amount of moisture absorbed in the silica gel is determined from the difference in weight of the silica gel bottle, after sampling and before sampling. Moisture content is then calculated from the weight of water absorbed by silica gel and volume of gas passed through it.

Stack gas density is determined by drawing a stack gas sample in a gas bottle or in a "Tedlar" bag and analyzing it on an Orsat apparatus or on a gas chromatograph (GC). Gas chromatographic analysis involves costly setup and highly skilled manpower, whereas an Orsat apparatus is a simple apparatus. It consists of a graduated measuring burette, an aspirating bottle, and three double reagent pipettes to absorb CO_2, O_2, and CO. Measuring burette is connected to aspirating bottle by means of rubber tube. The first reagent pipette next to measuring burette contains the saturated KOH solution to absorb CO_2. The second pipette contains alkaline solution of pyrogallic acid to absorb O_2, and the third pipette contains acidic solution of cuprous chloride to absorb CO. Each pipette is made of two pipettes joined together by a glass tube at the bottom as shown in Fig. 9. Each front pipette is provided with the number of glass tubes inside to increase the wetted surface area to accelerate the gas absorption. Initially, 100 ml of stack gas taken either in a gas bottle or in a Tedlar bag is transferred to the measuring burette, and it is brought in contact of KOH solution in the first pipette by raising the level of aspirating bottle and the process is repeated till absorption of CO_2 is completed. The same procedure is repeated with other two

pipettes for absorption of O_2 and CO to find the percentage analysis of O_2 and CO, respectively, in the flue gas. The remainder is N_2 gas. Thus, Orsat apparatus gives analysis of the dry gas (IS 13270:1992 1992). A typical Tedlar bag and an Orsat apparatus are shown in Figs. 8 and 9, respectively.

Continuous Emission Monitoring

In this technique, specific characteristics/properties of dust particles and gases are used for their detection and measurement. Since secondary properties are used for detection, these methods fall under secondary methods. Monitors or systems used here are known as continuous emission monitoring systems (CEMS) or online continuous emission monitoring systems (OCEMS). CEMS or OCEMS are usually permanently installed on the stacks, and in some cases stack gas is extracted through a pipeline and fed to the analyzer located at some nearby location under controlled environmental conditions.

Most monitors use one or more of the light interaction properties with the particles. When light falls on the surface of a particle, it may be absorbed, reflected, refracted, or diffracted by the particle fully or partly. Any one or more of the light interaction phenomena occurring are used to measure the concentrations of the particles. For this a suitable detector is used to measure the intensity of light received after their interaction with the particles. In the process detector also measures the intensity of reference beam. Change in intensity of the sample beam and reference beam is used for computation of the concentration of particles. In such monitors, usually, opacity or transmissivity through the cross section of the stack or duct is measured. A typical example of interaction of light with particle is shown in Fig. 10.

Continuous emission monitoring systems can be categorized into two types (Guidelines for Continuous Emission Monitoring Systems 2018):

1. Extractive type
2. In situ type

Fig. 8 A Tedler bag

Fig. 9 An Orsat apparatus

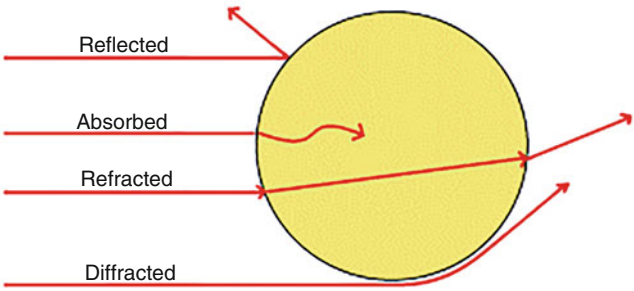

Fig. 10 Light interaction modes with particle

Extractive type systems draw flue gas from the stack and transport it continuously to the analyzer. These systems perform analysis at a single point, whereas in situ type systems carry out most of their operations in the stack itself. These can further be categorized as point in situ monitors and cross duct or path monitors. Point in situ systems carry out analysis at a single point in the stack, and path monitors carry out analysis over the entire stack or duct diameter. Again, there are two basic types of cross duct or path monitors:

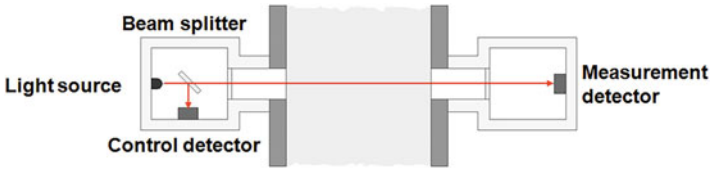

Fig. 11 Schematic diagram of a single-pass opacity monitor

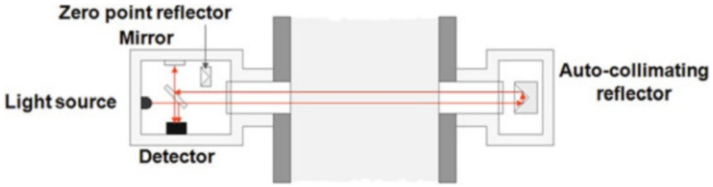

Fig. 12 Schematic diagram of a double-pass opacity monitor

1. Single-pass monitors
2. Double-pass monitors

In a single-pass monitor, one light beam from the source is passed to receiver or detector placed on the opposite side of the stack, whereas in a double-pass monitor, the beam is reflected back across the stack to the detector located on the side of light source. Double-pass monitors are more sensitive as compared to a single-pass monitor. Schematic diagram of a single-pass and double-pass opacity monitors is depicted in Figs. 11 and 12.

Again, all these monitors have two configurations: single-beam configuration and double-beam configuration. Single-beam configuration is simple and has a single beam of light passing across the stack, whereas in a double-beam configuration, the light emitted from the source is internally split into two beams, one becomes measurement beam and another becomes reference beam. Double-beam configurations are more sensitive as compared to the single beam.

Instruments with nonoptical technologies are also popular and used for measurement of particulate matter in stack emissions. Probe electrification technique is one of them. In this technique electrical current produced by particles interacting with a grounded rod protruding across the stack or duct is measured and correlated to dust concentration. Schematic diagram of probe electrification instrument is depicted in Fig. 13.

Presence of moisture in stack gases affects the monitoring response of all in situ technologies to an extent. In these instances, extractive systems give more reliable results. Beta attenuation is one of the widely used technologies for dust monitoring. In this technique moving gas stream is sampled and the particulate is collected onto a filter. The filter is advanced periodically into a measurement chamber, where radioactive beta particles are passed through the sample and the amount of beta particles

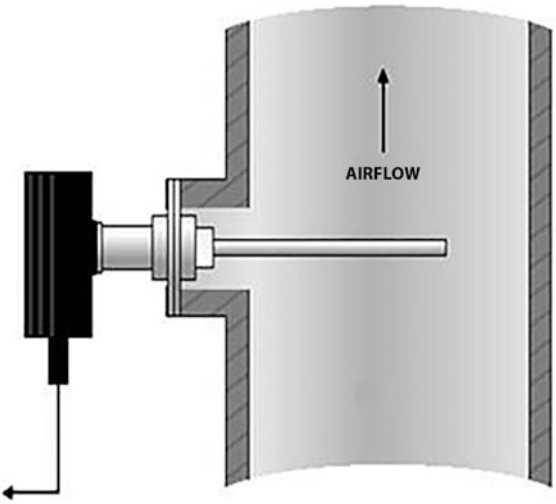

Fig. 13 Schematic diagram of a probe electrification instrument

transmitted through the sample is measured. The advantage of this technique is that the absorption of radioactivity is not significantly affected by the type of particle. Schematic diagram of a beta attenuation monitor is depicted in Fig. 14.

All the continuous particulate matter monitoring system (PM-CEMS) are calibrated against isokinetic sampling at different operational loads using a manual stack sampler, whereas gaseous analyzers are calibrated against standard span gases.

Another category of instruments used for obtaining information on stack gas constituents and in turn stack gas density are the flue gas analyzers. These analyzers are mostly sensor-based instruments and give quick information on the stack gas constituents. This data can be directly used for calculation of stack gas density required for computation of stack velocity and isokinetic flow rate. These instruments are microprocessor based and may also provide additional information like combustion efficiencies of the processes and also the presence of other pollutants in stack gases. Usually a specific type of sensor is used for detection of a particular constituent. A typical flue gas analyzer is shown in Fig. 15.

Ambient Air Quality Monitoring

Before planning air quality monitoring, it is necessary to have a clear idea of the monitoring objectives, since these determine the selection of appropriate pollutants and measuring methods, as well as the required level of accuracy and precision. Objectives may include the assessment of quality of air that a community or ecosystem is being exposed to and hence developing scientific understanding of

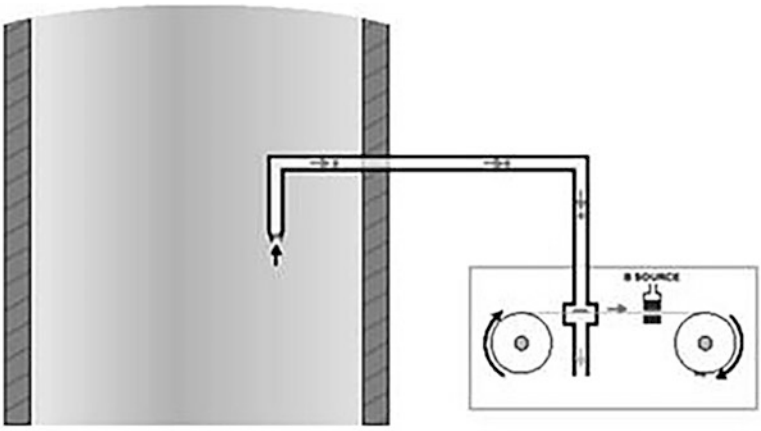

Fig. 14 Schematic diagram of a beta attenuation monitor

Fig. 15 A typical flue gas analyzer

causes; generation, impact, status, and trends; creating awareness; and for the purpose of setting standards/limits defining need for likely action or for evidence for punitive action.

More technical objectives may even include the identification and apportionment of pollution sources, land use planning, determination of spatial and temporal patterns of exposure, or identification of long-term trends. The long-term trends allow us to detect any deterioration in air quality arising from residential/industrial/economic development and/or the effectiveness of pollution control measures taken. In short, monitoring data are generally intended for use in developing strategies for management of air quality in a city, locality, region, or national level.

Air quality surveys are generally concerned with temporal and spatial variation of the concentrations of selected pollutants. The type and level of air pollution is a major factor in the quality of life of the community.

The data must also be of acceptable quality to satisfy the intended use, since proper quality assurance of data is the keystone to ensure realistic interpretation for correct decision-making. Obviously it would not be desirable to mix up networks with substantially different overall design, using different monitoring techniques or using varying levels of skilled manpower.

Air quality assessment is made using monitoring systems composed of carefully selected air quality monitoring techniques suitable for the application involved, and representative of the area. The classical pollutants measured at an ambient air monitoring station include suspended particulate matter (SPM), respirable suspended particulate matter (RSPM) or PM_{10}, fine particulate matter or $PM_{2.5}$, sulfur dioxide, nitrogen oxides, ozone, and carbon monoxide. However, these days many more other constituents are being considered as pollutants, and their measurement is also being carried out. Various methodical approaches, technical skills, and instruments to estimate the air pollutants have been developed and are still being developed. Broadly, monitoring systems available at present include manual samplers, online systems, and sensor-based instruments including remote sensing.

In the following sections, we have tried to briefly describe these techniques one by one. However, it may be stated that the choice of appropriate monitoring technique for any air quality assessment exercise will depend largely on its objectives, local resource constrains, and the availability of skilled manpower. There is a clear trade-off between instrument cost, complexity, reliability, and performance. More expensive systems, although they provide increasingly refined data, often tend to be less reliable and more difficult to use.

The simplest method that meets the specified monitoring objectives should be selected. Inappropriate, excessively complex, or failure-prone equipment can severely disrupt overall performance limiting the usefulness of data gathered. Automatic analyzers are required if short-term concentration peaks or the resulting acute health, amenity, or ecosystem effects are to be investigated, but manual samplers will often be adequate if long-term baseline levels or trends are of importance. Appropriate techniques and samplers for monitoring of particulates and gaseous pollutants in the ambient air are described here.

The dust found in the atmosphere is in the form of suspended dust particles and known as SPM. These particulates are small in size, usually below 100 microns, and remain suspended in the atmosphere for significant periods of time. Particles of size 10 micron and below present in the atmosphere are known as RSPM, and further

smaller particles of size 2.5 micron and below are termed as fine particulates. Fine particulates are usually more harmful than the bigger size of particles as these can penetrate deep into the lungs. Our respiratory tract retains particulates of varying sizes at different levels. Larger size particles are retained in the upper respiratory tract and only smaller ones can go down deeper.

Meteorological conditions such as wind speed, wind direction, temperature, relative humidity, rainfall, and atmospheric stability conditions play a very important role in the dispersion of the pollutants generated at any place, and therefore information on local meteorology need to be collected along with the monitoring of dust particles and gaseous pollutants for better understanding of the air quality. Broadly, four different techniques are used for monitoring ambient air quality:

(i) Manual samplers
(ii) Continuous ambient air quality monitoring systems
(iii) Sensor-based systems
(iv) Satellite-based systems

Manual Samplers

The basic technique for monitoring particulates in ambient air is filtration technique using manual samplers followed by gravimetric analysis. Among the particulates, coarser particles present in the atmosphere get settled quickly at the ground, whereas particulates of size 100 micron and below remain suspended in the air for appreciable time durations and are known as SPM or TSPM. SPM is measured using a high-volume air sampler wherein suspended dust particulates present in the air are directly collected on a filer paper, whereas particulates in other size ranges such as PM_{10}, $PM_{2.5}$, etc. are first separated in required size range and then collected onto a filter paper by passing a known volume of air through the filter paper using a particulate sampler, and the amount of dust collected on the filter paper is estimated from the difference in weight of the filter paper after the sampling and weight of filer paper before sampling. The common techniques for physical separation of dust particles are either an impactor or a cyclone. All such samplers have a particle separation device, an air flow meter for adjusting the required flow rate of air and a time totalizer for recording the total time of run. Volume of air sampled is then calculated by multiplying the average air flow rate with the total time of sampling. Concentrations of particulates present in the air are then calculated from the total weight of dust collected on the filter paper and dividing it by total volume of air sampled. Results are then reported in units of microgram per meter cube.

Instruments for Monitoring of SPM

High-volume air sampler (US EPA 40 CFR n.d.-a) is the most frequently used sampling device in air quality monitoring, so much so that they are often called

"Work horses of air quality management." The basic principle is sucking air at a constant prefixed rate for a known time through a filter (usually a glass microfiber filter) and determining the initial and post-sampling filter weights after appropriate conditioning of the filters. It is used for monitoring of SPM in air. The design of the air inlet of high-volume air sampler is unlikely to collect airborne particles with diameters greater than 100 micrometers (μm) in diameter. It is measured by passing air at a high flow rate of 0.8–1.2 cubic meters per minute through an $8'' \times 10''$ high efficiency glass fiber filter paper which retains the particles. Filter paper is installed over a wire mesh and tightened securely with the help of four screws. A detachable gable roof is provided to prevent the heavier settleable dust particles from reaching the filter. A water manometer and a time totalizer are provided for measurement of air flow rate and the duration of sampling. The volume of air sampled is determined from the average flow rate and duration of sampling, while the amount of particulates collected is determined by measuring the change in weight of the filter paper as a consequence of the sampling. A timer is also available in the instrument for programming the sampling schedule. If required, particulate matter retained on the filter can be analyzed to determine the concentration of metals such as lead or any other metals. A typical high-volume air sampler and an illustration of installation of a filter paper are shown in Figs. 16 and 17. These instruments are available with an attachment for sampling of gaseous pollutants which enables simultaneous sampling of gases like SO_2, NOx, etc.

Instruments for Monitoring of RSPM or PM_{10}

Respirable suspended particulates are the particles of size $\leq$10 μ. These particles are generated by combustion and non-combustion processes, including windblown dust, sea salt, industrial processes, motor vehicle engines, and fires. These particles can enter the human respiratory system and penetrate deeply into the lungs, causing adverse health effects. A respirable dust sampler (RDS) (Guidelines for Measurement of Ambient Air Pollutants 2012–2013) is used for monitoring of RSPM. It has a cyclone device to separate the dust particles in two fractions of size 10 micron and below and the other fraction of size coarser particles having size >10 microns. In such instruments particle cutoff of the cyclone close to 10 μ size is an important aspect and need to be properly designed. In a RDS air enters through the inlet cap and travels to the cyclone via the inlet pipe at a regulated flow rate in the range of 0.85–1.15 m^3 per min. In the cyclone dust particles get fractionated into two size ranges. Dust particles having size greater than 10 microns get separated in the cyclone and fall into the cup attached at the bottom of it, whereas finer particles which are of size 10 micron and below are carried to the filter paper and get deposited on the filter paper. The filtered air is then allowed to exhaust out of the instrument through the pump.

The instrument measures the flow rate with the help of a glass manometer directly calibrated in flow rate units of cubic meter per minute. A timer and a time totalizer are available for programming the sampling schedule and recording the sampling duration. Measuring the volume of air sampled and weight of dust collected on to a filter paper determines the concentration of PM_{10} particles in the air. The dust

Fig. 16 A high-volume air sampler

Fig. 17 Installation of filter paper on a high-volume air sampler

particles retained on the filter can be analyzed to determine the concentration of other pollutants. These instruments also have provision of attaching a gaseous sampling attachment for simultaneous sampling of gaseous pollutants. One can also assess the SPM by combining the dust collected in the cyclone cup with the dust collected on the filter paper. For very precise and accurate values, RDS or PM_{10} sampler has

electronically controlled system for maintaining constant flow rate. A typical respirable dust sampler and its schematic diagram are shown in Figs. 18 and 19.

Instruments for Monitoring of $PM_{2.5}$

The finer portion of the dust which enters deep into the lungs causes severe respiratory problems. This finer portion of the dust is usually referred to as $PM_{2.5}$ particles. A fine particulate sampler or $PM_{2.5}$ sampler is used for monitoring $PM_{2.5}$ in ambient air (US EPA 40 CFR n.d.-b).

In these instruments ambient air enters at a flow rate of about 16.7 liter per minute through an omnidirectional inlet designed to provide a clean aerodynamic cut point for particles of size greater than 10 μ. Particles in the airstream which are smaller than 10 μ proceed to a second impactor that has an aerodynamic cut point at 2.5 μ. The air containing fine particulates exiting from the $PM_{2.5}$ impactor is allowed to pass through a 47-mm-diameter Teflon filter membrane (PTFE filter) that retains the dust particles of size $\leq$2.5 μ. All these instruments are provided with a pump, a flow

Fig. 18 A respirable dust sampler

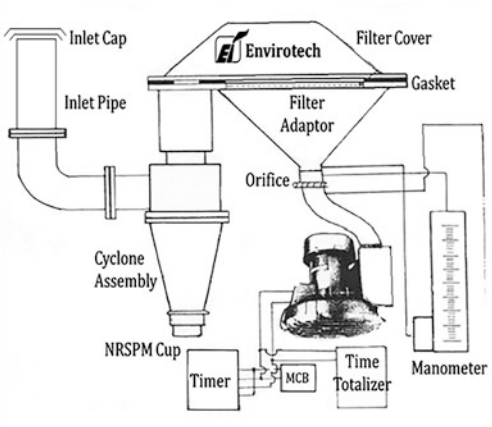

Fig. 19 Schematic diagram of a respirable dust sampler

rate-measuring device, a flow totalizer, timer, time totalizer, and a filter holder designed to accept any standard 47-mm-diameter filter media. A typical $PM_{2.5}$ sampler is shown in Fig. 20.

To ensure greater precision and accuracy, a mass flow sensor is also added to measure air flow rate. In these instruments sampling rate is held constant at 16.7 liter per minute by a microprocessor-based electronic flow controller which automatically adjusts the pump RPM with increasing pressure drop due to deposition of dust on the filter. An ambient air temperature sensor and barometric pressure sensor are provided for effective temperature and pressure corrections of volume of air. An additional filter pressure sensor is provided to record the filter pressure to ensure that the system terminates the sample collection if the pressure drop across the filter exceeds the safe limits. An electronic display of parameters in a $PM_{2.5}$ sampler is shown in Fig. 21.

Increase in temperature in the filter paper compartment may lead to loss of volatile matter present in the dust collected over the filter paper. Considering this, the suction pump is housed in a separate cabinet to minimize heat dissipation near the filter holder assembly. The two cabinets are then clamped together during operation.

Instruments for Monitoring Ultrafine Particulate Matter or PM_1

Recent studies sponsored by the USEPA have concluded that the submicron "ultrafine" particles penetrate further deep into the lungs as compared to PM_{10} and $PM_{2.5}$ particles and have serious adverse effects on the human health. These communities are now monitoring the submicron or PM_1 particulates in addition to the PM_{10} and $PM_{2.5}$. PM_1 monitoring instruments have similar features of a $PM_{2.5}$ sampler except that of the particulate separation device. Here an impactor to separate particles of size ≤ 1 μ is used. Sampling flow rate is maintained at about 10 liters per min. Ultrafine particulates leaving the PM_1 impactor are allowed to deposit on a PTFE filter paper, and the concentrations of PM_1 are determined from the amount of dust collected on the filter paper and the volume of air passed. A typical PM_1 sampler is shown in Fig. 22.

Fig. 20 A $PM_{2.5}$ sampler

Gaseous Sampling Attachments

In addition to particulates, a variety of gaseous pollutants like sulfur dioxide (SO_2), oxides of nitrogen (NOx), carbon monoxide (CO), ozone (O_3), ammonia (NH_3), and many more other gases also need to be monitored. These gases can be absorbed in specific chemical reagents/solutions. For this air is aspirated through these chemical reagents/solutions called absorbing solutions at a known flow rate for a specified time period. A rotameter of 0–3 lpm is available for setting the required flow rate. Usually, there is provision for placing up to four glass impingers of 35 ml capacity in an ice tray and a rotameter and a manifold is provided to set the required flow rates. For simultaneous sampling of one or more gases along with the particulate sampling, gaseous sampling attachments can be hooked with the particulate samplers.

Use of ice is common practice to maintain low temperature around impingers for better absorption of gases. But arranging ice all the time during sampling is often difficult and its availability in remote areas is not assured. To overcome this problem

Fig. 21 An electronic display of parameters in a $PM_{2.5}$ sampler

Fig. 22 A PM_1 sampler

gaseous attachments are now designed to deploy Peltier effect-based solid-state heat pumps to keep the temperature well below the ambient temperature. A built-in thermostat constantly monitors the cold box temperature and ensures that absorbing solution is maintained at set temperature. Silica gel filters are usually provided in the outflow path of each impinge to arrest the particulate that otherwise gets deposited in the needle valve which may result in drop of flow rate. A schematic of a typical gaseous sampling attachment having provision for cooling based on Peltier effect is shown in Figs. 23 and 24.

Instruments for Monitoring of Heavy Metals

Mining and mineral-based industries including crushers, cement plants, thermal power plants, steel and other metal refining and processing plants, coke ovens, brick/lime and pottery kilns, etc. all emit large quantities of pollutants in air, not just ordinary dust, smoke, CO_2, and CO but toxic, phytotoxic, and harmful gases and toxic particulates. Very often these include components of toxic heavy metals like As, Cd, Cr, Hg, Ni, Pb, etc. and also highly toxic organics. These cause serious human health problems, crop damage, and economic losses besides adverse ecological impacts. Since impacts of these on health are noticeable only over a long period, it is advisable to measure their annual averages.

A heavy metal sampler enables collection of dust samples at a flow rate of about 3 liters per minute for long durations. Samples of even 1-month duration can be collected over a single filter paper, and analysis of single sample gives the monthly average results of heavy metals, and one can obtain the annual averages from 12 such samples. A typical heavy metal sampler is shown in Fig. 25.

Continuous Ambient Air Quality Monitoring Devices

The exposure during peak concentrations of certain pollutants can be lethal, and it is therefore desirable to know the short-term, peak, and hour-to-hour concentration of

Fig. 23 A gaseous sampling attachment

Fig. 24 An independent gaseous sampler

pollutants. This helps to the communities to know about the critical periods of pollution levels during the day. It necessitated the requirement of real-time continuous recording type of instruments. Continuous recording type instruments use specific characteristics/properties of dust particles and gases for their detection and measurement. These devices have advantages such as ease of use, better accuracy, low cost per sample, robustness, and low time frequency up to only a few minutes. The principle used in these systems is some physical or chemical property of gas that can be continuously detected, usually by optical-electronic methods. Sampled air enters a reaction chamber where either optical property of the gas can be measured directly or a chemical reaction occurs and produces chemiluminescent or fluorescent light. A light detector produces an electrical signal which is proportional to the concentration of the pollutant being measured.

A sophisticated quality assurance is an integral part of the automatic analyzers. Continuous analyzers produce a large quantity of data which necessitates telemetry system for data acquisition and online compilers for subsequent processing and analysis.

However, these advanced capabilities of automatic analyzers are obtained at the expense of increased capital, maintenance, and support costs. In addition these instruments are also liable to be more susceptible to the technical problems than manual samplers, and require skilled manpower for routine operations.

All these analyzers and calibration systems are microcontroller-based instruments with large graphic LCD to provide continuous status updates including gas concentration, real-time zero/span calibration, sample flow, etc. employing a data acquisition system (DAS).

DAS is rack-mounted industrial PC running Windows-compatible software that has a client-server architecture. It is able to work unattended, i.e., captures analyzer values and sensor values automatically. If a user wishes to perform zero-span checks

Fig. 25 A typical heavy metal sampler

or simply wishes to view the data, he should be able to log in to DAS through a valid username-password. As such, the user can be located anywhere and not necessarily be close to DAS. Analyzers are interfaced to DAS and then get remotely connected to a user/scientist through modem and phone lines/Internet. It should be noted that man-machine interaction is achieved not only locally but remotely also. DAS is accessible by a remote computer for preparing reports or plotting graphs. Schematic diagram of a typical data acquisition system (DAS) is shown in Fig. 26.

For assessment of air quality of an area, district, or city, a typical continuous ambient air quality monitoring station consists of the following:

(a) Rack-mounted set of analyzers and calibration system
(b) Glass lined and heated inlet pipe with manifold
(c) Common external sample pumps with rack-mounted kit.

(d) Calibration system and span gases
(e) Data acquisition system (DAS)

A typical online air quality monitoring station produces thousands of data values every month. The report preparation software is therefore a vital aid to analyze the data recorded by the DAS. Good software can download data from different field stations to a central location for analysis, long-term storage, and dissemination of information. It supports communication via a variety of communication systems including PSTN land lines, TCP/IP, wireless or GSM modems, etc. The software is used to tabulate the data, export it to suitable formats such as MS Excel, or perform scientific analysis in the form of graphs/charts. A typical CAQMS is illustrated in Fig. 27. Common air pollutants and their measurement principles/techniques are given in Table 1.

Principles/methods used for measurement of these pollutants are described below.

Continuous Measurement of Sulfur Dioxide

The measurement of ambient SO_2 levels by the UV fluorescence SO_2 analyzer is based on the principle that SO_2 molecules absorb UV light at the wavelength of 214 nm. The absorbed UV energy excites the outer electrons to the next state. The excited electrons then return to the original state and emit photons at the wavelength of 390 nm. The first reaction step is:

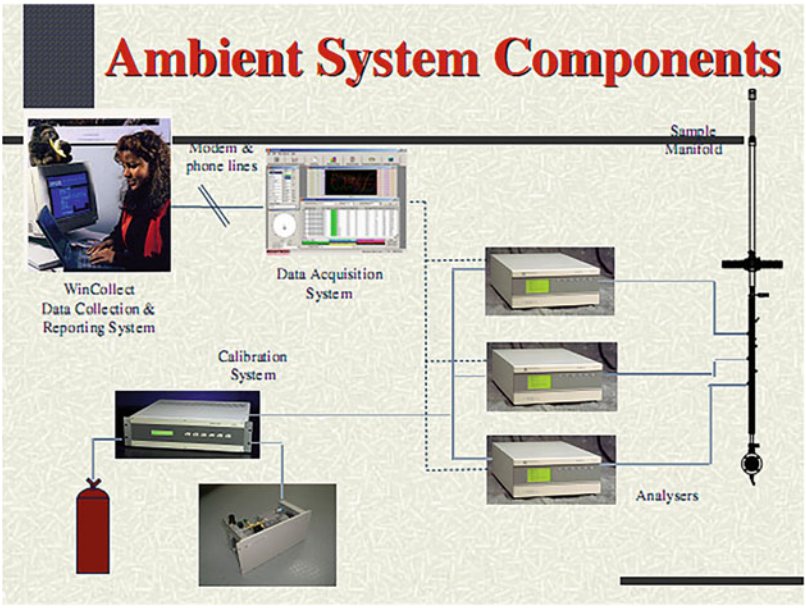

Fig. 26 Schematic diagram of a typical data acquisition system (DAS)

Fig. 27 A typical CAQMS

Table 1 List of common air pollutants and their measurement techniques

Air pollutants	Principle/technique
Sulfur dioxide (SO_2)	UV fluorescence
Nitrogen dioxide (NO_2)	Gas phase chemiluminescence
Ammonia (NH_3)	Chemiluminescence
Ozone (O_3)	UV photometry/chemiluminescence
Carbon monoxide (CO)	Nondispersive IR
PM_{10} & $PM_{2.5}$	Beta attenuation/TEOM
Benzene (C_6H_6)	Gas chromatography (GC)-based continuous analyzer/adsorption and desorption followed by GC analysis

$$SO_2 + h\upsilon_1 \rightarrow SO_2{}^*$$

Then in the second step, the excited SO_2* molecule returns to the original ground state, emitting an energy $h\upsilon_2$ according to the reaction:

$$SO_2{}^* \rightarrow SO_2 + h\upsilon_2$$

The intensity of the fluorescent radiation is proportional to the number of SO_2 molecules in the detection volume and is therefore proportional to the concentration of SO_2. A schematic diagram of a SO_2 analyzer is shown in Fig. 28.

Continuous Measurement of Oxides of Nitrogen

The measurement method is based upon the rapid chemiluminescence reaction of nitric oxide (NO) with excess ozone (O_3). The reaction is made to take place in a light-free chamber:

$$NO + O_3 \rightarrow NO_2^* + O_2$$

A portion of the resultant nitrogen dioxide is produced in a highly excited energy state (NO_2*) and subsequently decays to the ground level state emitting light in a broad frequency band with a peak at about 1200 nm:

$$NO_2^* \rightarrow NO_2 + h\upsilon$$

The intensity of the light emitted is linearly proportional to the nitric oxide concentration and is measured by a photomultiplier tube. This is done in two steps, in the first step NO present in the air sample is detected, and in the second step, NO_2 present in the air sample is first converted to NO in a catalytic converter and then total of NO and NO formed from the conversion of NO_2 is detected which gives NOx concentration. A schematic diagram of a NOx analyzer is shown in Fig. 29.

Continuous Measurement of Ammonia

The ammonia analyzer is a combination of NH_3 converter and an NO-NO_2-NOx analyzer. Ammonia in the air sample is oxidized to nitric oxide (NO) with molybdenum and carbon converters. The measurement method is based upon the rapid chemiluminescent reaction of nitric oxide (NO) with excess ozone (O_3). The reaction is made to take place in a light-free chamber:

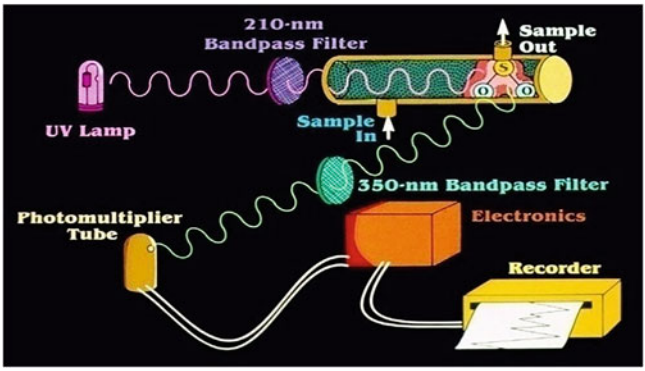

Fig. 28 Schematic diagram of a SO_2 analyzer

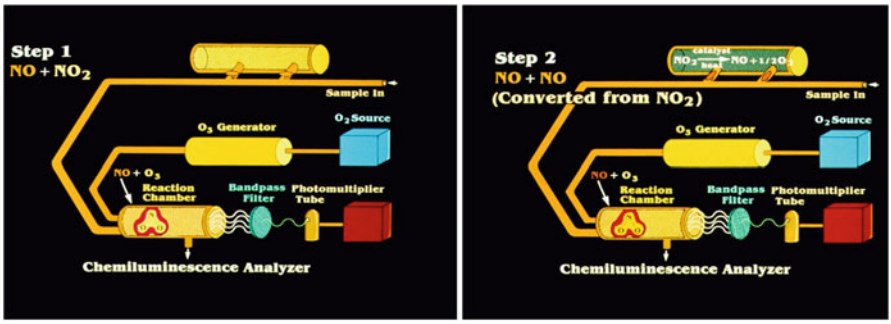

Fig. 29 Schematic diagram of a NOx analyzer

$$NO + O_3 \rightarrow NO_2^* + O_2$$

The instrument is designed for the measurement of total oxides of nitrogen (NOx) and nitric oxide (NO) and indirect determination of nitrogen dioxide (NO_2) and ammonia (NH_3). NO_2 and NH_3 are calculated by subtraction of NO from NOx and NOx from NOy as shown below:

$$\begin{aligned} NOx &= NO + NO_2 \\ NO_2 &= NOx - NO \end{aligned} \quad (1)$$

$$\begin{aligned} NOY &= NOx + NH_3 \\ NH_3 &= NOY - NOx \end{aligned} \quad (2)$$

Continuous Measurement of Ozone

The method is based on the photometric assay of absorption of ultraviolet light by ozone (O_3) molecules in a dynamic flow system. The concentration of O_3 is determined in an absorption cell from the measurement of the amount of light absorbed at a wavelength of 254 nm. The quantities are related by the Beer-Lambert law. A schematic diagram of an ozone analyzer is shown in Fig. 30.

Continuous Measurement of Carbon Monoxide

Carbon monoxide absorbs IR radiations at 4.7 μm. Instrument uses two parallel infrared beams one through a sample cell and the other through a reference cell and a selective detector. The detector signal is led to an amplifier, and the analyzer output is measured on a meter and recording system. A schematic diagram of a CO analyzer is shown in Fig. 31.

Continuous Measurement of $PM_{10}/PM_{2.5}$

A technique used for continuous measurement of PM_{10} and $PM_{2.5}$ particulates is beta-ray attenuation monitor (BAM). In this system dust-laden air is allowed to pass through a particle separation device usually a cyclone for separation of either PM_{10}

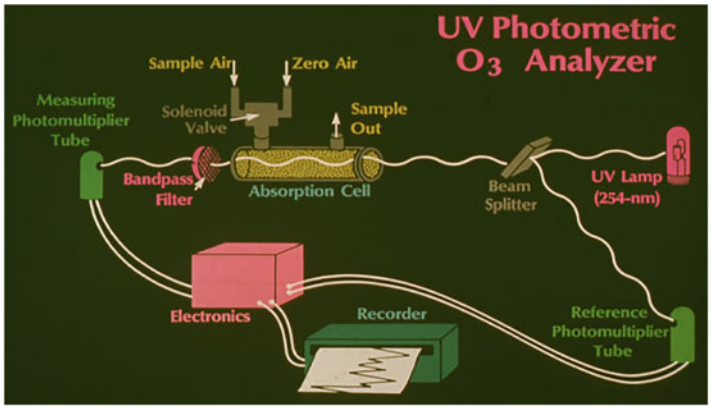

Fig. 30 Schematic diagram of an ozone analyzer

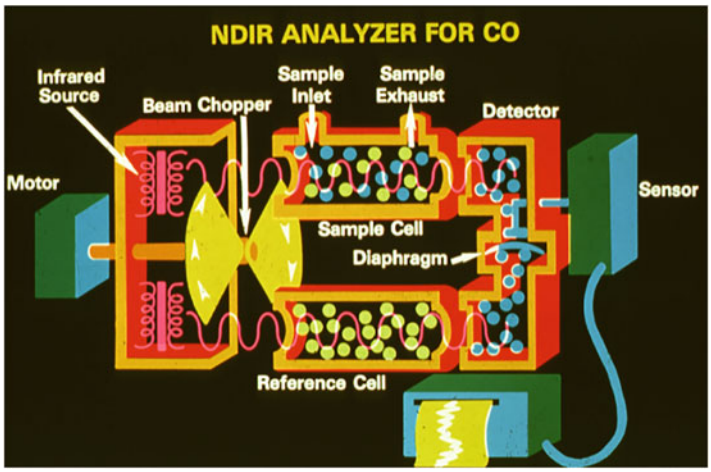

Fig. 31 Schematic diagram of a CO analyser

particles or $PM_{2.5}$ particles from the air. Instrument can measure either PM_{10} particulates or $PM_{2.5}$ particulates at a time. Required cyclone is placed in the line for measurement of either PM_{10} or $PM_{2.5}$ particulates. In this technique a small 14C (Carbon-14 or Krypton 85) element is a constant source of high-energy electrons known as beta rays through a spot of clean filter tape. These beta rays are detected and counted by a detector to determine a zero reading. The monitor automatically advances this spot of tape to the sample nozzle, where a vacuum pump then pulls a measured and controlled amount of dust-laden air through the filter tape, loading it with ambient dust. At the end of the hour, this dirty spot is placed back between the beta source and the detector, thereby causing an attenuation of the beta ray signal which is used to determine the mass of the particulate matter on the filter tape and the

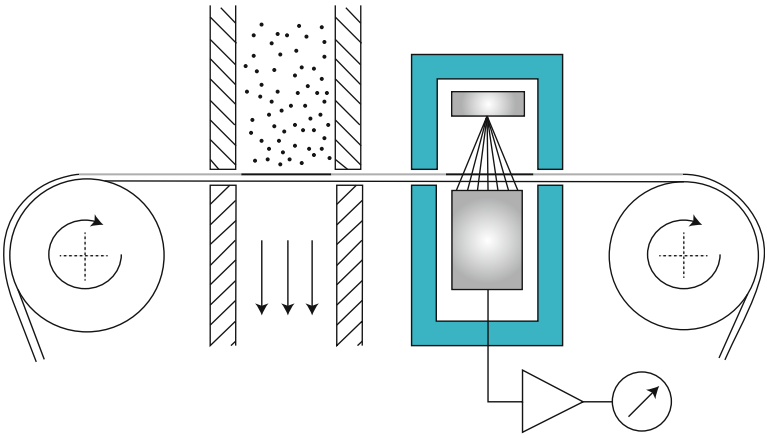

Fig. 32 Schematic diagram of a $PM_{10}/PM_{2.5}$ analyzer

volumetric concentration of particulate matter in ambient air. A schematic diagram of a BAM-based PM_{10}/ $PM_{2.5}$ analyzer is shown in Fig. 32.

Tapered Element Oscillating Microbalance (TEOM)

TEOM is an instrument used for real-time detection of aerosol particles by measuring their mass concentration. It makes use of a small vibrating glass tube whose oscillation frequency changes when aerosol particles are deposited on it increasing its inertia. TEOM-based devices have been approved by the US Environmental Protection Agency for environmental air quality monitoring.

The TEOM uses a hollow glass tube as a microbalance. Incoming particles are deposited on a filter at the tip of the tube, and the added mass causes a change in its oscillation frequency which is detected electronically. The element is periodically cycled to return it to its natural frequency. The inlet to the device only allows particles of the desired size range to enter. TEOM devices operate continuously and do not need frequent filter changes. A schematic diagram of a TEOM particulate monitor is shown in Fig. 33.

Sensor-Based Techniques for Monitoring Ambient Air

Sensor-based instruments provide high-resolution spatial and temporal air pollution data in real time. However, most of the particulate sensors used presently are based on light scattering in which the intensity fluctuations of the scattered light are detected in the presence of scattering particles and recorded as particle count. In this technique, recounting of same particle is a critical factor which often leads to errors in calculation of PM concentrations. In light scattering, reference index depends on composition of particles (carbon, silica, etc.), so the calibration factor developed on one kind of dust might not be relevant in another location. Besides, the calibration factor is strongly dependent on temperature and relative humidity which

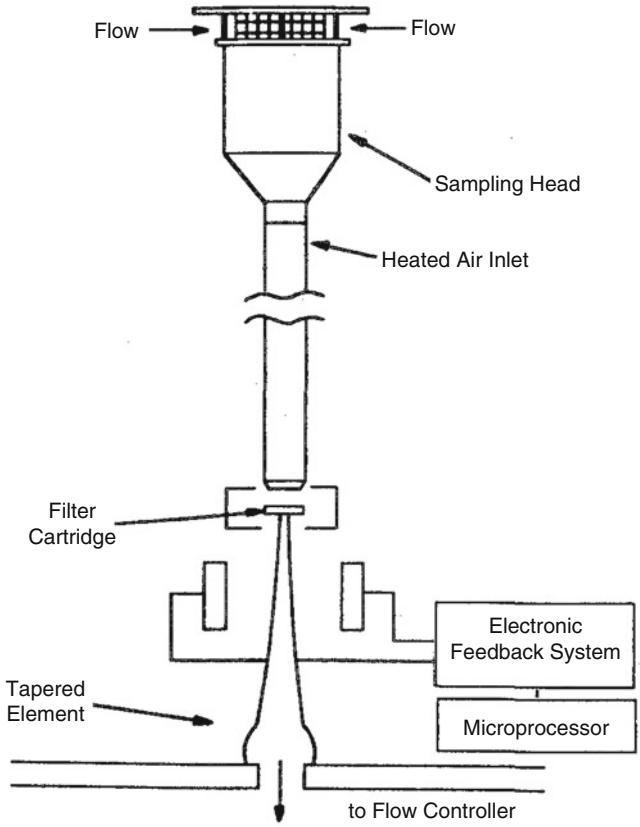

Fig. 33 Schematic diagram of a TEOM particulate monitor

are highly variable in Indian conditions, diurnally and seasonally. They convert number concentrations to mass using assumed density, shape, and composition. These instruments are not based on principles of gravimetric techniques or beta-ray attenuation monitors (BAM). That is why these are not presently used for regulatory purposes.

Air pollution sensors are still in an early stage of technology development, and have not yet been evaluated to determine the accuracy of their measurements. However, these low-cost, portable air quality sensors open an exciting opportunity for a wide range of applications beyond traditional regulatory monitoring. Some potential nonregulatory application areas for air sensors are summarized below:

1. Research aimed at discovering new air pollutants and identifying polluted areas/hot spots.
2. Assessment of personal exposure an individual is exposed to while carrying out his duty on his occupation.

3. Supplementing existing regulatory monitoring network.
4. Source identification and characterization of potential sources.
5. Education/information/awareness by using sensors for informal awareness on air quality.

Performance requirements of a sensor differ according to its application. The quality of a measurement is dictated by the basic performance of the sensor, the way the sensor is operated, and the way its measurements are analyzed. The quality of data collected with sensors varies greatly depending on sensor design and the deployment strategy. Understanding the strengths and limitations of an air sensor is important in making sure that the data collected is useful for the intended purpose. There are several things to think about before putting a sensor in use. First and foremost is to determine a target pollutant. This will guide each of the subsequent decisions, and ultimately lead to the most appropriate types of sensors for the intended application. Also important to consider are device specifications like detection range and detection limit, precision and bias, calibration procedures, etc. The major factors need to be considered in order to collect quality data from an air sensor are:

- Bias
- Precision
- Accuracy
- Drift
- Concentration range
- Detection limit
- Linearity of sensor response
- Life of sensor
- Calibration
- Interferences
- Climate susceptibility
- Data aggregation

Air Quality Monitoring Using Satellites

Monitoring air quality from satellites has played a key role in understanding the status of air pollution loadings and trends on the regional to global scale, by providing information on pollutant amounts, emission, and transport in a quantitative manner. The technology used to monitor air quality from space is complex. In general, satellite-based air quality monitoring operates by looking at how sunlight is scattered by ambient particulates, such as $PM_{2.5}$, PM_{10}, etc. However, this process can easily be disrupted by weather conditions, properties of the pollutant particles, atmospheric mixing, and other factors. Dependence on sunlight also means that this monitoring cannot operate during a cloudy day. In many applications, satellite air

quality monitoring data is fused with ground-based measurements to lend a "bigger picture" of air quality, for example, combining a variety of data points from the satellite monitor with cloud optical thickness or wind speed and direction and with ground-level air quality index (AQI). The commonly used satellites are polar orbiting satellites which generally have global coverage of once a day. Using such satellites, study of diurnal variations is not possible and spatial resolution is also about 10 km only. However, geostationary satellites which spin at the same rate of the earth and constantly focus on the same area enable the satellite to take a picture of the earth at the same location with less time duration.

Personal Exposure and Work Zone Air Quality Monitoring

The increasing general awareness of atmospheric pollution and its hazards on the health and well-being of industrial workers is resulting in greater stress on frequent assessment of work place pollution and worker's exposure. Work zone or workplace is the area where workers are engaged in various activities to complete their tasks. They usually work in shifts of 8 h and are exposed to the pollution during that period. Problem faced in monitoring worker's exposure is that most workers keep moving from one place to other on the shop floor as part of their normal duties. The instrument therefore must be worn by the worker. Instruments suitable for monitoring worker's exposure to dust and gaseous pollutants are described below.

Personal Samplers

Instruments used for measurement of workers' exposure are known as personal samplers. These instruments should be compact, lightweight, and battery operated and worn by the workers while working. These instruments usually operate at low flow rates of about 0–3 liters per minute. Collection of 8 hourly data makes it convenient to compare worker's dose to the specified TLV levels.

During sampling a personal sampler draws the air at low flow rates and allows it to pass through a filter paper of about 37 mm diameter. Dust deposited on the filter paper is measured gravimetrically, and volume of air sampled is obtained after multiplying the flow rate with the time of sampling. Concentration of total suspended particulate matter for which a worker is exposed is calculated in microgram per cubic meters and compared with the prescribed threshold limits. To measure workers' exposure to respirable dust fraction, instruments are equipped with a particle separation device such as a cyclone or an impactor which separates respirable fraction from the total dust and subsequently allows it to pass through a filter paper. In this case filter paper receives the respirable fraction of dust only, and concentration of respirable dust can be measured after gravimetric analysis of dust deposited on filter paper. A picture of the personal sampler is shown in Fig. 34.

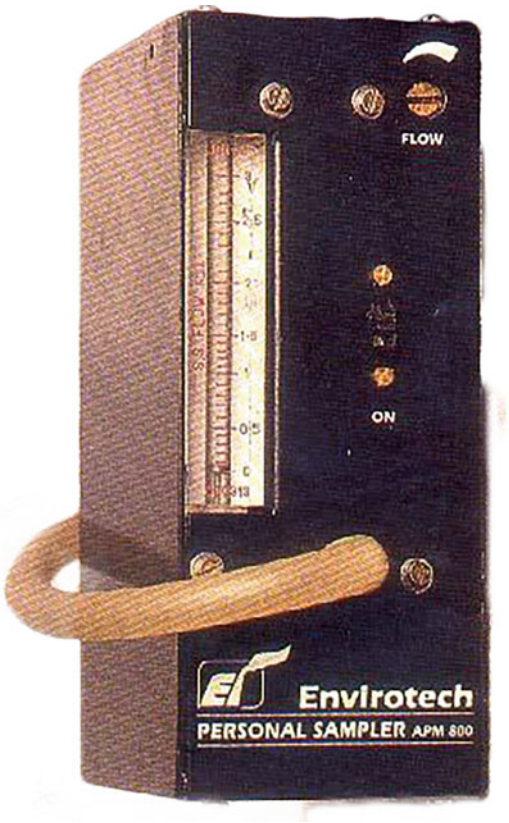

Fig. 34 A typical personal sampler

Handy Samplers

Workplace environment usually has higher concentrations of dust as well as gaseous pollutants. These are required to be monitored to assess the pollutant exposure on the shop floor. The instrument must be portable so that it can be kept at different locations on the shop floor and preferably battery operated. A typical handy sampler for such applications is shown in Fig. 35. Such instruments have provisions for placing a set of glass impingers in an ice tray, usually two impingers, for measurement of gaseous pollutants, where absorbing media is kept for the gases to be sampled. These instruments are compact, are lightweight, and have a flow rate-measuring device, usually a rotameter and a battery-operated pump to provide a flow rate in the range 0–3 liters per minute along with the battery backup of at least 8 h, so that samples for 8 h covering a full shift can be collected. A filter paper is put in the filter holder to arrest the particulates; filter holder is then attached to the impingers. The required sampling flow rate is set with the help of the rotameter, and instrument is allowed to run for the specified time duration. Instrument also has a timer to preset

Fig. 35 A typical handy sampler

the start and stop time of the sampling. Samples are subsequently analyzed in the laboratory using wet chemical methods. Dust concentrations can be assessed from the weight of dust deposited on the filter paper and the volume of air sampled.

VOC or Hydrocarbon Samplers

Over the years complex organic compounds are used in many diverse applications. While rural environments often have high levels of pesticides and other residues from sprays of weedicides and other chemicals used in modern farming, urban environments have high doses of a host of organics coming from paints and varnishes, lacquers, solvents, foam-blowing agents, sprays, etc. Majority of these compounds are highly toxic and many of them are reported to be carcinogenic. Replacement of lead by benzene and its derivatives in petrol as anti-knocking agent resulted their presence in atmosphere as part of vehicular pollution.

Unlike inorganic and some organic gases and vapors which react with and/or absorbed by solutions kept in impingers, most organic gases and vapors are too volatile and insoluble in aqueous reagents. The best option in most cases is adsorption on appropriate surfaces such as activated carbon. The flow rate has to be extremely low to allow such adsorption, generally lower than 200 ml per minute and often as low as 20 ml per minute, thus needing a low-flow pump and very accurate flow metering. Sampling flow rate can be set from 20 to 200 ml per minute. The hardware components include appropriate holders for the adsorbing media, i.e.,

activated charcoal tubes, flow control, and other auxiliaries. After allowing a known volume of sample to pass through the adsorption media, either it is desorbed through a thermal desorber or it is eluted with a solvent and analyzed in the laboratory. The method for measurement of VOCs/benzene requires gas chromatographic (GC) analysis with the following possible approaches:

(a) An air sample collected in the field in a Tedlar bag which can then be directly fed to a GC.
(b) VOCs present in ambient air are collected by their adsorption in activated charcoal tubes and desorbed later for analysis on a GC.

Both techniques require use of a battery-operated/portable instrument capable of drawing air sample at a low flow rate of a few milliliters per minute. A typical VOC sampler and activated charcoal tubes for sampling and adsorption of VOCs/HCs are shown in Figs. 36 and 37. Nowadays automated GC-based systems have also been developed for real-time monitoring of VOCs and their derivatives.

Fig. 36 A typical VOC/HC sampler

Fig. 37 Charcoal tubes for adsorption of VOCs/HCs

Indoor Air Quality Monitoring

Indoor air pollution is a relevant area of concern as it has a direct impact on mortality and morbidity. A large population throughout the world use coal and biomass (crop residues, wood, dung, and charcoal) as the primary source of domestic energy. Moreover, humans spend 80–90% of their routine time indoors, so indoor air quality (IAQ) leaves a direct impact on overall health and work efficiency. Our residential and office complexes are increasingly becoming air-conditioned and poorly ventilated leading to buildup of carbon dioxide levels as the day progresses. Also high levels of $PM_{10}/PM_{2.5}$ outdoors as well as high levels of noise prompt occupiers to keep windows shut in an attempt to prevent air pollution entering the inner spaces. Extensive use of air fresheners, paints, varnishes, and laminates is also adding VOCs in the air. Instances of "sick building syndrome" are increasingly being reported for our cities. The comfort parameters such as temperature, relative humidity, and airflow are important dimensions of indoor air quality. The essential parameters for IAQ measurement include CO_2, PM_{10}, $PM_{2.5}$, and PM_1, volatile organic carbons (VOCs), formaldehyde, ozone (O_3), carbon monoxide (CO), radon, bacteria, fungi, etc.

Fig. 38 Sensor-based indoor air quality monitor

Generally, low-cost sensor-based instruments are used for monitoring indoor air quality. Optical sensors are used for measurement of particulates (PM_1, $PM_{2.5}$, PM_{10}, TSPM, etc.), and electrochemical sensors, NDIR sensors, and PID sensors are used for measurement of various gaseous pollutants. Usually a small fan is provided to suck the air from the atmosphere and circulates it through the sensor. A typical low-cost sensor-based indoor air quality monitor is shown in Fig. 38.

Local Meteorology

Air pollutants disperse under the influence of local meteorological parameters like wind speed, wind direction, atmospheric temperature, atmospheric pressure, stability, and mixing height. No air quality or pollutant-dispersion modeling is possible without reliable information on the local wind trends and stability conditions at different times of the day and seasons of the year. A typical instrument to monitor local meteorological conditions is shown in Fig. 39.

These instruments usually have sensors for wind speed, wind direction, temperature, relative humidity, rainfall, barometric pressure, and solar radiation. Required numbers of sensors are attached to a processing unit and processed data is stored in a data logger.

Instrument can also display the real-time data on a LCD display. Data can be retrieved from the data logger through a laptop/PC or cloud server PC. A typical system configuration of a meteorological monitoring instrument is shown in Fig. 40.

An important use of these instruments is to plot wind rose diagrams. Wind roses are graphical charts that characterize the speed and direction of winds at a location. A wind rose gives a very concise but information-laden view of how wind speed and direction are typically distributed at a particular location. Presented in a circular format, the wind rose shows the frequency of winds blowing "from" particular directions. The length of each "spoke" around the circle is related to the frequency of time that the wind blows from a particular direction. Each concentric circle

Fig. 39 A typical meteorological monitoring station

represents a different frequency, emanating from zero at the center to increasing frequencies at the outer circles. The available software generates colored wind roses in the standard format as shown in Fig. 41.

Liquid in glass thermometers, bimetallic thermograph, resistance thermometer, or a thermocouple can be used for measurement of temperature. However, thermistors are preferred as air temperature sensors. It is because these semiconductor devices can make air temperature measurements from +100 °C to −100 °C with high resolution and accuracy and are available in a wide variety of shapes and sizes as bead, disc, and rods, and the response time can be manipulated better than a second.

For wind direction measurements, wind vane is the standard device. To get fairly fast response and avoid over−/undershooting, wind vanes are properly balanced and critically damped. Wind vanes are fixed on a stand that has markings for the 16 main directions (N, NNE, NE, ENE, E, ESE, SE, SSE, S, SSW, SW, WSW, W, WNW, NW, and NNW). Readings are taken every 15 min or as desired. For sensitivity one needs a low-friction bearing, but damping may also be needed to avoid too much fluctuation in readings.

Devices used for monitoring wind speed are of two types: those which employ mechanical sensors, e.g., cup anemometers, and propeller anemometers, and those which employ nonmechanical sensors, e.g., sonic anemometers and hot wire

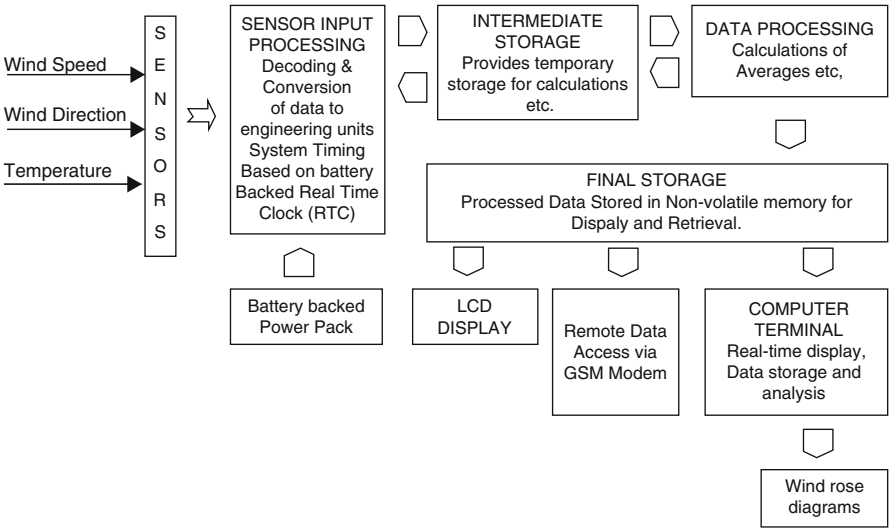

Fig. 40 System configuration

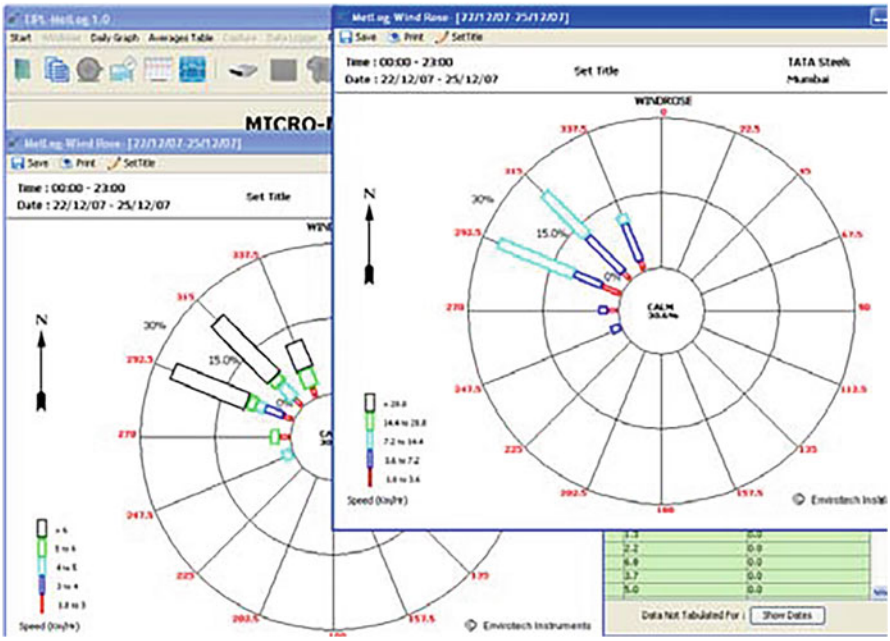

Fig. 41 A typical wind rose diagram

anemometers. In the mechanical devices, suitable transducer is coupled to convert rotations into electric signals which are recorded. Low inertial systems give fast response with a limited range. With proper design, fairly good response and measurement range can be obtained.

For relative humidity measurements, dry and wet-bulb psychometer, dew point hygrometer, and infrared humidometer are used. For continuous measurement of relative humidity, resistive sensors are most popularly used.

For barometric pressure measurements, mercury barometer, aneroid barometer, or a barograph can be used. As a sensor capacitance, aneroid is used. In this device the expansion of aneroid is translated into capacitive change by connecting one plate of the parallel plate condenser with the free end of the aneroid. With this arrangement continuous measurement of pressure is possible.

The solar radiation sensors measure the total energy or radiation coming from the sun. It is measured in watts per meter square (W/m^2). It has to be mounted in a vertical position without any obstructions from shadows and reflections. The sensor uses a semiconductor solar cell which converts solar energy to an electric voltage. The voltage is amplified and transmitted to the data logger via its cable. The data logger will convert the voltage back to W/m^2 Units or calories/cm^2/min (CCM).

The tipping bucket rain gauge is used for measuring the rainfall. It contains an 8-inch-diameter collecting funnel which directs the collected rainfall into a small precision tipping bucket. The bucket is calibrated to tip for every 0.5 mm of rainfall. When the bucket tips, a magnetic reed switch is triggered which sends a pulse signal to the data logger. The data loggers total up the received pulse and count the number of tips to calculate the total rainfall.

Noise Monitoring

Noise pollution is described as any disturbing or unwanted sound that interferes with or harms human health or wildlife. Cities are often considered to be very noisy. Exceptionally loud music, devotional songs, and prayers over loudspeakers are part of the daily life of our city dwellers. To this is added noise from honking of horns and other commercial and industrial activities. All limits are exceeded during periods of festivity and marriage season. However, excessive noise is known to be harmful and considered as a pollutant to be controlled.

Sound or noise is a form of energy produced by a vibrating object or by an aerodynamic disturbance propagated in the form of waves/pressure variations through a material medium. As these pressure variations reach our eardrums, they cause them to vibrate. The transmission of these vibrations to the inner ear and their interpretation by the brain result in our sensory perception of sound. Sound characteristics most important to human hearing include frequency and intensity. Humans can hear sounds in the frequency range of 20–20,000 Hz. All frequencies are not, however, heard equally well as humans hear best, those frequencies which correspond to human speech (500–4000 Hz). There are three internationally standardized characteristics, termed as “A,” “C,” and “Z,” weighting networks. A-weighted sound

level is useful for assessment of human response, as also for rank ordering of noises with respect to loudness level as long as these noises are of similar character. Weighting networks "C" and "Z" do not give good correlation. The reason being that equal loudness contours from where these networks have been chosen are based on experiments with pure tones while most common sounds are complex signals rather than pure tones. The loudness of sound is measured in decibels (dB).

A common instrument used for measuring noise is the Sound Level Meter (*SLM*). A simple *SLM* consists of a microphone, amplifier, attenuators, weighing networks, electronic circuits, and a readout display. The microphone detects the small air pressure variations associated with sound and changes them into electrical signals. These signals are then processed by the electronic circuitry of the instrument. The weighing networks are an integral part of the instrument. They take into account the subjective response of the human ear. The readout displays the sound level in decibels (dB). With most *SLMs*, the readings can be taken on either *SLOW* or *FAST* response. The response rate is the time period over which the instrument averages the sound level before displaying it on the readout. Workplace noise level measurements should be taken on *SLOW* response. Two types of sound level meters are available: Type 2 and Type 1. Type 2 *SLM* is sufficiently accurate for industrial field measurements, whereas Type 1 *SLMs* are primarily used in engineering, laboratory, and research work. These are more precise and accurate.

A standard *SLM* takes only instantaneous noise measurements which is adequate for workplaces with continuous noise levels. But in workplaces with impulse, intermittent, or variable noise levels, the *SLM* makes it difficult to determine a person's average exposure to noise over a work shift. An integrating sound level meter is an instrument that measures sound energy over a period of time and displays it in Leq values. An integrating sound level meter is more suitable for measuring the noise exposure at such places. Further, no data is valuable unless it is interpreted properly. With modern software tools, even a novice user can do the classical data analysis from the recorded data. Nevertheless, ambitious users can use high-end software tools to interpret their data and can get percentiles, scatterplots, pie charts, histograms, and exceedance curves etc. A typical sound level meter is shown in Fig. 42.

While making field measurements, the user will often be required to select/set up the following functions marked on the sound level meter:

1. Range: Typically the default range will be the middle range with an operating sound level from 30 to 140 dB.
2. Time weighting: This function alerts the response time of the instrument. Most sound level meters will have at least two modes – *SLOW* and *FAST*. Some instruments will also have an *IMPULSE* mode. The *SLOW* level has a response time of 1 Sec. and is the default mode in most instruments. Most field measurements will be made in this mode.

   Fast response has a time constant of 1/8 sec or 125 Milli-Sec and should be selected if rapidly changing sound levels are to be monitored, e.g., at a traffic junction.

Fig. 42 A typical integrating sound level meter

3. Averaging period: Besides instantaneous sound pressure level (*SPL*), it is often desired to monitor Leq and/or the sound exposure level (*SEL*). These measurements are integrated over time. In modern instruments a recording or data logging mode is available. In this mode Leq values integrated over 1 min are stored in the instrument's memory; these may be downloaded to a PC software to be used to compute Leq values over desired integrating/averaging period.

Application of various instruments and techniques described above for monitoring of air pollution and air quality is summarized below.

Type of instrument	Application
Stack sampler	Stack emission monitoring
Flue gas analyzer	Determination of stack gas composition
Probe electrification instrument	Continuous emission monitoring of PM
Beta-ray attenuation monitor (BAM)	Continuous monitoring of PM in emissions and $PM_{10}/PM_{2.5}$ in ambient air

(continued)

Type of instrument	Application
Tapered element oscillating microbalance (TEOM)	Continuous monitoring of PM_{10}/$PM_{2.5}$ in ambient air
High-volume air sampler	Monitoring of SPM in ambient air
Respirable dust sampler	Monitoring of PM_{10} in ambient air
$PM_{2.5}$ sampler	Monitoring of $PM_{2.5}$ in ambient air
PM_1 sampler	Monitoring of PM_1 in ambient air
Gaseous attachments to ambient air quality samplers	Monitoring of gaseous pollutants in ambient air
Heavy metal sampler	Monitoring of heavy metals in ambient air
Personal sampler	Monitoring of worker's exposure to dust in work environment
Handy sampler	Monitoring of gaseous pollutants in work environment
VOC/HC sampler	Monitoring of VOCs/HCs and other organic pollutants in ambient air
Sensor-based real-time monitors	Monitoring of TSPM/PM_{10}/$PM_{2.5}$/VOCs & other gaseous pollutants in indoor air and outdoor air.
Meteorological monitoring station	Monitoring of wind speed, wind direction, temperature, relative humidity, atmospheric pressure, rainfall, solar radiation, etc.
Sound level meter	Noise monitoring

Maintenance and Calibration of Air Quality Monitoring Instruments

To ensure smooth working of any instrument, it is essential to provide regular maintenance. Preventive maintenance helps to keep the instrument at its best performance and extends its life. Maintenance of manual samplers is easier as compared to real-time online continuous analyzers. Skills required for maintenance of manual samplers are also low and can be easily developed through a short training. Spare parts are also easily available for indigenous instruments, whereas maintenance of a real-time analyzer is difficult and requires highly skilled manpower. Availability of spares and consumables is a problem in case of analyzers, which often are imported. As a result of this, it becomes difficult to keep such systems operational.

Similarly, periodic calibration of instruments is very important to check the accuracy and to determine the traceability of the measurement. Several factors are considered to decide the calibration frequencies such as the environmental conditions in which instruments are used and the frequency of their use.

In addition to periodic calibration of instruments, time-to-time calibration checks or calibration verification by the users need to be performed at specified frequencies by using secondary calibrators. This is done to ensure that the results of calibration still meet the accuracy levels. Calibration checks are also performed after an instrument has gone some major repairs or the instrument is transported from one

location to another location or the instrument starts giving inaccurate results. Right calibration helps in overall quality assurance and quality control of the results. Required standards of performance can be achieved only through effective planning and execution of maintenance programs. Common issues related to maintenance and calibration of the air quality monitoring instruments are described below.

Preventive Maintenance of Manual Samplers

PM_{10} and $PM_{2.5}$ Samplers

1. Only distilled water need to be filled in the manometer.
2. Check the cracks and leaks in various rubber gasket and "O"-rings once every 6 months. Replace to avoid leakages.
3. Replace PVC pipes once in a year.
4. "O"-rings of cyclone where cup is fitted need to be checked and replaced once these are loose.
5. Inlet pipe gasket should be checked periodically and shall be glued if it has become loose.
6. Wash the rotameter with mild soap solution, when becomes dirty. Never use an organic solvent.
7. Cyclone and the inlet pipe should be cleaned thoroughly.
8. Inlet pipe bend should also be cleaned regularly.
9. Hardware needs to be tightened periodically.
10. Time totalizer checking must be done regularly.
11. Wire mesh should not be loose.
12. Electrical wires and connectors must be checked periodically.
13. Ensure stocking of some frequently required spares like PVC pipe, impinger, manometer tube, "O"-rings, gaskets, mains cord, and miscellaneous hardware.
14. Ensure regular calibration of rotameter, flowmeter, and time totalizer.
15. Ensure stabilized power supply to the instrument. It should be 220 $\pm$ 10 V output.
16. Ensure length of the mains cord should not be more than 10 meters and without joints.

Stack Samplers

1. Clean instrument after each monitoring.
2. Clean the brass fittings used to connect hoses once every 2 months.
3. Check "O"-rings of the filling/drain plug and replace them in case they are excessively flattened or damaged.
4. Clean the impingers After Every monitoring.
5. Replace the thermocol of impinge box after one year or earlier in case of damage.
6. Use detergent solution to clean hose pipes, if necessary allow the probes to dry, or otherwise flush the components with compressed air before use.

7. Check the oil level in the pump before every monitoring and top up with fresh recommended oil.
8. Check the mounting screws of the pump.
9. Check the wiring regularly.

Meteorological Instruments

The most important precaution while setting up a meteorological system is alignment of the direction sensors. This has been described below in brief. The installation of other sensors is easier, and the reader is recommended to refer respective manuals of different weather monitoring systems:

1. Position the tripod where you can get a clear and safe view of the sensor. The best position for mounting of sensors is usually to 10–30 meters from ground.
2. Level the compass by using the circular bubble level. The compass is correctly sighted on both arms: front side and the crossarm or orientation vane. Check the bubble in the circular level to confirm that it is still level. The north-seeking end of the needle should be pointing to 0 degree ± 0.5 degree. If the correct declination is used and the compass is properly sited, the crossarm or alignment vane should be aligned to true north. To confirm that the sensors are properly aligned, it is helpful to view the mast from the opposite side (180 degrees) of the orientation direction.
3. The use of an orientation pointer may make alignment of sensors to true north easier.
4. Alignment of sensors is best done by two persons, one person to orient the sensor and another person to read the compass.

Calibration

Periodic calibration of critical components of the instruments is required under the following situations:

1. When instrument is manufactured.
2. When instrument is transported to a new location and in different climatic conditions.
3. If instrument is operated after interruption of several months.
4. After repair or overhaul of key components.
5. After observing significant drift in zero or span values or in monitoring results.
6. On expiry of validity of calibration (usually 1 year).

Conclusions

Selection of an appropriate instrument for monitoring either emissions from sources or ambient air quality or indoor air is dependent on the objectives of monitoring. For assessment of impacts, devices giving time-weighted average values are most

desirable, and for assessment of short-term hourly variations, real-time continuous monitoring systems are more desirable. To assess exposure of workers who keep moving while working, a different type of instrument is required. Movement of air in the local environment is important to understand buildup or dispersion of pollutants. To protect people's hearing impairment, instant and Leq levels of noise are required to be monitored.

We hope authors have adequately described the various types of instruments to meet the objectives of monitoring.

Abstract

Reliability of the measurement data in today's world lays a strong foundation for effective policy making, resource allocation, and many such significant decisions for a country. The world of metrology relies that every measured data has an uncertainty associated with it, the lack of which often questions its credibility. Thus, metrological traceability, which links the measured results to a stated reference through an unbroken chain of comparisons along with all the stated uncertainties, has become essential. However, estimation of uncertainty is quite simpler for physical measurements, but in the field of chemical/biological/environmental measurements, this idea still needs propagation. The qualitative and quantitative measurements in environmental science forms the basis for environmental legislations; even small inaccuracies/errors can prove to be lethal. This enhances the role of traceability in environmental measurements. The analytical methods of the environmental measurements consist of several steps pre-treatment (extraction) of the sample, sample storage, and chemical/biological analysis. However, the estimation of uncertainties is quite a challenging process in environmental measurements due to partial recovery of an analyte, improper handling of samples during extraction, and improper storage of the samples. The knowledge of uncertainty associated with analytical environmental measurements and its procedures which determine the quality of the data produced is still needed to be understood and explored in detail. This chapter discusses how traceability using documented standards and certified reference materials can be perceived in analytical environmental measurements with an attempt to link the associated uncertainties at each step of the measurement of atmospheric particulate matter (PM) concentration as well as during analytical determination of its chemical components.

Traceability · Analytical environmental measurements · Uncertainty · Certified reference materials · Unbroken chain of comparison

Introduction

The accurate measurements in different sectors are the key to growth and development of a country. Be it cross-border trade, fashion industry, manufacturing industry, healthcare and medical sector, civil sector, environmental measurements, and other fields of science and technology, the fundamental component is accurate and precise measurements. The quality of goods relies on the quality of measurements carried out at different stages. All the measurement results have some uncertainty related with them. The uncertainty of measurements is an important parameter that is used to judge the quality of a measurement. Indeed, the results of measurement lack its credibility without the statement of associated uncertainty in measurement.

Consequently, the reliability of a measurement is an important part of product development and quality control which is established through traceability.

In the scientific world, numerous measurements and their comparisons are being made on a daily basis on local, regional, or global scale. The science of comparison usually examines the underlying similarities (or differences) in two or more things. Sometimes, achieving comparability becomes challenging when these measurements are made at different locations, at different times, and using different methods. Therefore, the need for traceability arises in the measurements which would be able to remove these biases. Nowadays, the metrological traceability has become crucial in the world of measurement sciences which is aimed to attain quality data. Traceability connotes that the result of a measurement, no matter where it is made, can be related to a national or international measurement standard, and that relationship is documented. In addition, the measuring instrument is calibrated by a measurement standard that is itself traceable. The idea of establishing traceability to national or international measurement standards has evolved considerably over the past few decades. However, there is still a necessity of its deep inculcation in every field of scientific measurement to compare these measurements in time and space. Metrological traceability implies that the measured results can be traced back to a common national/international standard through an unbroken chain of comparisons. The third edition of International Vocabulary of Basic and General Terms in Metrology (VIM) defines metrological traceability as "property of a measurement result whereby the result can be related to a reference through a documented unbroken chain of calibrations, each contributing to the measurement uncertainty" (JCGM 2008a). This definition of traceability includes three main components, i.e., stated references, unbroken chain of calibrations/comparisons, and measurement uncertainties. These components are required to be inferred in relation to the environmental measurements (Valcarcel and Rios 1999; Quevauviller 2000; Walsh 1999).

The stated references may be reference methods/reference materials/SI (Syste'me International) units as per definition of the ISO (International Standards Organization) (ISO 1993; King 1997). Theoretically, traceability indicates that all measurements should be traceable to SI units. The idea of traceability infers that measurement data are linked to stated references through an unbroken chain of comparisons, all with stated uncertainties (Yadav et al. 2020a). The traceability was initially limited to physical parameters like mass, time, length, etc. for more than 100 years. Now, it is has become important even for chemical, biological, and environmental measurements (Valcarcel et al. 1998; King et al. 1999; Quevauviller and Donard 2001; Quevauviller 2004). But in chemical/biological/environmental measurements, the theoretical aspect of traceability is impractical as there are several steps involved in such measurements with a possibility for missing links for unbroken chain of comparisons (King et al. 1999; Maroto et al. 1999). Nowadays, metrology in chemistry, biology, and environment is a matter of concern for reliable data quality (Valcarcel et al. 1998; King et al. 1999; Quevauviller 2001). Theoretical metrology is not directly applicable to chemical, biological, and environmental measurements as there is a considerable difference between these measurements and the physical measurement processes (Quevauviller and Donard 2001). However,

chemical/biological/environmental measurements are based on sampling methods, storage of samples, extraction of samples, comparisons of amounts, and instrumental response (sensitivity and selectivity) to an analyte. In the case of analytical chemical/biological/environmental measurements, traceability may be achieved in relation to either a reference material (RM) or certified reference material (CRM)) through a standardized method (King 1997). For example, analytical environmental measurements include many steps starting from its sampling to final determination of an analyte/component. Therefore, the application of concept of traceability and uncertainty in analytical environmental measurements is quite challenging due to complexities involved in measurement processes. In analytical environmental measurements, the measured results can even get influenced by the initial preliminary steps involved like sampling, storage of samples, extraction of samples, etc. Also, the quantitative estimation of environmental matrices is very difficult as the same chemical component can be analyzed through different analytical procedure in different matrices. The traceability concept is profound in the field of physical measurements; however, in chemical/biological/environmental measurements, this idea still needs propagation. This chapter discusses about how traceability to SI units through stated references, unbroken chain of comparisons, and measurement of uncertainties is perceived in analytical environmental measurements.

Traceability in Analytical Environmental Measurements

Environmental measurements include diversified range of several biotic and abiotic entities. Biotic entities comprise living organisms like flora and fauna, while abiotic entities include air, water, soil, etc. Any variation in the environment gets incorporated in these biotic and abiotic components which are well reflected in their physical and chemical properties. Thus, these entities have a great potential for environmental studies. Ever since the anthropogenic activities have started dominating and impacting the earth system, there is continuous need for qualitative and quantitative monitoring of these environmental entities which are analyzed at different concentration levels for a wide variety of chemical and biological components. Though environmental measurements are difficult due to its complex matrices, still there is a need for the quality data. Since the qualitative and quantitative estimation is quite sensitive and forms the basis for environmental regulations/legislations, even minute inaccuracies/errors can prove to be lethal. Thus, there is a need for a reliable data with all possible sources of uncertainty in environmental measurements. Thus, the role of traceability in environmental measurements is very crucial (Quevauviller 2004a). Any method which is traceable to a documented reference may not be the accurate one, but an accurate method is always traceable to the nearest true value (ISO 1993). Occasionally, traceability is misunderstood as accuracy and/or precision. Similarly, accuracy and precision are two different concepts and not to be confused with one another. Accuracy is the closeness of the measured result with the true value of a measurand, while precision is the closeness of a number of replicate measurements to each other or it's a set of dispersion of values.

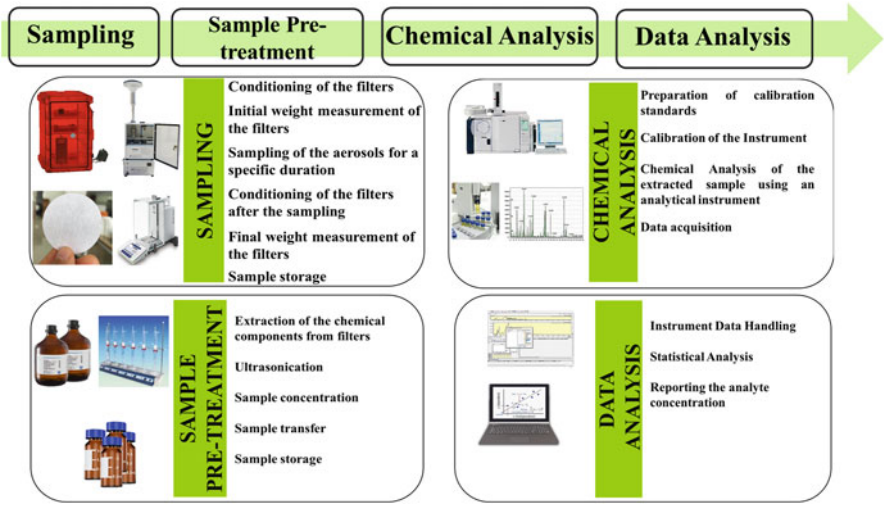

Fig. 1 Potential sources of uncertainty in aerosol monitoring and chemical analysis

Environmental measurements are far more complex in nature, so theoretical metrology may not be useful to that extent (Horwitz 1992; Griepink 1990). In the 1990s, many environmental chemists did not focus much on data quality and reliability of analytical results. The quality of data for environmental monitoring depends on the reliable analysis of abiotic and biotic entities. There are a number of carcinogenic and toxic constituents present in the environment in different concentration levels. During the last two decades, the focus on quality assurance (QA) of environmental analysis is increasing which has led to the development of a number of guidelines and documented standards, e.g., sampling, method validation, etc., and use of Certified Reference Materials (CRMs) in analytical procedures and interlaboratory comparison through proficiency testing (Gunzler 1996; Quevauviller 1995; Subramanian 1995; Barcelo 2000; Quevauviller and Maier 1999). Analytical environmental measurements mainly involve several steps, e.g., sampling for collection of samples, storage of samples, chemical extraction of collected samples for quantitation, calibration of instrument, analytical determination of chemical components of interest, data analysis, and results (Fig. 1). Considering these steps, let us understand the concept of traceability in the context of analytical environmental measurements.

Stated References/Documented Standards in Environmental Measurements

The documented standardized procedures include sampling protocols and analytical techniques with reference to specific measurements. In analytical environmental measurements, i.e., environmental monitoring and analytical procedures,

standardization is the key component. The documented standards contain appropriate steps of methods and/or techniques required for regulations of environmental measurements. It fulfills the minimum requirements of traceability which further helps in improving the comparability of analytical results. The implementation of a standardized method does not mean that an error will not occur; it only offers a background for a given measurement as the reference. In environmental monitoring, sample collection and storage are primary sources of error. These are the weakest links in traceability chain as it is very difficult to make a standard procedure for sample collection and storage (Quevauviller 1995; Barcelo 2000). Similarly, in analytical environmental procedure, it is difficult to get the 100% recovery of an analyte from the extraction of a sample (Ure and Davidson 1995). For example, in the determination of organic compounds in atmospheric particulate matter sample using a single or sequential extraction procedure, the measurements do not relate to specific organic compounds. If the documented extraction procedures are not properly followed, then the data comparability is not possible (Quevauviller 1998). Any change in the proper implementation of the documented procedure might lead to the infringement of traceability chain. Therefore, the documented extraction procedure would be considered as a reference for traceability of analytical results.

The Unbroken Chain of Comparisons in Environmental Measurements

The unbroken chain of comparison means that there is no missing link of information in analytical environmental measurements while following an environmental monitoring and analytical procedure. In environmental monitoring, the steps include sample collection and sample storage. The missing links in environmental monitoring may be improper sample collection and sample storage, which are crucial for unbroken chain of comparisons. The analytical procedure includes several steps like extraction of sample, storage of extracted sample, and analysis of sample using a suitable instrument. But the missing link may be the partial recovery of an analyte, contamination of a sample while doing extraction, improper storage of extracted sample, using an uncalibrated instrument, etc., which are crucial for unbroken chain of comparisons. The lengthier analytical procedure has more possibility of missing links which may disturb the unbroken chain of comparison. There are additional steps involved in an analytical procedure while using an analytical technique for detection of individual chemical components, e.g., lack of sensitivity and/or selectivity of the instrument which may break the chain of comparisons. Therefore, both environmental monitoring and analytical procedure for detection of chemical components in environmental measurements are essential parts of unbroken chain of comparisons for traceability. In analytical environmental measurements, the uncertainty component is inevitable for traceability, and it must be assessed at each stage of an environmental monitoring and analytical procedure. Since the unbroken chain of comparison and uncertainties are inter-linked, the smaller chain of comparison will provide better understanding of uncertainty of the results.

Uncertainty in Environmental Measurements

The word *uncertainty* generally relates to "not sure" or "doubtful." But scientifically, the uncertainty is related with the result of a measurement and tells the limits of dispersion of the values ascribed to the measurand. For a measurement, uncertainty does not indicate a distrust about the validity; rather it provides more confidence in the validity of a result. The term uncertainty is also misunderstood as precision. The term precision is closeness of agreement between the results obtained by applying the same experimental procedure several times under prescribed conditions. Both random and systematic errors are included in uncertainty while precision only includes the random errors (Valcarcel and Rios 1999). Further, error and uncertainty are two separate concepts. These two should not be confused for one another. The difference between the true value and the measured value of a parameter is called the error while a range of values within which a parameter is supposed to remain is called the uncertainty. Errors can be random or systematic. Random errors are always present. The sources of random errors may occur due to the errors made by the operator or changes in experimental conditions which are out of control of the operator. Random errors can be minimized by taking repeated measurements and calculating the average of the same. Systematic errors are typically present which may be predictable. The sources of systematic error are instrumental, physical, or human limitations, e.g., instrument is out of calibration. The systematic errors can be minimized by careful calibration of the instrument and by using best suitable analytical techniques.

As discussed above, one needs to consider three major components to achieve traceability in any measurements including analytical environmental measurements, i.e., stated references, unbroken chain of comparisons, and measurement uncertainties. Further, one needs to focus on quality assurance/quality control components to achieve three major components of traceability especially in analytical environmental measurements.

Quality Assurance/Quality Control in Environmental Measurements

To understand the concept of quality assurance and quality control (QA/QC), one should have clear concept of the term "quality." In general, the word quality implies to inherent characteristics of a product/device/service that guarantees to meet the needs of a customer. The quality includes design, conformance, and performance of the product/device/service. ISO 9000:2015 defines quality as "degree to which a set of inherent characteristics of an object fulfils requirements" (ISO 9000 2015). In analytical domain, the quality can be understood as furnishing the reliable information about a measurement data under specific conditions. The specific conditions include accuracy and precision of the measured data which is directly related to "fit-for-purpose." To achieve the quality of the desired result, method validation, measurement uncertainty, and metrological traceability are the key elements. Thus, to accomplish quality, a proper quality management system is required which should be

aimed at minimizing the frequency of quality failures along with their timely identification and eradication. ISO 9000:2015 provides the basic concept, principles, and vocabulary for quality management system (QMS). The ambit of QMS comprises two main components, quality assurance (QA) and quality control (QC).

EURACHEM/CITAC Guide, 2016 defines QA as "part of quality management focused on providing confidence that quality requirements will be fulfilled" and QC as "part of quality management focused on fulfilling quality requirements" (Eurachem/CITAC Guide 2016). QA includes all the activities undertaken by a laboratory to ensure the fulfillment of quality requirements, while QC includes the measures taken at an individual level to fulfill those requirements as shown in Fig. 2. QC is mainly intended to prevent or reduce the occurrence of errors.

However, various sources of errors can slide in when an analytical environmental procedure is performed, for example, sampling error, calibration error, loss of analytes from the sample, interferences of other components in sample matrix, incompetent operator, etc. The improper sampling or sample handling can produce significant amount of errors. Non-representative sampling and/or non-representativeness of sampling site must be avoided and taken care of to minimize errors. Loss of analytes during sample pre-treatment procedures (extraction) due to oxidation, volatilization, heat-degradation, etc. can also contribute significantly to errors. This type of error can be reduced by following a set of valid and documented procedures. Incompetent operator can also be the source of error and produce erroneous results. The errors can slide in while performing any step of analytical procedure like dilution, marking of samples, calculation mistakes, or biasness toward a method or result. Thus, the analyst should have proper educational qualification along with relevant hands-on training. The laboratory should maintain all the records from sampling till analysis and reporting of data.

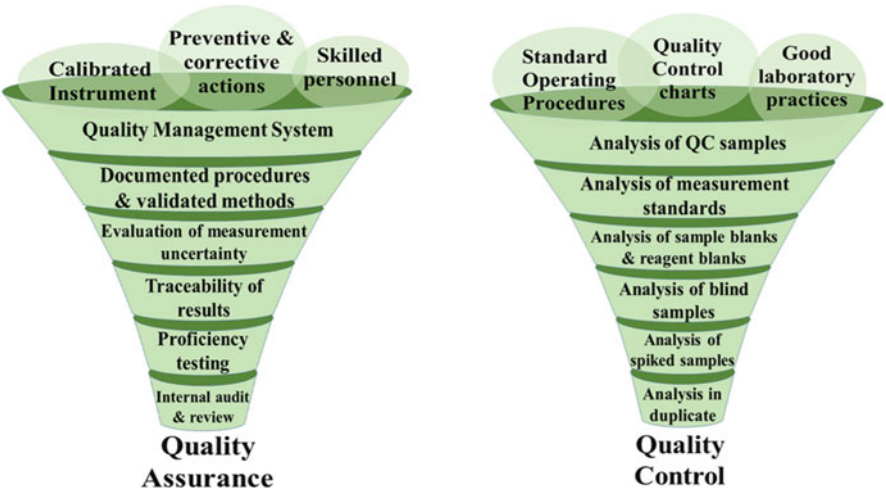

Fig. 2 Main elements of quality assurance and quality control

Method Validation in Environmental Measurements

The scientific laboratories around the world perform several experiments or test every day using various methods. The scientific measurements form the base of a society and its growth and development. These methods need to be checked several times before putting it into routine use so that their performance could be validated for a particular application. The method validation helps to perform check on such methods. The main aim of performing method validation is to validate that a method under consideration is "fit-for-purpose" (Eurachem Guide 2014). This means that the method is capable of producing similar results as per the requirement of the customer. The method validation also ensures that a result delivered by a laboratory is reliable or not (Stauffer 2018a). Method validation is needed when it is required to express that the performance characteristics of the method are suitable for a specific purpose.

As per ISO/IEC 17025 guidelines, a laboratory can validate non-standard methods, laboratory-developed methods, and standard methods used outside their intended scope or otherwise modified (ISO/IEC 17025 2017). Method validation is also required to state similarity of results acquired by two methods, e.g., a new method and an existing standard/regulatory method. The key approaches to determine the validity of a method involves linearity, selectivity, limit of detection (LOD)/limit of quantification (LOQ), ruggedness, trueness, precision, and measurement uncertainty as shown in Fig. 3 (Eurachem Guide 2014). Similar to accuracy in other fields, the method validation is very important in analytical environmental measurements. The different components of method validation have been explained as follows:

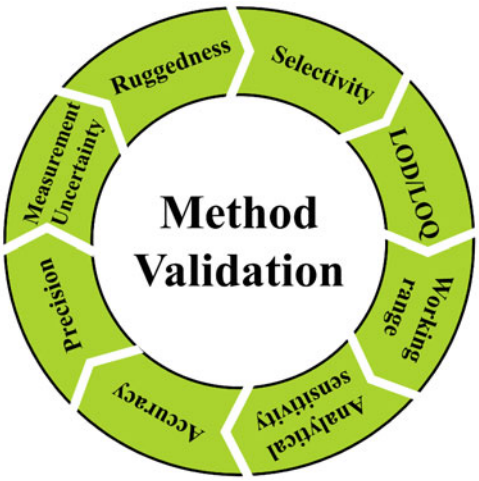

Fig. 3 Key components of a method validation

Selectivity

The selectivity of an analytical method means the ability of a method to determine a particular analyte in a mixture without interference from any other components having similar characteristics (Eurachem Guide 2014). The applicability of the method should be studied using response from a range of samples, i.e., from a measurement standard to mixture having complex matrices which is applicable in analytical environmental measurements.

Specificity The word selectivity and specificity are often used interchangeably; however, there is slight difference. Specificity implies that the analytical method determines or measures quantitatively the component of interest in the matrix without separation. The International Union of Pure and Applied Chemistry (IUPAC) defines specificity as the ultimate selectivity which means there is no expected interference (Bievre et al. 2011).

Analytical Senstivity Sensitivity of an instrument is a measure to detect or differentiate the small changes in the concentration (Eurachem Guide 2014). Sometimes sensitivity is also referred to as limit of detection (LOD). It can be measured by slope of the calibration curve (calibration sensitivity). It can be represented as:

$$S = mC + S_{Blank}$$

where, S = signal; m = slope of the calibration curve; C = concentration; S_{Blank} = signal for blank

Linearity (Working Range)

For an analytical method, the working range can be determined by inspecting the samples having different analyte concentrations and determining the range of concentration for which an acceptable uncertainty can be achieved. In other words, the interval between higher and lower levels can be determined with accuracy, precision, and linearity. Linearity of an analytical method can be determined by different levels of stock solution/standard dilution and plotting a calibration curve for more than three concentration levels which are very important in environmental measurements due to high variability in the concentration levels of chemical components in the samples (Zonen et al. 1998).

Calibration

Calibration is a process related to measured analytical signal to the concentration of analyte. All types of analytical methods require calibration for quantification. Calibration is defined as an "operation that, under specified conditions, in a first step, establishes a relation between the quantity values with measurement uncertainties provided by measurement standards and corresponding indications with associated measurement uncertainties, and in a second step, uses this information to establish a relation for obtaining a measurement result from an indication" (Eurachem/CITAC Guide 2016). Calibration curve is used to understand the response of an instrument

for a particular analyte and predict the analyte concentration in the unknown sample. Three calibration methods are commonly used for calibration purpose in analytical environmental measurements, i.e., standard addition, external standard, and internal standard.

Standard Addition

In analytical environmental measurements, the sample may contain multiple components called the matrix along with the analyte. The matrix might alter the analyte signal, and change its response, known as matrix effect. The method of standard addition is used to compensate for the matrix effect. In this method, known amounts of the standard analyte are spiked to the fixed amount of sample to establish response and create calibration curve. The concentration of the analyte is determined by extrapolating to the x-intercept (Taylor 1985; Danzer and Currie 1998).

External Standard

In analytical environmental measurements, the external standard method is most commonly used to determine the concentration of an analyte in an unknown sample. In this method, a number of standards including at least one blank are used. The standard solutions are prepared with known and increasing concentration of analyte, while the blanks contain no known amount of analyte. Same reagents are used in sample as well as standard preparation. The method is called external as the standard solutions of known concentrations and unknown sample are analyzed separately under similar conditions. The responses of the blank and standards are compared to remove the blank signal and get the response of the analyte only. The adjusted response is then used to get a calibration equation to find out the concentration of analyte in unknown sample (Stauffer 2018b; Harvey n.d.).

Internal Standard

In this method, a known amount of a chemical species known as internal standard different from the analyte of interest is added to the standard solutions, blanks, and the unknown sample to determine the concentration of analyte. Ratios of the signal of analyte to the internal standard and concentration of analyte to the internal standard are calculated for the blank and the standard solutions. The signal ratios are then plotted against the concentration ratios to get a calibration curve. The equation used for calculating relative response factor is as follows:

$$\frac{Area\ of\ analyte\ signal}{Concentration\ of\ the\ analyte} = F\left(\frac{Area\ of\ standard\ signal}{Concentration\ of\ the\ standard}\right)$$

where F is the response factor (also known as relative response factor) of the analyte which is further used in the calculation of the concentration level of an analyte in analytical environmental measurements (Stauffer 2018b; Harvey n.d.).

Limit of Detection (LOD)/Limit of Quantitation (LOQ)

LOD is the minimum concentration of an analyte that can be measured by the specific method at a stated level of confidence (Shrivastava and Gupta 2011). In other words, LOD can be defined as minimum concentration that an instrument can detect but cannot quantify. LOD is determined by signal-to-noise ratio (S/N) (magnitude of the signal)/(magnitude of the noise). Noise is an unwanted baseline fluctuation in the absence of analyte signal (standard deviation of the background). The amount of analyte necessary to yield a net signal equal to 2 or 3 times the standard deviation of the background (Harvey n.d.; Theodorsson 2008).

The term LOQ is defined as the lowest concentration at which the instrument is able to detect and quantify an analyte. LOQ is the lowest concentration of analyte in a sample that can be determined with acceptable level of accuracy and precision. Sometimes, LOQ is the concentration of lowest calibration point on the calibration graph (Fig. 4).

The determination of LOD and LOQ become significant when determining an undesired or forbidden component of a matrix, for example, pesticide in food and arsenic in drinking water and PAHs in environmental particulate matter samples.

The LOD and LOQ are calculated manually by multiplying standard deviation with suitable factors as represented in Fig. 5 (Eurachem Guide 2014).

Limit of Linearity (LOL): The concentration at which the linearity of the calibration curve departs.

Dynamic Range: The minimum to maximum range of concentration detectable by an instrument.

Accuracy/Trueness

Accuracy of an analytical method is the degree of closeness between the measured/observed value to the true value/reference value. Accuracy is also referred to as trueness of the measurement. The accuracy of the analytical procedure can be determined by "bias." Biasness of a method is the measure of inherent systematic

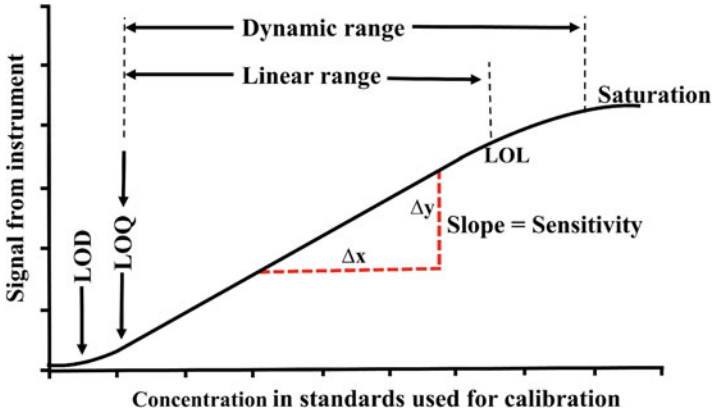

Fig. 4 Calibration curve representing limit of detection, limit of quantitation, and linear range

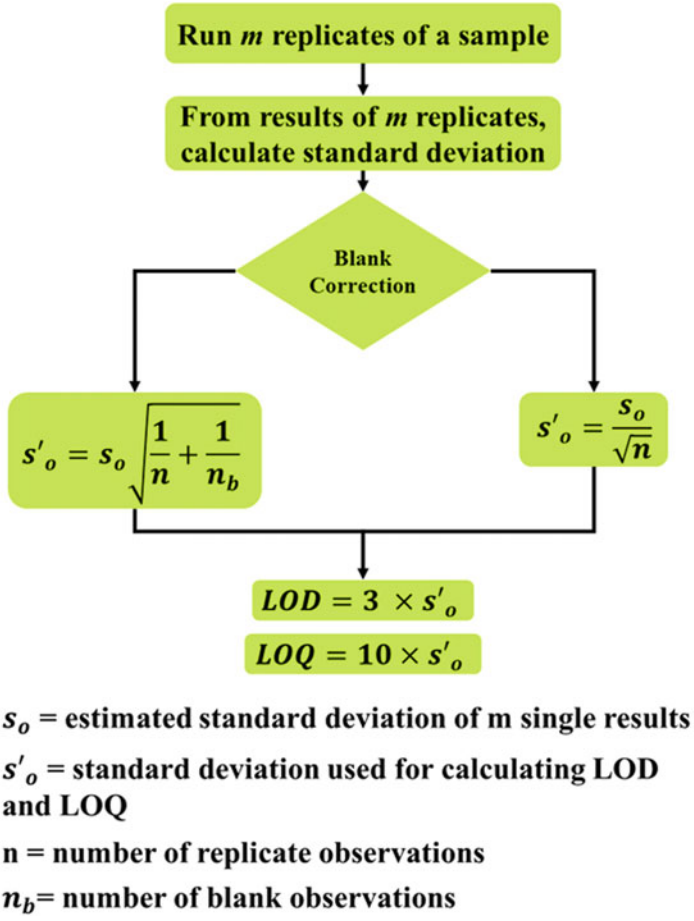

Fig. 5 Steps to determine limit of detection and limit of quantitation

errors, regardless of which laboratory uses it. Bias can be determined by analysis of RMs, by spike studies, or by comparing the obtained results to the results obtained by some other method (Eurachem Guide 2014).

Ruggedness (Robustness)

Ruggedness of an analytical procedure or an instrument is a measure of its capacity to remain unaffected by small yet deliberate variations in method parameters (Draghici and Manciulea 2016).

Precision

Precision is a measure of closeness of a series of measurement results determined under specific conditions. Repeatability and reproducibility are two types of precision. Repeatability measures the variability in values of observations when an

experiment is repeated by the similar person under similar environmental conditions. Reproducibility, whereas, measures the variation in values of observations when the measurements are performed in different laboratories. Reproducibility is not needed frequently in case of single-lab validation. In fact, it proves to be beneficial when many laboratories are going to use an analytical method or standardize it.

Tools to Validate Analytical Methods

To validate an analytical procedure in analytical environmental measurements, various tools that can be used are as follows:

Blanks

Blanks can help in knowing and evaluating the response of the instrument for a particular analyte. Reagent blanks and sample blanks are commonly used to check the measured signal of the instrument. Reagents that are used during analytical processes are analyzed to check their contribution to the measured signal. Sample blanks are sample matrices having no analyte. The measured signals are corrected from the signal obtained for these blanks to eliminate their contribution in measurement results.

Routine Test Samples

The routine analysis performed on the test samples provides useful information on precision, interferences, etc.

Spiked Material/Solution

A known amount of analyte of interest is deliberately added to the sample/standards resulting in spiked solution. Spiking can help in determining the response of the analyte to be measured and calculated in terms of the amount added, although the actual amount of the analyte in the sample was unknown before and after spiking of the sample.

Incurred Material

These are materials in which the analyte of interest may be essentially alien but has been introduced to the bulk at some point prior to the material being sampled. The analyte is thus more closely bound in the matrix than by spiking.

Reagents and Solutions

Proper labelling of reagents and solutions should be done. Deteriorated or outdated reagents and solutions should not be used. The date of opening a reagent or solution should be mentioned on the bottle. Care should be taken if the reagent or solution should be stored in ambient temperature or refrigerated. The expiry date of the reagents and solutions should be checked before use.

Certified Reference Materials (CRMs)/Reference Materials (RMs)

Certified Reference Materials (CRMs) are certified standards traceable to SI units. These standards are used to check the quality and metrological traceability of products, to validate analytical measurement methods, or for the calibration of instruments. Standards make a massive and positive influence to most aspects of human beings. Standards ensure desirable features of products and services such as quality, safety, reliability, environmental friendliness, efficiency, and interchangeability at an economical cost. When products and services meet the expectations, people tend to take this for granted and be unaware of the role of standards. However, when standards are absent, it is soon noticed. It is noticed when products turn out to be of poor quality, do not fit, are incompatible with equipment that one already has, or are unreliable or dangerous. When products, systems, machinery, and devices work well and safely, it is often because they meet standards. And the organization responsible for many thousands of the standards which benefit the world is the International Standards Organization (ISO). The ISO makes the development, manufacturing, and supply of products and services more efficient, safer, and cleaner; facilitates trade between countries and make it **fairer**; provides governments with a technical base for health, safety, and environmental legislation and conformity assessment; shares technological advances and good management practice; disseminates innovation; safeguards consumers, and users in general, of products and services; and makes life simpler by providing solutions to common problems.

The CRMs are used to achieve highest level of accurate measurements, uncertainty, and traceability; however, RMs do not provide the same level of accuracy in the measurements. One of the advantages of using RM is that they are cost-effective and easier to produce. RMs are also ISO compliant, without any certified uncertainty associated with it.

Proficiency Testing

Proficiency testing (PT) also known as external quality assessment is an external way of assuring quality control by comparing the performance of the laboratories. As defined by ISO/IEC 17043:2010, PT is the evaluation of participant performance against pre-established criteria by means of interlaboratory comparisons (ISO/IEC 17043 2017). In other words, PT is an interlaboratory comparison of a method or a standard to establish stated references under same conditions, i.e., equipment, analytical procedure, etc. PT enables to bring out the variations among the laboratories and also helps in identifying the underlying inaccuracies (Eurachem/CITAC Guide 2016). In the process of proficiency testing, the material/matrix is sent to different laboratories for the determination of value for a component. The material is tested by each laboratory, independently, and the results are submitted to the coordinating body. The results of all the participating laboratories are evaluated by the coordinating body, and a performance report is issued to each participating

laboratory. If there is drastic difference in the results of the different laboratories even by following the same method, this process helps in identifying the underlying sources of errors in the method. Proficiency testing for a single method establishes precision. The stated references must meet stability and homogeneity requirements. PT provides laboratories an opportunity to achieve comparability of their results to a reference, which is a very useful method for achieving comparability of measurements. PT is used to determine the reproducibility of a method, to develop reference standards, and to verify new method of analysis (Guide 2021).

The results obtained by different laboratories are often converted to a value/score so that the underlying biasness (if any) can be evaluated for taking proper remedial actions. Two methods that are widely used to assess the PT results are Z-score and E_n score.

Z score: Z-score is a statistical measure of how much the observed result deviates from the population mean. The evaluation identifies and excludes the outliers from the PT results. The Z-score is calculated as:

$$Z = \frac{\chi - X}{\sigma}$$

where, χ = measurement result of a participating lab; X = assigned value (indicates population mean after excluding the outlier values); σ = standard deviation of the population.

If |Z-score| $\leq$2, the result would be regarded as "satisfactory."

2 < |Z-score| <3, the result would be regarded as "questionable."

|Z-score| $\geq$ 3, the result would not be accepted and regarded as "unsatisfactory."

The assessment Z-score and acceptance of the results is based on the concept of normally distributed data. This implies that the normally distributed analytical results would lie within three standard deviations ($\pm 3\sigma$) with a probability of 99.7% and within two standard deviations ($\pm 2\sigma$) with a probability of 95%. The outliers or unsatisfactory results indicate possible inaccuracies in the method of analysis undertaken. The laboratories must examine the cause of underlying problems and eradicate that through proper remedial actions.

E_n score: When the participating laboratories submit their results with uncertainty estimate, the assessment of the results are done with the help of E_n score. The E_n score is calculated as:

$$E_n = \frac{\chi_{lab} - X_{ref}}{\sqrt{U^2{}_{lab} + U^2{}_{ref}}}$$

where χ_{lab} = measurement result of a participating lab; X_{ref} = measurement result of reference lab; U_{lab} = expanded uncertainty (at 95%) of participating lab; U_{ref} = expanded uncertainty (at 95%) of reference lab.

If | E_n| $\leq$1, the results are regarded as "satisfactory."

| E_n| >1, the results are regarded as "unsatisfactory."

Thus, PT also becomes a significant part of QA/QC program that enable to monitor the comparability of results at national and international levels.

Analytical Methods in Environmental Analysis

There are several spectroscopic techniques, i.e., atomic absorption spectrometer (AAS), inductively coupled plasma-atomic emission spectrometer (ICP-AES), inductively coupled plasma-mass spectrometer (ICP-MS), flow injection analyzer (FIA), UV-vis spectrophotometer, X-ray diffraction (XRD), and X-ray fluorescence (XRF), and chromatographic techniques, i.e., high-performance liquid chromatography (HPLC), liquid chromatography-mass spectrometer (LCMS), gas chromatography (GC), gas chromatography-mass spectrometer (GCMS), capillary electrophoresis (CE), capillary electrophoresis-mass spectrometer (CEMS), and ion chromatography (IC), for analytical environmental measurements (Fig. 6) (Draghici and Manciulea 2016). All these techniques require calibration for making measurements. Instrument validation is necessary for any analytical laboratory. Data produced by "faulty" instruments may give the appearance of valid data. The frequency for calibration, re-validation, and testing depends on the instrument and extent of its use in the laboratory. Whenever an instrument's performance is outside the "control limits," reports must be discontinued. Whenever an analysis is to be performed, important questions are needed to be answered for any analytical instrument, e.g., the purpose for instrument being used for, the standards used for the calibration of the instrument traceable to national standards, if the instrument is within specification and documentation to prove this, if the instrument is not within specifications, the deviation factor, and action to be taken to overcome the issue to

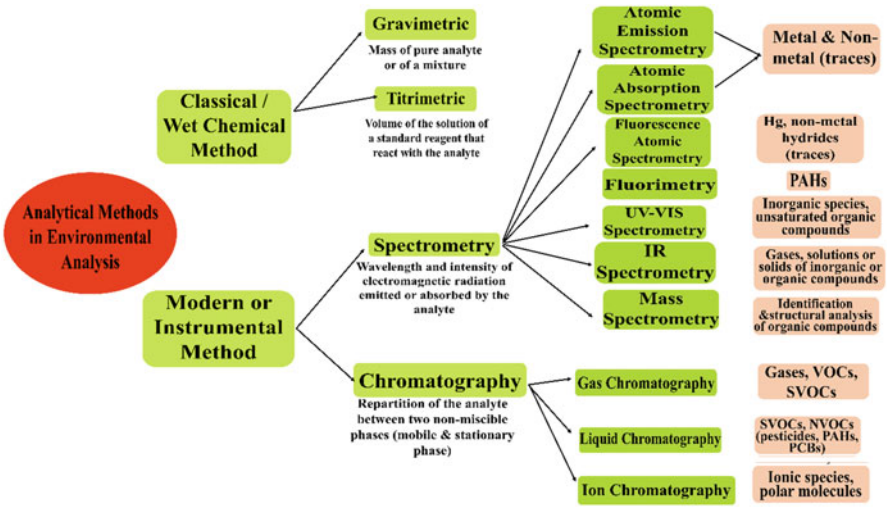

Fig. 6 Various analytical methods in environmental analysis

get the reliable analytical results. All types of analytical methods require calibration for quantification. In analytical environmental measurements, CRMs are available in matrix for a mixture of standard compounds. A minimum of three-point calibration curves are plotted in the range of the analyte to be measured. This helps to know the concentration of an unknown compound.

After considering all the abovementioned parameters during analytical environmental measurements, one may attempt to get the uncertainty for an analyte.

Evaluation of Uncertainty in Environmental Measurements

In 1980, the *Bureau International des Poids et Measures* published recommendation INC-1 on the statement of uncertainties, which dealt with expression of measurement uncertainty (JCGM 2008b). The guide suggests that the uncertainties of a measurement should be grouped and reported into two categories, Type A and Type B, depending on whether they were estimated statistically or based on scientific judgment. Type A uncertainties can be determined by using any valid statistical method like standard deviation in case of series of measurements, least squares to fit a curve to data in order to estimate the parameters of the curve, and their standard deviations one-way or two-way ANOVA (The NIST reference on Constants, Units, and Uncertainty 2022). Type B uncertainties which are determined on scientific judgment can include information from calibration certificate, manufacturer's specification, previous measurement data, etc. (The NIST reference on Constants, Units, and Uncertainty 2022). Further, in 1993, the document was revised as "Guide to the Expression of Uncertainty in Measurement" (GUM) which was later revised and updated accordingly with time. GUM provides a comprehensive outlook on how to deal with uncertainties in metrology across a broad spectrum of measurements. The current version of this guide is published as ISO/IEC Guide 98–3:2008 "Uncertainty of measurement –Part 3: Guide to the expression of uncertainty in measurement" (ISO/IEC 98–3 2008). EURACHEM/CITAC Guide titled "Quantifying Uncertainty in Analytical Measurement" is a document used for estimating the measurement uncertainty in the field of analytical chemistry (Eurachem/CITAC Guide CG4 2012). This guide demonstrates that the concepts and principles of physical measurements stated in ISO GUM guide can also be applied in chemical measurements. The methodology used in the EURACHEM/CITAC guide for determining uncertainty in chemical measurements is in close association with the requirements of ISO/IEC 17025:2017 (Damasceno and Couto 2018). As per EURACHEM/CITAC Guide, the following are the steps that can be followed to determine uncertainty in analytical measurements which is also useful in analytical environmental measurements:

Step 1: Specification of the Measurand In uncertainty estimation, the first and foremost step is to identify "what is to be evaluated and the mathematical expression associated." In other words, "specification of the measurand" which means a clear and explicit statement of what is to be measured is required along with the

mathematical expression that connects the value of the measurand to the various factors on which it depends. The factor may or may not directly influence the measurand.

Step 2: Identify and Characterize Uncertainty Sources The next step consists of collecting a comprehensive list of all the possible sources of uncertainty that may affect the factors of the identified measurand directly or indirectly. According to GUM guide, there are mainly two types of uncertainties, Type A and Type B. Type A uncertainty arises from statistical analysis, and it generally includes uncertainties arising from accuracy, linearity, repeatability, and reproducibility. Type B uncertainty is determined by scientific judgment or any other source of information. One of the most convenient ways to identify possible uncertainty sources is cause-effect diagram or fishbone diagram to establish the relationship among the measurand, variables affecting measurand, and sources affecting these variables. In the process of determining a measurement result, there may appear several uncertainty sources. Even if it is quite challenging to report all the possible uncertainty sources, a few of them are (Eurachem/CITAC Guide CG4 2012) as follows:

Sources of Uncertainty

(a) Ambiguous or incomplete definition of the measurand.
(b) Biased sampling procedures or random variations between different samples resulting in non-representative sampling.
(c) Personal bias in performing and reporting the measurement values of the experiment.
(d) Uncertainty in reference standard which is introduced from the purity of the reference material.
(e) Uncertainty arising due to stability of the reagents and reference material.
(f) Assumptions made during measurement procedures.
(g) Limitations of the instrument.
(h) Repeatability which is measurement of the precision under a set of repeatable conditions.
(i) Reproducibility that determines the variability in measurements under reproducible conditions, for example, operator vs operator, instrument vs instrument, method vs method, day vs day, and environmental conditions vs environmental conditions.
(j) Drift which determines the change in response of a measuring instrument over time.
(k) Environmental conditions at which measurements are made.

Step 3: Quantifying Uncertainty In the process of uncertainty measurement, the next step involves quantification of the estimate of uncertainty by considering all the identified sources in Step 2. In other words, the numerical value that is assigned to each possible source is calculated in this step. Further, all the uncertainties must be specified as a form of standard uncertainty, i.e., standard deviation or standard deviation of the mean. Fig. 7 shows the calculation of standard uncertainty from

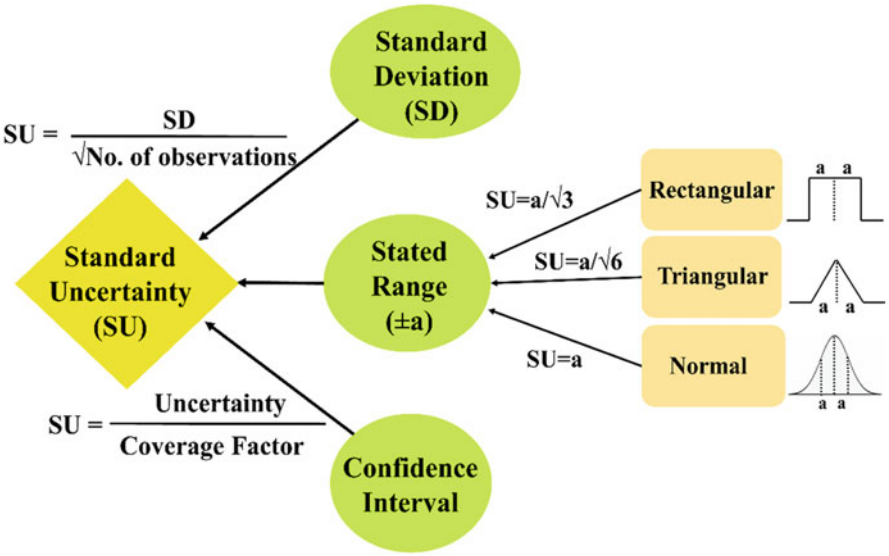

Fig. 7 Calculation of standard uncertainty from various forms of uncertainty

various forms of uncertainty. For this, the estimate of individual uncertainty component is divided by a probability distribution that characterizes the data set. Most common probability distributions are normal or Gaussian, rectangular or uniform, and triangular.

Step 4: Calculating the Combined Uncertainty The standard uncertainties calculated in Step 3 are combined and expressed as combined standard uncertainty which can be expressed as follows:

$CU = \sqrt{u_1}^2 + u_2^2 + \cdots + u_n^2$, where u_1, u_2, …, u_n are individual standard uncertainties.

In other words, root sum of squares of each standard uncertainty can give combined uncertainty.

Reporting Uncertainty As per ISO/IEC 17025:2017 requirements, uncertainty must be reported in the form of expanded uncertainty at the confidence interval of 95% in all situations unless specified.

$u = k \,.\, CU.$

(Result): (x ± U) (units)

where U = expanded uncertainty.

k = coverage factor.

CU = combined standard uncertainty (calculated in step 4).

x = the measurand, of which the uncertainty has to be estimated.

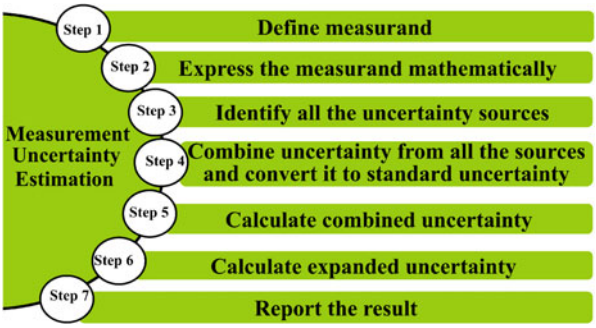

Fig. 8 Steps to evaluate measurement uncertainty

Figure 8 shows the simplified steps that can be followed while estimating the measurement uncertainty.

Environmental Sampling and Chemical Analysis

Environmental pollution especially air pollution is a topic of national and international importance along with transboundary pollution as a major problem in some countries. Can these data be actually compared? Surprisingly, no. Until, there exists a common documented measurement procedure, measured through an unbroken chain of comparisons, no measurements could be compared.

To better understand the concept of measurement traceability and uncertainty in environmental matrices, let's take example of air as matrix and discuss the involved steps from sampling to chemical analysis in detail.

Sampling of the Aerosols

Air consists of nitrogen, oxygen, and other trace gases. Apart from that, there exist numerous tiny suspended solid or liquid particles called aerosols, ranging from few nanometers to 100 μm. Additionally, some gaseous pollutants are also present in the air. These aerosols and gaseous pollutants are responsible for the contamination of the environment. The aerosols directly or indirectly modify the earth's radiation budget and have severe detrimental effects on plants and animals. Thus, aerosols form an important constituent whenever ambient air quality is considered. In most of the countries, aerosols are considered as crucial parameters in their ambient air quality guidelines. Mostly, aerosols having aerodynamic diameter $\leq$2.5 μm and $\leq$10 μm (i.e., $PM_{2.5}$ and PM_{10}) are considered for the regulatory purposes along with their measurement methods.

To monitor the physico-chemical properties of air, the samples of aerosols are collected. The aerosol samples are generally collected by two different methods offline and online measurements. Offline measurement (manual sampling) is the

most widely used method which determines the concentration of particulate matter in air. Offline measurement method further involves active and passive sampling. Active sampling implies that air is sucked at a constant rate using a pump while in passive sampling, the air is allowed to deposit over any collection media at natural rate of deposition. Active sampling can be used to collect total suspended particulate matter (TSPM), respirable suspended particulate matter (RSPM) or PM_{10}, and fine particulate matter ($PM_{2.5}$, PM_1, or finer fraction) on a collection media called "filters." There are various types of filters on which PM can be collected such as glass fiber, cellulose, quartz microfiber, nylon membrane, and Teflon (Watson et al. 2017). The selection of filters depends on the objectives of study due to their specific advantages and disadvantages. Since, passive sampling does not involve a fixed rate of air deposition, determining the volume of air deposited over the collection plate is quite difficult. Thus, the deposition flux (concentration over area) of various species is determined directly. In passive sampling, size selective sampling is not possible. In fact, it determines the average concentration of pollutants deposited over time. The documented steps that are included in active sampling of particulate matter are shown in Fig. 9 (40 CFR Appendix J 1987; 40 CFR Appendix L 1997; National Ambient Air Quality Standards for Particulate Matter 1997; CENTRAL POLLUTION CONTROL BOARD 2013; McMurry 2000).

The initial step involves the conditioning of the filter, which means the filter is to be kept in controlled environment (fixed temperature and humidity) for minimum of 24 hours. The recommended temperature is 25.0 ± 2.0 °C while humidity should be $45 \pm 5\%$. This is done to ensure that the moisture content of the filter should not affect the weight measurements. These standard conditions account for variations arising due to moisture during pre- and post-weighing period as the filter media have high affinity for changes in relative humidity. For the same reason, cellulose and cellulose ester membrane filters are not suggested for gravimetric assessment of particulate matter in ambient air. After conditioning of the filter, its weight is measured using analytical microbalance. During weight measurements, various sources of uncertainties can arise like uncertainty of analytical balance due to limited accuracy, variation arising from multiple measurements (run to run variation), and

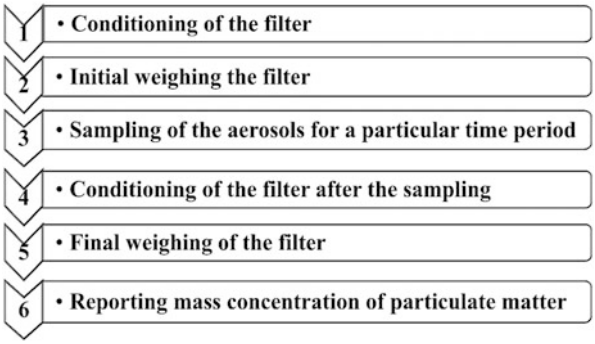

Fig. 9 Steps in sampling of particulate matter

the physical factors like temperature and humidity changes. The uncertainties arising from analytical balance can be determined by its calibration and considering the expanded uncertainty from calibration certificate. The uncertainties arising from the precision of the analytical microbalance can be determined from repeated measurements of the same sample. After weighing, the sampling is performed for a specific period of time to collect the particulate matter on a filter. During aerosol sampling, air is sucked through a size-selective inlet at a constant volumetric flow rate. The volume of the air collected is an important parameter which determines the mass of particulate matter in that particular volume of air. The volume of air collected depends on the flow rate of the instrument and duration for which the instrument is operated. The uncertainty arising from the flow rate and time measurements results in the uncertainty in volume measurements. Thus, calibration of flow rate and time are crucial parameters for traceability in environmental measurements. In these samplers, the individual units of flow measurement and time (time totalizer) are calibrated, which helps to find the uncertainty in the measurement of that parameter. There are various flow meters which are used to calibrate the flow rate of the instrument like manometer/rotameter. The inlet design depends on cut-off diameter which is designed on the basis of 50% particle collection efficiency. This means the inlet is collecting at least 50% of the particles in the size range similar to cut-off diameter. Still, it does not provide the uncertainty in size cut-off measurements. In India, there are no calibration facilities or reference method for calibration for air monitoring instruments. The CPCB uses Federal Reference Method/Federal Equivalent Method of the US EPA for calibration of their samplers (CENTRAL POLLUTION CONTROL BOARD 2013). The manufacturers get their instrument calibrated outside the country or sometimes a calibrated sampler is used as a reference sampler to calibrate other sampler by comparing mass of filters. Lately, CSIR-National Physical Laboratory (CSIR-NPL) has established first and unique National Calibration Facility that would test and calibrate $PM_{2.5}$ and PM_{10} samples for both their cut-off size and flow rate (CSIR-NPL n.d.). CSIR-NPL, India, has also been designated as the apex calibrating body for all such instruments getting manufactured in India. Further, there may be an uncertainty source arising from run to run variation which could be determined by repeated measurements. And finally, after sampling, the filters are removed, conditioned again for 24 hours, and weighed post sampling. Mathematically, the mass concentration of particulate matter is calculated as:

$$\text{Mass concentration} = \frac{\text{final weight of the filter} - \text{initial weight of the filter}}{\text{volume of the air sampled}}$$

After sampling, the sample (filter) is preserved and stored until samples are subjected to pre-treatment process. The main reason behind proper sample storage is to minimize physical and chemical losses in the sample due to volatilization, diffusion, chemical reactions, or photochemical reactions. In such case, the physical and chemical properties of the sample may vary to give erroneous results (Pokhariyal et al. 2019). To avoid this, the samples are sealed in baked aluminum foil and put in

locked polybags and kept inside airtight containers. These airtight containers are kept in refrigerator below 4 °C.

Monitoring Instrument

Figure 10 shows a manual low volume air sampler used to collect $PM_{2.5}$ samples. The air is drawn through inlet using a vacuum pump to pass through a quartz microfiber filter to collect particulate matter on the filter surface. The first impactor has cut-off diameter of 10 μm which allows particles having size $\leq$10 μm to continue to the stream in the sampler. Similarly, the second impactor has cut-off diameter of 2.5 μm which allows particles having size $\leq$2.5 μm to get deposited on the filter surface. The air is drawn at the rate of $1m^3$/hour which is held constant through a critical orifice. The total volume of the air sampled is measured directly with the help of a dry gas meter. The flow rate in this case can be determined by dividing the air volume sampled with total time for which the instrument is operated. The uncertainty in volume measurements can be estimated by calibration of the instrument (Type B) and run to run variation (Type A). The cause-effect diagram shows the various sources of uncertainty in calculating mass concentration of particulate matter (Fig. 11).

Steps to Determine Uncertainty Associated with Calculation of Mass Concentration of $PM_{2.5}$

To understand the uncertainty calculations that are involved in enumeration of mass concentration of $PM_{2.5}$, the $PM_{2.5}$ samples are collected over a 47 mm quartz microfiber filter using a low volume $PM_{2.5}$ sampler as shown in Fig. 10. The filter has to be conditioned for at least 24 hours prior to the sampling so that initial weight of the filter could be taken. The filter is then placed in the sampler operating at flow rate of $1m^3$/hour for a particular period of time. The duration of the sampling depends on the objectives of sampling. After that, the filter is removed, conditioned

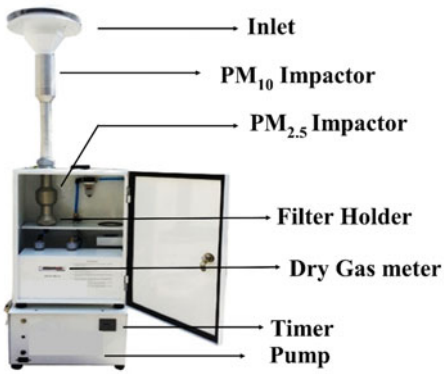

Fig. 10 Low volume $PM_{2.5}$ sampler

for 24 hours, and weighed again. For example, the initial and final weighings are repeated for 5 times, and the weights obtained are m_1, m_2, m_3, m_4, and m_5 mg for initial measurements and m_1', m_2', m_3', m_4', and m_5' mg for final measurements. The initial and final volume readings observed are V_i and V_f m^3, respectively.

As per, Eurachem/CITAC, QUAM 2012 the steps to determine uncertainty are:

1. **The First Step Is Defining the Measurand, i.e., What Is To Be Measured.**

So, the measurand here is mass concentration of $PM_{2.5}$ for which the mathematical equation is as follows:

$$PM_{2.5}\ mass\ concentration = \frac{m_f - m_i}{V}$$

where m_f = final weight of the filter.

m_i = initial weight of the filter.

V = total volume of the air sampled.

The measurand has two major variables which can affect its measurement, i.e., weight change and volume of the air sampled. The weight change of the filter can be calculated as the difference in averages of final and initial weights. Similarly, the volume of the air can be calculated as the difference in final and initial volume readings of the instrument.

Volume of the air sampled (m^3) = final volume –initial volume.

= ($V_f - V_i$) m^3.

$$= \Delta V\ m^3 \tag{1}$$

Thus, $PM_{2.5}$ mass concentration can be given as:

$$mass\ concentration, C_m = \frac{m_f - m_i}{V_f - V_i} = \frac{\Delta m}{\Delta V}\ mg/m^3$$

Since the mass concentration of particulate matter is generally reported in $\mu g/m^3$, the obtained mass concentration C_m can be written as:

$$C_m = \frac{\Delta m}{\Delta V} \times 10^6\ \mu g/m^3$$

$$C_m = X\ \mu g/m^3 \tag{2}$$

2. **Identify All the Uncertainty Sources Affecting the Variables of the Measurand.**

The uncertainties in weight change are due to calibration of the analytical balance (Type B) and repeatability of the measurements (Type A). Similarly, uncertainty in

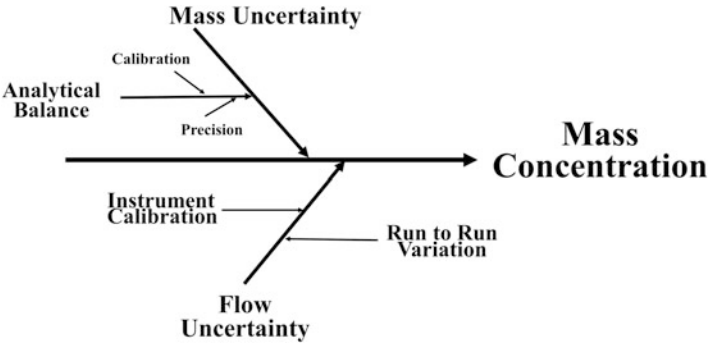

Fig. 11 Cause-effect diagram for determination of uncertainty in mass concentration of particulate matter

volume can be determined from the calibration certificate of the instrument (Type B). The cause-effect diagram is shown in Fig. 11.

3. **Combine All the Uncertainty Sources and Convert Them into Standard Uncertainties.**
   i. Uncertainty arising from repeated measurements of mass or precision of the measurement:
      In a single measurement, the standard deviation is used as standard uncertainty whereas for results subjected to averaging, the standard uncertainty is the standard deviation of the mean (Table 1).
   ii. Uncertainty arising from calibration of analytical balance:
      The calibration certificate of an electronic balance (N19040058/D1.01/C-011) states that at confidence interval of 95% (coverage factor of 2), the expanded uncertainty is ±0.32 mg for load weights up to 100 g while ±0.33 mg for load weights up to 200 g. In this case, the uncertainty would be ±0.32 mg, while to obtain standard uncertainty, the uncertainty would be divided by the coverage factor (2).
   iii. Uncertainty arising from calibration of the instrument:
      The uncertainty in volume readings of the manual low volume $PM_{2.5}$ sampler can be obtained from the calibration certificate of the sampler.

   Now, the uncertainty in mass, arising from two different components, can be combined together and expressed as:

$$u_{mass} = \sqrt{(uncertainty\ due\ to\ precision)^2 + (uncertainty\ due\ to\ calibration\ )^2}$$

where uncertainty due to precision is standard error of the repeated mass measurements = SE and uncertainty due to calibration of analytical balance = $(u_{cal})_{bal}$

Table 1 Repeated weight measurements of filter

Initial weight (mg)	Final weight (mg)
m_1	m_1'
m_2	m_2'
m_3	m_3'
m_4	m_4'
m_5	m_5'
Average initial weight = m_i	Average final weight = m_f

Weight difference = Δm; Standard deviation = SD; Standard error, SE = SD/√n, where n = no. of observations taken for weight measurement. Here n = 5

Thus,

$$(u_{mass})_{total} = \sqrt{(SE)^2 + (u_{cal})_{bal}^{\ 2}} \tag{3}$$

4. **Calculate Combined Uncertainty.**

The combined uncertainty is calculated using root sum of squares of all the relative standard uncertainties which is determined by dividing the standard uncertainty with the numerical value of the variable.

Combined uncertainty in mass concentration

$$\frac{u_{C_m}}{C_m} = \sqrt{\left(\frac{(u_{mass})_{total}}{\Delta m}\right)^2 + \left(\frac{u_{\Delta V}}{V}\right)^2} \tag{4}$$

Equation (4) can be re-written as:

$$u_{C_m} = C_m \times \sqrt{\left(\frac{(u_{mass})_{total}}{\Delta m}\right)^2 + \left(\frac{u_{\Delta V}}{V}\right)^2}$$

where u_{C_m} = uncertainty in mass concentration of $PM_{2.5}$.

C_m = mass concentration of $PM_{2.5}$, can be obtained from Eq. (2).

$(u_{mass})_{total}$ = uncertainty in mass measurement arising from both precision and calibration of analytical balance, can be obtained from Eq. (3).

Δm = difference in averages of final and initial weights (Table 1).

$u_{\Delta V}$ = uncertainty in volume of air sampled.

V = Volume of air sampled, obtained from Eq. (1).

Calculation of Expanded Uncertainty. The expanded uncertainty is determined at the coverage factor of 2 or 95% confidence interval.

Expanded uncertainty at k = 2.

$$U_{exp} = 2 \times u_{C_m}\ \mu g/m^3 \tag{5}$$

To report the measurement uncertainty in mass concentration of $PM_{2.5}$ for 24 hours sampling duration, the reported expanded uncertainty = (X ± U_{exp}) μg/m^3. The measurement result in this case would be traceable to the SI units as each step has its contribution to the total uncertainty. However, the uncertainty related to cut-off diameter is also needed to be considered in addition to volume in m^3.

Chemical Analysis

The atmospheric aerosols contain useful information about the chemistry of atmosphere, particles, and gases which is subject to proper chemical analysis. Thus, after sampling and gravimetric analysis, the filters can be used for qualitative and quantitative estimation of various inorganic and organic chemical components present in the atmosphere. Fig. 12 represents the steps involved in the chemical analysis of the particulate matter.

Inorganic compounds like trace metals, anions, cations, etc. can be detected by using different analytical instruments like atomic absorption spectroscope (AAS), inductively coupled plasma (ICP) with mass spectrometer or optical emission spectrometer as detector, ion chromatograph, etc., while organic compounds can be determined using liquid chromatograph (LC), liquid chromatograph-mass spectrometer (LC-MS), gas chromatograph, gas chromatograph-mass spectrometer (GC-MS), etc. But a common process involved in both inorganic and organic estimation is pre-treatment of the sample, i.e., extraction of the chemical components from the sample matrix (filters) using a suitable solvent. Deionized water or other aqueous solvents can be used as a solvent for inorganic determination (also known as aqueous extraction) while a suitable organic solvent can be used for organic determination based on the compounds of interest. Since the organic compounds possess more complex nature than inorganic compounds, the techniques involved in extraction are dependent on solubility of the analyte in polar or non-polar solvents and

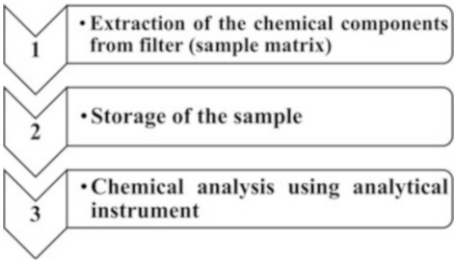

Fig. 12 Steps involved in the chemical analysis of the particulate matter

phase transformations. The procedures for extraction of some compounds are documented by the United States Environmental Protection Agency (USEPA) like Method TO-13A for PAHs, Method TO-4A for pesticides and polychlorinated biphenyls, MLD073 for levoglucosan and galactosan etc., which are usually followed among the scientific community to achieve high accuracy and precision (Centre for Environmental Research Information 1999a, b; California Environmental Protection Agency, California Air Resource Board 2014). The extraction of the chemical components from the sample matrix is not the only aspect involved in enumerating the levels of chemical species in atmospheric particulate matter. The other aspects which are considered for uncertainty in measurement results are sample storage, quality control, and quality assurance during chemical analysis of the samples. The sample storage involves both short-term storage that includes immediate analysis after extraction and long-term storage which includes reanalysis of the samples for precision and accuracy of the data. Thus, the sources of uncertainty during extraction and storage of the sample mainly arises due to accuracy of glasswares which can be determined through calibration and uncertainty values provided on the calibration certificate. In case of absence of calibration certificate of glasswares, repeated measurements for the samples can be done, and the uncertainty can be calculated by standard deviation of the repeated measurements. Another source that will produce uncertainty in the results would be purity of the chemicals provided by the manufacturer.

For analytical measurements, the primary step is to check for the calibration of the instrument to be used for chemical analysis. Accuracy of quantitative results depends on robustness of the analytical method and preparation of samples and standards. Traceability of the reference material and confidence in the property value (concentration) is critical for ensuring quality and accuracy of laboratory test results. ISO/IEC 17025 and ISO guide 34 require that laboratories maintain traceability and uncertainty of their reference materials as a key element of their quality system (ISO/IEC 17025 2017; ISO 17034 2017). The stated concentration of a solution standard is usually accompanied by an uncertainty statement expressed as an expanded uncertainty with a specified coverage factor. Understanding the uncertainty of the concentration of reference standards is critical for laboratories seeking to ensure compliance with ISO/IEC 17025.

Reference Material (RM) or Certified Reference Material (CRM) is needed for the calibration of an analytical instrument. ISO Guide 31:2015 Defines RM as "material sufficiently homogenous and stable with respect to one or more specified properties, which has been established to be fit for its intended use in a measurement process" (ISO Guide 31 2015). And CRM is defined as "reference material, characterized by metrologically valid procedure for one or more specified property, its associated uncertainty and a statement of metrological traceability" (ISO Guide 31 2015). CRMs are mostly produced by metrology institutes of any country like CSIR-National Physical Laboratory (CSIR-NPL), India; and National Institute of Standards and Technology (NIST), United States; and other such NMIs around the

world. The use of RMs and CRMs ensure the validity and accuracy of the analytical methods which help in comparability of the measurement results among various laboratories over time and space.

Different concentration levels of CRM or RM can be used to calibrate the analytical instrument. The slope of the calibration plot is used to enumerate the compounds of interest. The sources of uncertainties that can arise during quantitative estimation of a chemical analyte are uncertainty associated with CRM/RM obtained from the manufacturer's certificate, accuracy of glasswares, steps involved in making working standards from CRM/RM, instrumental accuracy and precision, and run to run variation.

Uncertainty Calculations in Analytical Determination of BaP in $PM_{2.5}$

The concept of measurement uncertainty estimation can also be applied in analytical environmental measurements. Let us understand the application of concept of uncertainty with an example of determination of particle-bound PAHs in the collected $PM_{2.5}$ sample. PAHs are group of non-polar organic compounds that naturally occur in coal and petroleum and emitted in the atmosphere by their ignition (EPA Factsheet for PAHs 2008). They are also emitted by burning of wood, trash, and tobacco. PAHs have proved to be carcinogenic, mutagenic, and teratogenic to various life forms. Thus, they have become a contaminant of significant concern.

Benzo(a)pyrene (BaP), a criteria pollutant in Indian National Ambient Air Quality Standards (NAAQS), is one of the PAHs, which is the most common carcinogen present in the ambient air with established effects on humans (Yadav et al. 2020b). To monitor and regulate the concentration of PAHs in atmosphere, CPCB considers BaP as representative of all PAHs and has set a maximum concentration of 1 ng/m^3 (24-h average) as NAAQS (Yadav et al. 2020b).

To understand the uncertainty calculations involved in determination of the concentration of PAHs (BaP as example) in $PM_{2.5}$ by using GC-MS as analytical instrument, the steps are as follows (Eurachem/CITAC Guide CG4 2012; Sungur et al. 2014).

Defining the Measurand

The measurand is concentration of particle-bound polycyclic aromatic hydrocarbons (PAHs). The concentration of PAHs (in ng/m^3) in aerosol samples is determined by the following equation (Elorduy et al. 2018):

$$Concentration\ \left(ngm^{-3}\right) = \frac{C\ \left(\mu g.mL^{-1}\right) \times V_s\ (mL)}{V_{air}(m^3)} \times 1000 \qquad (6)$$

where C = concentration of the target compound obtained from calibration ($\mu g.\ mL^{-1}$).

V_s = final volume of the sample (mL).

V_{air} = volume of the air sampled (m^3).

Identification of all the Uncertainty Sources Affecting the Variables of the Measurand and Converting Them into Standard Uncertainties

Here, the measurand depends on three main variables, i.e., the concentration of the targeted compound obtained from final volume of the sample, calibration curve, and volume of the air sampled. Thus, the various sources of uncertainty are shown in Fig. 13.

Uncertainty Derived from Final Volume of the Sample The sample matrix is extracted in 20 mL of dichloromethane and sonicated for 3 hours to extract the PAHs. In this case, the uncertainty arises from calibration of the measuring cylinder (Type B). The temperature variation in the laboratory also affects the uncertainty in glasswares (Type A). The extracted fraction is then transferred to Kuderna-Danish extraction apparatus to evaporate the solvent up to 2–3 mL using a heating mantle (~40 °C). Finally, the content is transferred to a vial and reduced to 1 mL using pure nitrogen gas stream. The uncertainty from final volume of sample depends on the uncertainties associated with measuring cylinder and vial which is calculated as follows:

$$\left(\frac{u_{volume\ of\ the\ sample}}{V_s}\right)^2 = \left(\frac{u_{measuring\ cylinder}}{V_{measuring\ cylinder}}\right)^2 + \left(\frac{u_{vial}}{V_{vial}}\right)^2 \tag{7}$$

where $u_{volume\ of\ the\ sample}$= uncertainty in the final volume of the sample.

V_s =volume of the final solution =1 mL.

$u_{measuring\ cylinder}$ = uncertainty in volume measurement of measuring cylinder.

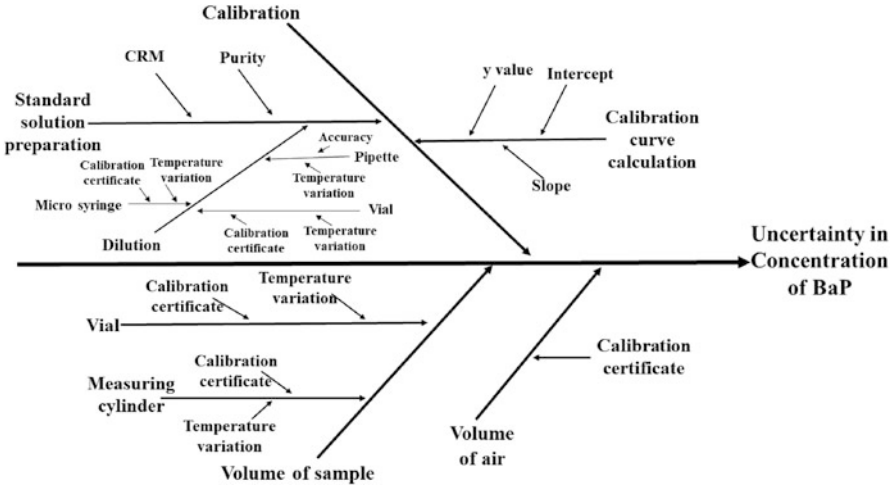

Fig. 13 Cause-effect diagram for determination of uncertainty in concentration of BaP in $PM_{2.5}$

$V_{measuring\ cylinder}$ = volume of measuring cylinder = 50 mL.
u_{vial} = uncertainty in volume measurement of vial.
V_{vial} = volume of vial = 1 mL.

The uncertainty in measuring cylinder due to calibration can be determined from calibration certificate (N19050149/D1.01/C-059) which states that the uncertainty for 50 mL volumetric flask is ±0.050 mL at 95% confidence interval. Thus, for standard uncertainty, the uncertainty given is divided by a factor of 2.

The temperature variation in the laboratory can affect the volume measurements of the glasswares. The EURACHEM/CITAC 2012 Guide mentions/states that a variation of ± 3 °C is allowed during the chemical measurements which can be calculated as follows (Yenisoy-Karakas 2012):

$$u_T = \frac{3 \times V \times Q}{1.73} \tag{8}$$

where V = measured volume and Q = coefficient of the volume expansion of the solvent used.

And for DCM, Q = 1.44x 10^{-3} $°C^{-1}$ (at 25 °C).

So the total uncertainty in volume measurement of measuring cylinder can be given as follows:

$$u_{measuring\ cylinder} = \sqrt{(u_{cal})^2 + (u_T)^2} \tag{9}$$

Similarly, volume of vial =1 mL.

Uncertainty in vial due to calibration can be obtained from calibration certificate (N19050149/D1.01/C-060) which states that the uncertainty for 1 mL vial is ±0.015 mL at 95% confidence interval. Thus, for standard uncertainty, the uncertainty value given is divided by a factor of 2.

Uncertainty in vial due to temperature variation, u_T, can be obtained from Eq. (8).

So, the total uncertainty in volume measurement of vial can be given as:

$$u_{vial} = \sqrt{(u_{cal})^2 + (u_T)^2} \tag{10}$$

And the relative uncertainty in volume of the sample can be calculated by putting Eqs. (9) and (10) in Eq. (7).

The account of loss or addition of the analyte (recovery) during pre-treatment procedures (extraction) is quite a challenging process but it should be considered while estimating the measurement uncertainty. In present case, the recovery of the sample is not considered for calculations due to some limitations. However, it can be estimated by adding a known amount of standard before the sample pre-treatment procedure and then performing the extraction. The concentration of the added standard can be determined from the analytical instrument and the percentage recovery could be estimated.

Uncertainty Derived from Calibration The uncertainty associated with the calibration can be determined by combining the individual uncertainties arising from preparation of calibration standards and fitting of calibration curve.

So, the uncertainty arising from calibration can be expressed as:

$$\left(\frac{u_{Cal}}{C}\right)^2 = \left(\frac{u_{std}}{C_{std}}\right)^2 + \left(\frac{u_{Cx}}{C_x}\right)^2 \tag{11}$$

where u_{std} is the uncertainty from preparation of the standard solution, u_{Cx} is the uncertainty from linear least square fitting, C_{std} is the concentration of prepared standard solution, and C_x is the predicted analyte concentration.

Uncertainty Derived from Preparation of Calibration Standards The preparation of working calibration standards from CRM involves an intermediate step of stock solution preparation. This means a stock solution has to be prepared from CRM by dilution first and then working calibration standards of different concentrations prepared by serial dilution of the stock solution formed. The sources of uncertainty contributing in preparation of working standards include uncertainty of CRM as per the certificate (Type B), stock solution preparation, and series of dilution. The stock solution and dilution series further consist of uncertainties arising from vial calibration (Type B), micro syringes calibration (Type B), accuracy of the pipettes (Type A), and purity of the solvent used (Type A). Thus, relative uncertainty in preparation of standards can be given by:

$$\left(\frac{u_{std}}{C_{std}}\right)^2 = \left(\frac{u_{CRM}}{C_{CRM}}\right)^2 + \left(\frac{u_{Dilution}}{Dilution\ Factor}\right)^2 + \left(\frac{u_{purity}}{Purity\ of\ the\ solvent}\right)^2 \tag{12}$$

where,

$$(u_{dilution})^2 = \left(\frac{u_{microsyringe}}{V_{microsyringe}}\right)^2 + \left(\frac{u_{pipette}}{V_{pipette}}\right)^2 + \left(\frac{u_{vial}}{V_{vial}}\right)^2 \tag{13}$$

where u_{CRM} is the uncertainty of CRM; $u_{Dilution}$ is the uncertainty due to dilution, u_{purity} is the uncertainty associated with the purity of solvent used, and $u_{microsyringe}$, $u_{pipette}$, and u_{vial} are the uncertainty due to micro syringe, pipette, and vial used, while C_{CRM} is the concentration of CRM and $V_{microsyringe}$, $V_{pipette}$, and V_{vial} are the volumes of micro syringe, pipette, and vial.

A CRM of mixture of 18 PAHs (CRM 47543, Sigma Aldrich) having concentration 2000 μg/mL is used for making the calibration standards. To prepare the stock solution of 20 μg/mL, the CRM having 2000 μg/mL concentration has been diluted two times. Further, the calibration standards of levels 0.1, 0.5, 1, 2, and 5 μg/mL can be prepared by serial dilution.

Initially a solution of 200 µg/mL is prepared by diluting 100 µL of the 2000 µg/mL CRM/standard with 900 µL of DCM. Further 20 µg/mL is prepared by diluting 100 µL of the 200 µg/mL CRM/standard with 900 µL of DCM. A series of working standards ranging from 0.1, 0.5, 1, 2, to 5 µg/mL are prepared by diluting the stock solution and the successive standards formed. For example, 1 mL working standard of 5 µg/mL can be prepared by diluting 250 µL of 20 µg/mL with 750 µL of DCM, 2 µg/mL can be prepared by diluting 400 µL of 5 µg/mL with 600 µL of DCM, 1 µg/mL can be prepared by diluting 500 µL of 2 µg/mL with 500 µL of DCM, 0.5 µg/mL can be prepared by diluting 500 µL of 1 µg/mL with 500 µL of DCM, and finally, 0.1 µg/mL can be prepared by diluting 200 µL of 0.5 µg/mL with 800 µL of DCM.

To prepare the standards, micro syringes (HAMILTON, 500 µL), micro-pipettes (Eppendorf, 100–1000 µL), and vials (Borosil) are used. Tables 2, 3, and 4 summarize the uncertainties obtained from micro-syringe, pipette, and vial for each dilution stage. Table 5 shows uncertainty arising from calibration standards of different levels.

Table 2 Uncertainty associated with microsyringe used during preparation of CRM solution for each dilution stage

Dilution stage	Concentration of the solution µg/mL	Volume of syringe used µL	Measured volume µL	$(u_{microsyringe})_{cal}$ µL	$(u_{microsyringe})_T$ µL	$(u_{microsyringe})$ total µL
1	200	500	100	0.075	0.25	0.79
2	20	500	100	0.075	0.25	0.79
3	5	500	250	0.075	0.62	0.97
4	2	500	400	0.075	0.99	1.24
5	1	500	500	0.075	1.25	1.46
6	0.5	500	500	0.075	1.25	1.46
7	0.1	500	200	0.075	0.5	0.90

Table 3 Uncertainty associated with autopipette used during preparation of CRM solution for each dilution stage

Dilution Stage	Concentration of the solution µg/mL	Volume of pipette used µL	Measured Volume µL	$(u_{pipette})$ µL	$(u_{pipette})_T$ µL	$(u_{pipette})$ total µL
1	200	1000	900	0.00035	2.25	2.25
2	20	1000	900	0.00035	2.25	2.25
3	5	1000	750	0.00035	1.87	1.87
4	2	1000	600	0.00035	1.50	1.5
5	1	1000	500	0.00035	1.25	1.25
6	0.5	1000	500	0.00035	1.25	1.25
7	0.1	1000	800	0.00035	2.00	2.00

Table 4 Uncertainty associated with vial used during preparation of CRM solution for each dilution stage

Dilution stage	Concentration of the solution µg/mL	Volume of vial mL	(u_{vial}) cal	$(u_{vial})_T$	(u_{vial}) final mL
1,2,3,4,5,6,7	200; 20; 5; 2; 1; 0.5; 0.1	1	0.075	0.0025	0.075

Table 5 Uncertainty associated with calibration standards

Concentration of the solution µg/mL	Dilution factor	Concentration of CRM µg/mL	u_{CRM} µg/mL	$\left(\frac{u_{std}}{C_{std}}\right)$
5	4	2000	29.5	0.026
2	2.5	2000	29.5	0.029
1	2	2000	29.5	0.031
0.5	2	2000	29.5	0.031
0.1	5	2000	29.5	0.025

Uncertainty in microsyringe due to calibration can be taken from calibration certificate (N19050149/D1.01/C-058) which states that the uncertainty value for 500 µL microsyringe is ±7.5 µL at 95% confidence interval. Therefore, for obtaining standard uncertainty, the value is divided by a factor 2.

Uncertainty in microsyringe due to temperature variation, u_T, can be calculated using Eq. (8). The uncertainty in microsyringe due to temperature variation is calculated for each dilution stage where measured volume is 100, 100, 250, 400, 500, 500, and 200, respectively, as shown in Table 2.

So, the total uncertainty in volume measurement of microsyringe can be given as follows:

$$u_{microsyringe} = \sqrt{(u_{cal})^2 + (u_T)^2}$$

Uncertainty in pipette due to accuracy can be estimated from manufacturer's specifications which states that the accuracy for 1000 µL volume is ±0.06%. To get the standard uncertainty, the accuracy value is divided by √3 by using rectangular probability (Fig. 7).

Uncertainty in pipette due to temperature variation, u_T, can be calculated using Eq. (8). The uncertainty in pipette due to temperature variation is calculated for each dilution stage where measured volume is 900, 900, 750, 600, 500, 500, and 800, respectively, as shown in Table 3.

So, the total uncertainty in volume measurement of pipette can be given as:

$$u_{pipette} = \sqrt{(u_{cal})^2 + (u_T)^2}$$

Since there are a total of seven stages of dilution, thus Eq. (13) can be re-written as:

$$(u_{dilution})^2 = \left\{ \left(\frac{u_{microsyringe}}{V_{microsyringe}}\right)^2 + \left(\frac{u_{pipette}}{V_{pipette}}\right)^2 + \left(\frac{u_{vial}}{V_{vial}}\right)^2 \right\}_1 + \left\{ \left(\frac{u_{microsyringe}}{V_{microsyringe}}\right)^2 + \left(\frac{u_{pipette}}{V_{pipette}}\right)^2 + \left(\frac{u_{vial}}{V_{vial}}\right)^2 \right\}_2 + \left\{ \left(\frac{u_{microsyringe}}{V_{microsyringe}}\right)^2 + \left(\frac{u_{pipette}}{V_{pipette}}\right)^2 + \left(\frac{u_{vial}}{V_{vial}}\right)^2 \right\}_3 + \left\{ \left(\frac{u_{microsyringe}}{V_{microsyringe}}\right)^2 + \left(\frac{u_{pipette}}{V_{pipette}}\right)^2 + \left(\frac{u_{vial}}{V_{vial}}\right)^2 \right\}_4 + \left\{ \left(\frac{u_{microsyringe}}{V_{microsyringe}}\right)^2 + \left(\frac{u_{pipette}}{V_{pipette}}\right)^2 + \left(\frac{u_{vial}}{V_{vial}}\right)^2 \right\}_5 + \left\{ \left(\frac{u_{microsyringe}}{V_{microsyringe}}\right)^2 + \left(\frac{u_{pipette}}{V_{pipette}}\right)^2 + \left(\frac{u_{vial}}{V_{vial}}\right)^2 \right\}_6 + \left\{ \left(\frac{u_{microsyringe}}{V_{microsyringe}}\right)^2 + \left(\frac{u_{pipette}}{V_{pipette}}\right)^2 + \left(\frac{u_{vial}}{V_{vial}}\right)^2 \right\}_7 \quad (13a)$$

The purity of the solvent, dichloromethane, used is ≥99.9% as per the manufacturer's specification that means the purity lies between 99.9 and 100%. And whenever a range is specified like a ± Δa, then, the uncertainty can be expressed as $\Delta a = \frac{max - min}{2}$. Thus, here the maximum purity can be 100% while minimum purity is assigned as 99.9%. Since there is no other information about the sources of uncertainties, rectangular distribution is applied.

$$\Delta a = \frac{100 - 99.2}{2} = 0.05$$

$$u_{purity} = \frac{0.05}{\sqrt{3}} = 0.03 \quad (14)$$

For uncertainty in CRM, a single compound, i.e., BaP, has been considered for calculation purpose. The uncertainty associated with BaP is ±59 μg/mL at coverage factor of 2 (CRM 47543 calibration certificate) for CRM having concentration of 2000 μg/mL.

$$u_{CRM} = \frac{59}{2} = 29.5\ \mu g/mL \quad (15)$$

$\left(\frac{u_{std}}{C_{std}}\right)$ is calculated by using Eqs. (13a), (14), and (15) in Eq. (12).

Uncertainty Derived from Linear Regression Fitting of the Calibration Curve The uncertainty derived from linear least square fit of calibration curve can be calculated as follows:

$$\left(\frac{u_{Cx}}{C_x}\right)^2 = \left(\frac{u_{y\ value}}{mean\ value\ of\ y}\right)^2 + \left(\frac{u_{slope}}{slope\ value}\right)^2 + \left(\frac{u_{intercept}}{intercept\ value}\right)^2 \quad (16)$$

where $u_{y\ value}$ is the uncertainty of linear regression curve and u_{slope} and $u_{intercept}$ are the uncertainty obtained for slope and intercept of calibration curve. Thus, the relative standard uncertainty from linear regression fitting of the calibration curve can be obtained using Eq. (16).

Determining Combined Uncertainty

The main sources of uncertainty in determining the concentration of particulate bound PAHs is calibration curve which is used to determine the concentration of the analyte, final volume of the sample, and volume of the air sampled. The combined uncertainty is calculated by combining the uncertainties from individual components using the following equation:

$$\frac{u_{combined}}{C} = \sqrt{\left(\frac{u_{cal}}{C}\right)^2 + \left(\frac{u_{volume\ of\ the\ sample}}{V_s}\right)^2 + \left(\frac{u_{volume\ of\ the\ air}}{V_{air}}\right)^2} \quad (17)$$

Equation (17) can be re-written as:

$$u_{combined} = C \times \sqrt{\left(\frac{u_{cal}}{C}\right)^2 + \left(\frac{u_{volume\ of\ the\ sample}}{V_s}\right)^2 + \left(\frac{u_{volume\ of\ the\ air}}{V_{air}}\right)^2}$$

where u_{cal} is the uncertainty from calibration (μg), C is the amount of analyte (ng/m^3), $u_{volume\ of\ the\ sample}$ is the uncertainty in final volume of the sample (μL), V_s is the final volume of sample (μL), $u_{volume\ of\ the\ air}$ is the uncertainty in air volume sampled (m^3), and V_{air} is the total air volume sampled (m^3).

The amount of analyte, C (ng/m^3), can be estimated using Eq. (6).

Determining Expanded Uncertainty

And expanded uncertainty at 95% confidence interval can be given by $U_{exp} = 2 \times u_{combined}\ ng/m^3$.

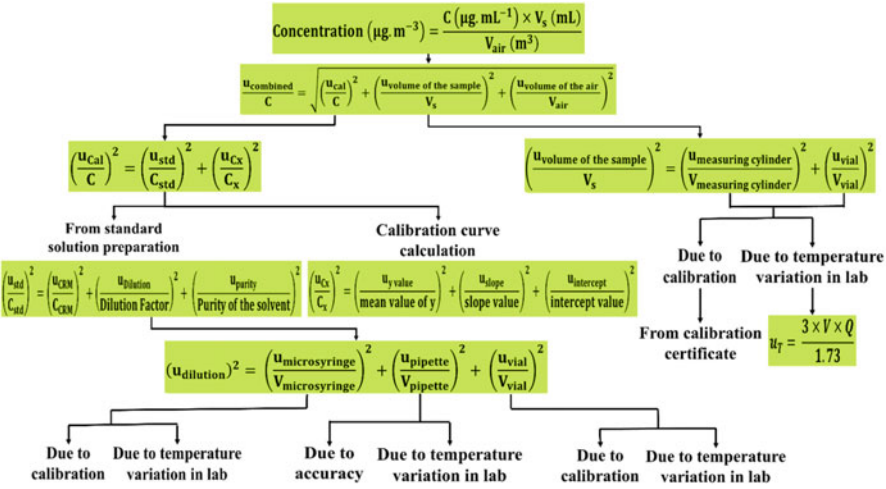

Fig. 14 Flowchart depicting the calculations involved in uncertainty estimation in analytical measurement

Reporting Result

The uncertainty in concentration of Benzo(a)pyrene in sample may be expressed as follows:

Reported Uncertainty $= (C \pm U_{exp})\ ng/m^3$.

Finally, the calibration curve, volume of the sample, and volume of the air sampled are identified as the sources of uncertainty in determination of particle bound PAHs in aerosol sample.

The above process of calculation of uncertainty at each stage is summarized as a flowchart in Fig. 14.

Conclusion

Accurate and reliable measurements form the basis of growth and development among various sectors of the country. Particularly, the fields of environmental protection, healthcare, and medical facilities along with food and nutrition require quantitative analyses. Metrological traceability and measurement uncertainty are becoming the latest buzzwords in the arena of measurement science to attain quality data. Both are required to remove the biases of measurements made in different time and space. The idea of traceability is well-rooted in the field of physical measurements; however, in chemical/biological/environmental measurements, it still needs propagation. Since, the qualitative and quantitative estimation in environmental measurements form the basis of environmental legislations, the uncertainty estimation of the measurement results become imperative. The uncertainty estimation in analytical environmental measurements requires traceability of the measurements

through documented references and unbroken chain of comparisons. However, the field of analytical environmental measurements is quite vast as it contains a variety of matrices which make sampling and sample handling completely different for different measurements. Thus, there cannot be a single standard operating procedure that could apply in all cases. Consequently, estimation of uncertainty becomes a challenging process in the field of environmental measurements.

An example of determination of mass concentration and particle-bound PAHs (BaP) in $PM_{2.5}$ with the calculation of uncertainties associated at each step has been discussed. The uncertainty measurements of mass concentration have two major variables, i.e., uncertainty in mass measurements of the filter (sampling substrate) and uncertainty in volume of air sampled. Uncertainty in mass measurements originates from calibration of the analytical balance and repeatability of the measurements, while uncertainty in volume measurement depends on calibration of instrument flow meter. At present, the manual air monitoring instruments generally do not have calibrated cut-off diameter of the impactor/sampler.

In the case of analytical determination of environmental measurements, the calibration curve, final volume of the sample maintained after extraction, and volume of the air sampled are key contributors in uncertainty in determination of particle bound PAHs (BaP) in aerosol samples. The identified missing link in the present study is the determination of uncertainty due to cut-off diameter of the instrument used for sampling of the particulate matter. Additionally, sample recovery during the extraction procedures are not considered for the uncertainty calculations.

Thus, in analytical environmental measurements, accurate determination of amount of an analyte is very challenging and difficult to be achieved practically. For this purpose, the missing links in the analytical environmental measurements are needed to be addressed. Still there exists a need of investigation regarding the references being used in the field of environmental studies so that accurate measurements could be achieved without any compromises. This will ensure the traceability of the measurement results to the references and accurate determination of the environmental contaminants.

Abstract

For the better understanding of potential environmental and human health impacts of airborne particulate matter (PM), the accurate and precise measurement of ambient PM is prerequisite. Various methods and instruments are available, ranging from filter-based sample collection for off-line laboratory analysis to on-line instruments that detect the airborne particles and give information of

size distribution, particle mass concentration, and chemical data in real time. Different measurement strategies, sampling devices, and instruments based on different principles are used depending on the scientific objectives of the study. The improvements in time resolution achieved by the continuous methods have proven to be useful in monitoring of PM concentration, characterizing ambient PM, and are becoming essential in allowing decision-makers to make policies and scientists to investigate sources of particulate pollution and to probe into the dynamics and mechanisms of aerosol formation in the atmosphere. It is important for the researchers working in air quality field to have a detailed understanding of the principle and limitations associated with different PM measurement techniques. In this view, here this chapter provides overview of the measurement principle of techniques available and used worldwide for PM measurement.

Particulate matter · Aerosol measurement techniques · Manual method · Automated method · Chemical characterization

Introduction

Airborne particulate matter severely effects human health, and its control is still a challenging task. Many countries have categorized particulate matter (PM) as criteria pollutant under their National Ambient Air Quality Standards (NAAQS). Federal Reference Method (FRM) based on gravimetric measurement and Federal Equivalent Method (FEM) based on the beta attenuation and tapered element oscillating microbalance method for PM measurement are included in NAAQS of different countries (e.g., EN 12341 2014; US EPA 2017; Aggarwal et al. 2013). Apart from these, there are other measurement methods available based on optical property, electrical mobility, time-of-flight of particle, and many more. Therefore, it is important for the researchers making aerosol measurement to be able to access the details regarding measurement technique, size range, precision, accuracy, and appropriate application of each instrument available in the market to have a more refined choice of instrument according to the requirement of study.

Different techniques use different principle to determine particle size leading to difference in size reported for the same particle. The particle aerodynamic size obtained with impactors and aerodynamic particle sizers depend on particle shape and density while the electrical mobility size determined by electrostatic classification depends on particle shape and size. Optical sizes obtained by the amount of light scattered by individual particles depend on particle refractive index and shape. Also, converting sizes from one measurement technique to another is essential in utilizing aerosol measurements but it involves significant errors. Therefore, it is important to understand the available techniques used to measure sizes, PM concentration, and properties of aerosols including shape, density, and refractive index. The objective of this chapter is to provide readers with an up-to-date overview of the available PM

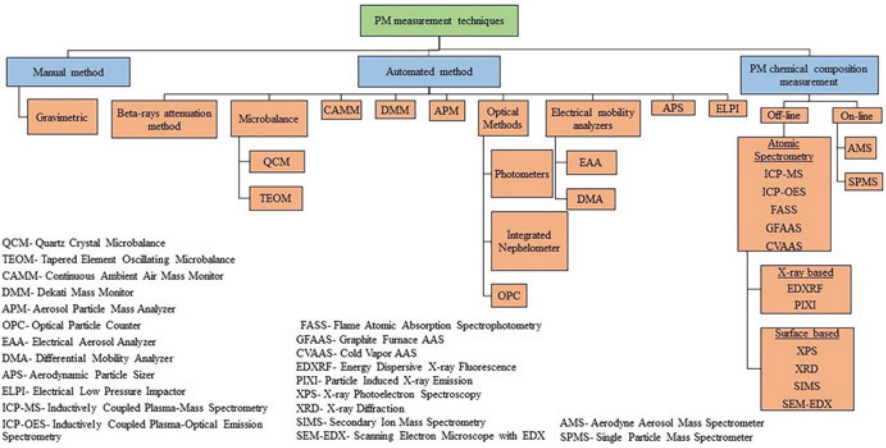

Fig. 1 Techniques and instruments for PM measurement

measuring techniques, substantiated with a technical discussion about the principle of measurement, features, and limitations intrinsic of each technique. Choosing the appropriate instrument for a particular application is of critical importance, and it is a function of a number of associated parameters such as the particle properties being studied, sampling and measurement time, access to available facilities, and the costs associated to equipment acquisition. Figure 1 classifies particle measuring instruments into manual method, automated methods, and methods for PM chemical composition measurement.

Manual PM Measurement Method

Gravimetric method, also known as manual method for the sampling of PM involves drawing of ambient air through filter material using a pump with subsequent quantification of particle mass with weighing balance. This method is considered as a primary or reference method and reliable in measurement as it is traceable to SI unit (Aggarwal et al. 2013). This manual method is used to measure the particulate matter concentration worldwide. The process involves weighing a blank filter on a laboratory balance, drawing ambient air through it at known flow rate and duration, re-weighing the filter, then the blank filter weight is subtracted, and the weight gain is divided by the sample volume to determine the PM concentrations over the sample period. The basic components of manual sampling system include a size-selective inlet, filter substrate, filter holder, pump, and flow controller (Chow 1995). The size-selective inlet defines the sampled size fraction of $PM_{2.5}$ and PM_{10} (particles with aerodynamic diameters $\leq$2.5 and $\leq$10 μm). They are designed to deliver all particles smaller than a specified diameter with 50% collection efficiency (i.e., D_{50}). Size-selective inlets use inertial, diffusion, or centrifugal classification. The most commonly used classifiers for selective $PM_{2.5}$ collections are Very Sharp Cut Cyclone

(VSCC) (Kenny et al. 2004) and Well Impactor Ninety-Six (WINS) (Peters et al. 2001).

Inertial Impaction

Inertial separators are widely used for the collection of fine and coarse particles. The general principle of inertial separation is that the particulate-laden air is forced to change the direction because of the obstacle. As the air changes direction, the inertia of the particles causes them to continue in the original direction and be separated from the air stream (Fig. 2). Impaction devices accelerate the aerosol through circular jet or slit toward an impaction substrate. Adhesion of particles is caused by the electrostatic attraction and molecular surface phenomena known as the van der Waals forces. The impactor separates the sampled particulate mass into the particles larger than the cutoff size (collected on the impaction plate) and the particles smaller than cutoff size (collected on the filter). The collection surface in many impaction devices is coated with a thin film of oil or light grease to increase particle retention or overcome the re-bouncing issue. The probability that a particle will diverge from the air streamlines can be expressed as a function of the Stokes number (Stk) defined by:

$$\mathrm{Stk} = \frac{\rho_\mathrm{p} C_\mathrm{c} D_\mathrm{p}^2 U}{9\eta d_\mathrm{n}} \tag{1}$$

where ρ_p and D_p are the particle density and diameter, U and η are the relative velocity and dynamic viscosity of the carrier air respectively, d_n is the nozzle diameter, and C_c is the slip correction factor. The higher the Stokes number, the more efficient the inertial transport is and the more likely particles will deposit by inertial impaction.

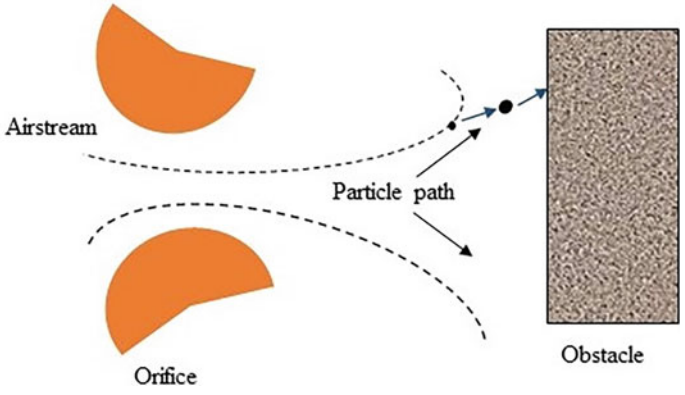

Fig. 2 Particle collection by impaction

The following section discusses various impactor-based devices:

Cascade Impactor

It is a multi-stage impactor containing stages with many, defined evenly spaced nozzles of different sizes in each stage. Impactors (stages) are arranged in the order of decreasing cutoff size by reducing the size of nozzle with the largest cutoff size first (Fig. 3). Filter at each stage can be removed for gravimetric and chemical measurement of the collected particles. This gives distribution of total mass fraction in each aerodynamic size range. In cascade impactors, particles are lost in the first two stages primarily due to inertial removal at bends in the flow path. These inter-stage losses can be reduced by modifying impactor in a way to minimize sharp bends in the inter-stage flow path of the initial stages by operating at a lower flow rate. Another problem with impactor is the re-entrainment, i.e., buildup of particle deposit

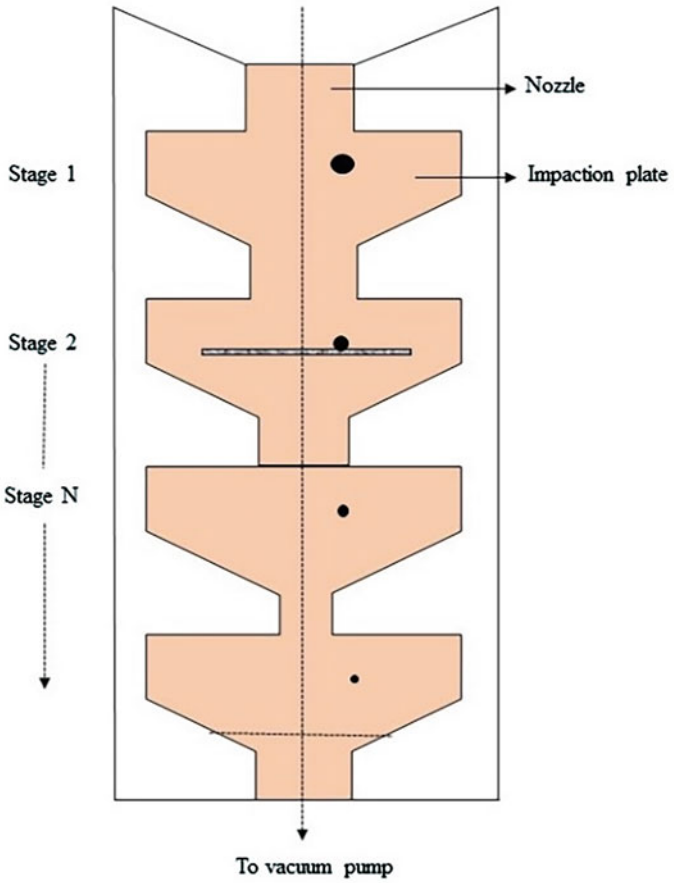

Fig. 3 Schematic of cascade impactor

which changes the flow geometry and the cutoff size. Andersen sampler is an eight-stage cascade impactor, which is used to measure the different particle size concentration ranging from the 0.4 μ m to 9.0 μ m. The stages of Andersen sampler are numbered 0 to 7, with different size range orifice divisions according to the particle aerodynamic diameter as stage 0 (>9.0 μm), stage 1 (5.8–9.0 μm), stage 2 (4.7–5.8 μm), stage 3 (3.3–4.7 μm), stage 4 (2.1–3.3 μm), stage 5 (1.1–2.1 μm), stage 6 (0.7–1.1 μm), stage 7(0.4–0.7 μm), and backup stage (<0.4 μm). Every stage of the impactor contains a series of nozzles through which the air is drawn, directing the particles toward the surface of the collection plate for that particular stage. Particles having enough inertia will impact on that particular stage collection plate, while smaller particles will remain entrained in the air stream and pass to the next stage. The stages are assembled in a stack or row in the order of declining particle size. The sampling flow rate of the sampler is 28.3 lpm. Another group of cascade impactors uses micro-orifice nozzles for jet acceleration, commonly known as Micro Orifice Uniform Deposit Impactor (MOUDI). This sampler is equipped with combinations of impactor stages, covering wide range of particle sizes and collecting particles smaller than 0.056 μm. It reduces particle bounce by rotating the impaction plate relative to the nozzles, thus resulting in uniform deposit and prevents heavy build-up of particles under the nozzles (Maenhaut et al. 1993).

Virtual Impactor

The problem of bounce, overloading, and non-uniform particle deposition can be overcome by virtual impactors. Here, instead of the larger particles impacting onto a solid impaction plate, they impact into a collection probe and are later collected on a filter downstream (Fig. 4). Large particles impact through a virtual surface and smaller particles are carried radially away from the jet axis by the major air flow and are collected on filter downstream. Most of the flow reverses in the collection probe carrying with it the particles that are smaller than the cutoff size. In virtual impactor, particles larger than cutoff size and those smaller than the cutoff size are collected on separate filters. Virtual impactors, beside an inertial classifier, can also be considered a particle concentrator for particles larger than cutoff size and this is useful when sampling particles that are of low concentration or sampling particles into an instrument that requires greater concentrations (Bergman et al. 2005; Keskinen et al. 1987; Liebhaber et al. 1991; Romay et al. 2002; Wu et al. 1989). Virtual impactors usually have only one or two stages due to complexity of controlling two flows for each stage. The first device to incorporate a virtual impactor was described by Conner (1966).

Cyclone

Cyclone is designed such that air drawn through it moves in either a circular or a helical path of decreasing radius, thereby increasing its collection efficiency for small particles. Cyclones are cone-shaped devices in which the sampled aerosol enters tangentially, rotates several times about the axis, and exits vertically through

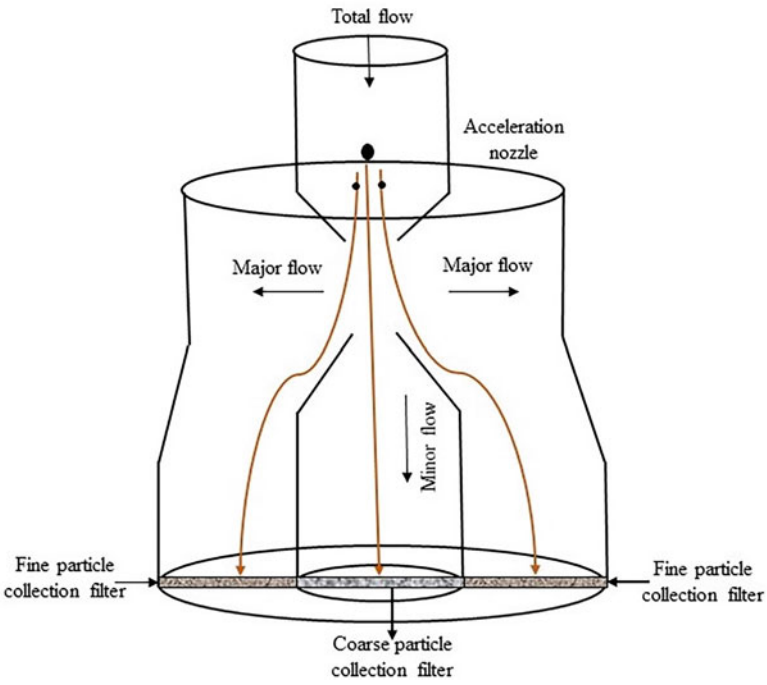

Fig. 4 Flow schematic of co-cylindrical virtual impactor

an opening located on the axis at the top. As the air stream surges through the cyclone, particles adhered to the cyclone's wall as the velocity approaches zero due to the centrifugal force. In most cyclone samplers, liquid particles adhere to the wall, while solid particles settle into a dust collection cavity (cup). The collection efficiency of a cyclone sampler is dependent on flow rate. VSCC $PM_{2.5}$ fractionator is a centrifugal separation device used to collect $PM_{2.5}$. In VSCC, there is no need for the application of oil as required in WINS impactor.

Diffusion

Diffusion technique is useful in the collection and size distribution of nanoparticles. Small particles do not settle down through sedimentation or impaction process, while due to Brownian diffusion, they coagulate easily. Diffusion samplers separate particles by differential diffusion mobilities. There are two types of diffusion samplers used in air sampling, a diffusion battery to measure the size distribution of sub-micrometer particles and a diffusion denuder to separate and collect gases or vapors from airborne particles. The rate of deposition of particles onto a unit area of surface is determined by applying Fick's first and second law:

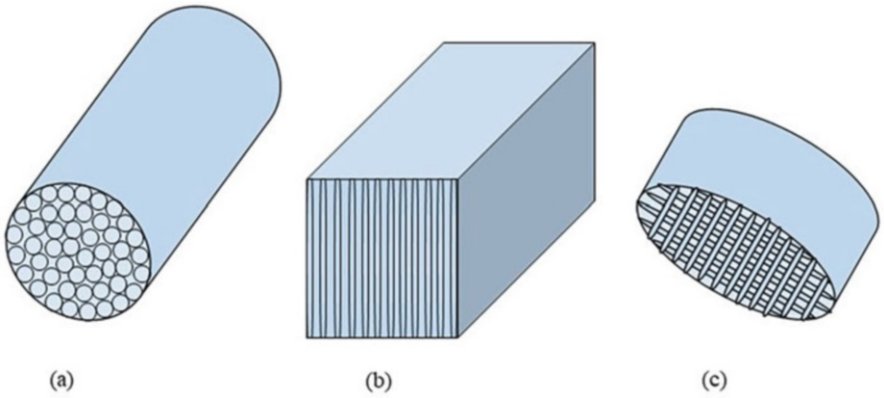

Fig. 5 Diffusion batteries: (**a**) tube bundle, (**b**) parallel plate, (**c**) screen batteries

$$J = n\frac{\sqrt{D}}{\pi t} \tag{2}$$

where J is the deposition flux, n is the initial number density, D is the diffusion coefficient, and t is the time. Equation (2) can be integrated to determine the concentration at each moment of time. Diffusion batteries remove small particles from a laminar-flow of aerosol. It is applicable to particle sizes from 0.002 to 0.2 μm. Several types of diffusion batteries have been designed including tube bundle, parallel plate, and screen batteries (Fig. 5).

Automated PM Measurement Methods

Manual method which is a filter-based sampling of particulate matter is more accurate and precise for the detailed study of the airborne particles (chemical analysis) during intensive experiments, but when used in routine monitoring, it has drawbacks associated with it. They do not provide information in real time. There is time lag between the sample collection and data availability which make it impossible for regulatory agencies to monitor peak concentration events. This time lag, long sampling time, and chances of sample contamination can be avoided by the use of real-time continuous instruments for PM measurement. Real-time instruments relatively need less attention; time resolution is in the order of minutes and can also be used for the study of PM in the areas where the concentration is generally low such as the North Pole. Available automated techniques and their principle of PM measurement are discussed in the following section.

Beta-Rays Attenuation Method

Beta gauge monitors based on beta-rays attenuation method are used to measure the concentration of PM (PM_{10} or $PM_{2.5}$) in ambient air. It is included in NAAQS. A schematic of beta gauge monitor is shown in Fig. 6. It consists of a size-selective PM_{10} inlet, a $PM_{2.5}$ classifier (VSCC), a movable filter tape for sample collection, a beta particle source, and a detector. It determines the mass concentration of collected PM by measuring the attenuation of beta particles when transmitting through the filter before and after sample collection. Continuous measurement is achieved by the automatic advancement of filter tape after specific time (1–6 hours). The relationship between the beta counts and sample mass was initially proposed in Jaklevic et al. (1981).

$$I = I_{0\ e^{-\mu x}} \tag{3}$$

where I and I_0 are the attenuated and un-attenuated beta counts, respectively, through mass density x (mg cm^{-2}) of collected sample and μ (cm^2 mg^{-1}) is the mass

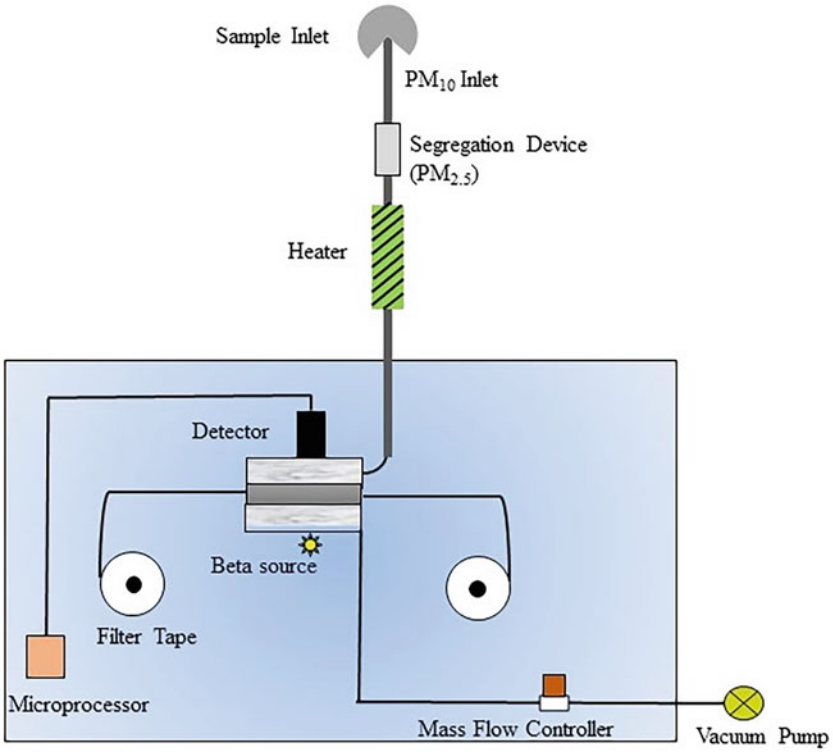

Fig. 6 Schematic of beta gauge monitor

absorption coefficient for beta particle absorption. The ambient concentration C (μg m^{-3}) of PM can be calculated as:

$$C = \frac{A \ln \frac{I_0}{I}}{\mu Q t} \times 10^6 \quad (4)$$

where A (cm^2) is the surface area of sample deposited, Q (L min^{-1}) is the sampling flow rate, and t is the time in minutes.

The choice of beta particle sources depends on the energy spectrum and half-life of radioisotope source. Beta particle sources which have been incorporated in beta gauge units in the past include ^{63}Ni ($t_{1/2} = 85$ y, $E_{max} = 67$ ke V), ^{14}C ($t_{1/2} = 5730$ y, $E_{max} = 156$ ke V), ^{147}Pm ($t_{1/2} = 2.62$ y, $E_{max} = 225$ ke V), and ^{85}Kr ($t_{1/2} = 10.76$ y, $E_{max} = 720$ ke V) (Wedding and Weigand 1993). However, current beta gauge monitors are usually equipped with ^{14}C source (Jaklevic et al. 1981). Detector should be sensitive to the beta particles, various detectors which have been used in the past include solid-state semiconductor, silicon surface barrier, ion-implanted silicon semiconductor, Geiger counter, and photomultiplier tube with scintillation device. Literature showed differences in PM concentration measured by gravimetric and beta gauge method (Arends et al. 2000; Chang et al. 2001). The major influence on measurement biases is due to high relative humidity. The inorganic hygroscopic particles which get collected on the filter absorb water as relative humidity rises above the deliquescence RH which result in growth in the size of particles, thus causing high concentration measurements by beta gauge monitors (Bagtasa et al. 2007; Chang et al. 2001; Khlystov et al. 2005; Salminen and Karlsson 2003; Shin et al. 2011; Tsai et al. 2006). Negative sampling artifact such as evaporation losses of semi-volatile species, such as NH_4Cl, NH_4NO_3, and organics (VOC) during sampling process, also contribute to the measurement difference between the methods (Le et al. 2020a; Liu et al. 2014). Biases in beta gauge measurement are also reported to vary with high particle mass loading and other ambient conditions such as low boundary layer height and ventilation coefficient along with high RH (Shukla and Aggarwal 2021). To overcome the effect of high RH, beta gauge monitors were modified to include an inlet heater to limit the relative humidity below 35%. Various correction approaches are applied to beta gauge measurements in order to obtain reference equivalent data from automated beta gauge monitors (Gehrig et al. 2005; Le et al. 2020b; Shukla and Aggarwal 2021).

Microbalance Methods

Quartz Crystal Microbalance (QCM)

The quartz crystal microbalance (QCM) is a well-established method for measuring mass (Mecea 2006), and it is commonly used to determine airborne PM mass concentration (Chen et al. 2016; Sarangi et al. 2016). It can measure nanogram to microgram level changes in mass per unit area. QCM uses piezoelectric crystal which undergoes mechanical deformations (vibration) when an electrical potential is

applied (Ward and Buttry 1990). Here, aerosol particles get deposited by inertial impaction or electrostatic precipitation onto the surface of an oscillating piezoelectric quartz crystal disk. Crystals have a resonant vibrational frequency that depends on the material thickness, and this frequency gets changed as the particle mass get deposited on vibrating surface. Then the change in sampling crystal frequency is electronically compared with that of a clean reference crystal, generating a signal that is proportional to the collected mass. Figure 7 shows the schematic of QCM. Frequency change (Δf) of oscillating quartz can be linearly related to its mass change (Δm) (Sauerbrey 1959).

$$\Delta f = -C_{\mathrm{f}} \times \Delta m \times A \tag{5}$$

where Δf is the change in the resonance frequency (Hz), Δm is the change in mass (μg), C_{f} is the sensitivity factor of the crystal (56.6 Hz ug^{-1} cm^2 for a 5 MHz AT-cut quartz crystal (cut made from y axis at 35° theta rotation) at room temperature), and A is the piezoelectrically active area (the area between the electrodes, cm^2).

Sensitivity of quartz crystal is around hundred hertz per microgram and measures mass concentration of about 10 μg m^{-3} in less than 1 min (Olin and Sem 1971). Collection efficiency can be increased by coating grease on the collection electrode to improve adhesion of particles to the quartz surface. This technique has some drawbacks, such as a low resonance frequency under high mass loading, sensitivity

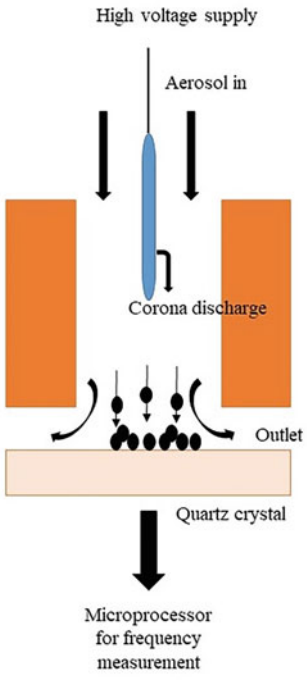

Fig. 7 Schematic of quartz crystal microbalance

to temperature and relative humidity, and a high frequency of the electrode surface, which disproves the relationship between frequency variation and mass estimation. The deposition surface needs to be cleaned and re-greased between each measurement to avoid particle bouncing (Tzou 1999). Some modifications can be incorporated in this instrument for more accurate and precise high concentration measurement such as lowering dead volume in the sensing chambers to reduce internal losses, improve response time, and include isokinetic sampling inlet.

Tapered Element Oscillating Microbalance (TEOM)

Tapered Element Oscillating Microbalance (TEOM) system is widely used to measure particle mass concentration in air quality networks. A schematic of TEOM is shown in Fig. 8. It draws ambient air through filter at a constant flow rate, continuously weighing the filter and calculating the mass concentration. The particles are

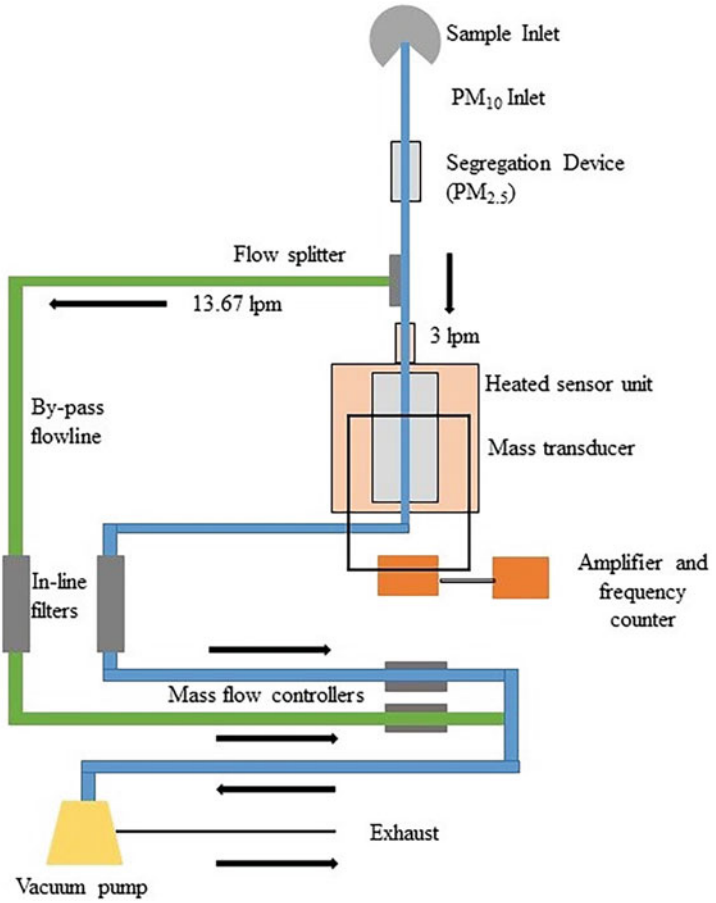

Fig. 8 Schematic of tapered element oscillating microbalance

collected on a replaceable filter, incorporated in a microbalance that is free to oscillate. Air is drawn through a size-selective inlet at the rate of 16.67 lpm. The sampled air is split into two channels, one with major flow (e.g., 13.67 lpm) which is discarded and the remaining with minor flow (e.g., 3 lpm) which is directed down a tube onto a sample filter resting on the end of a hollow tapered tube with the wider end of the tube being fixed. The air then passes through the filter with particles getting deposited on the filter and the filtered air then passes through the tapered tube to a flow controller. The tapered tube with the filter on its end is maintained in a fixed amplitude oscillating motion. The oscillation frequency of the tapered tube changes as the particles deposit on the filter and it depends upon physical characteristics of the tapered tube and the mass collected on its free end.

The resonant frequency of TEOM can be related to the mass of the sampled air by the equation of motion for simple harmonic oscillator:

$$\Delta m = K_{\mathrm{O}} \left(\frac{1}{f_{\mathrm{b}}^2} - \frac{1}{f_{\mathrm{a}}^2} \right) \tag{6}$$

where Δm is the mass of the sample deposit, f_{b} is the frequency of the oscillating element after sample deposit, f_{a} is the frequency before sample deposit, and K_{o} is a constant (spring constant) unique to each tapered element.

There are biases associated with the measurement of PM with TEOM which lead to discrepancy in data collected. The major problem associated with TEOM is the possibility of volatilization of collected material when heating the sample to 50 °C. This results PM concentration measured by the TEOM to be lower than measurements by the federal reference method due to loss of particle-bound semi-volatile compounds (Rizzo et al. 2003; Tortajada-Genaro and Borrás 2011; Zhu et al. 2007). Therefore, TEOM must be kept at a constant temperature to minimize thermal expansion. To overcome this issue, various modifications are incorporated in TEOM. Some modified versions are Real-Time Ambient Mass Sampler (RAMS) which eliminates gas-phase compounds to avoid losses of semi-volatile material (Eatough et al. 2001); Sample Equilibration System Tapered-Element Oscillating Microbalance (TEOM-SES) operates at a reduced temperature of 30 °C, and to avoid condensation of humidity, a diffusion dryer precedes the TEOM; differential TEOM which works with electrostatic precipitator to remove positive and negative filter artifacts (Jaques et al. 2004) and TEOM equipped with a Filter Dynamics Measurement System (TEOM FDMS) include a diffusion dryer and cold filter maintained at 4 °C to remove particles prior to passage to the TEOM.

Continuous Ambient Air Mass Monitor (CAMM)

Change in pressure drop across the filter due to particle deposit can be used to measure PM. The CAMM measures ambient PM by pressure drop difference between a reference airstream channel and particulate matter airstream channel. It

includes an impactor with a cut size of 2.5 μm, a diffusion dryer to remove particle-bound water, and a membrane filter tape which advances every hour. The detection limit of CAMM is ≈5 μg m^{-3} at a flow rate of 0.3 lpm and sampling time of 1 hour. The pressure drop across the filter depends on particle size. Chung et al. (2001) showed good correlation between the CAMM and reference sampler. Discrepancy of CAMM with semi-volatile material is reported by Lee et al. (2005).

Dekati Mass Monitor (DMM)

The Dekati Mass Monitor (DMM) is the on-line particle measurement instrument which is the combination of mobility analyzer and six-stage impactor. It consists of inlet with a separator of 1.3 μm cutoff, and particles get electrically charged in a corona charger, then pass through one-stage mobility analyzer where highly mobile small particles get precipitated to an electrode connected to an electrometer, and less mobile particles enter into six-stage electrical impactor with electrometer amplifier to determine the current of precipitated particles (Fig. 9). This instrument gives information about particle density and size distribution which are used to determine mass of particles. There are chances of error if the density is size dependent as mobility analysis is applied only to small particles and impaction to only large particles. Studies showed that DMM overestimate the mass (around 20–39%) in comparison to reference method (Lehmann et al. 2004; Mamakos et al. 2006).

Aerosol Particle Mass Analyzer (APM)

Measurement of aerosol particles in Aerosol Particle Mass Analyzer (APM) takes place according to particles mass-to-charge ratio (Ehara et al. 1996). Initially aerosol particles pass through a bipolar charger to achieve equal charge distribution and then enter into annular space between two coaxial rotating cylindrical electrodes having inner radius r_1 and outer radius r_2 (Fig. 10). The two electrodes rotate at same

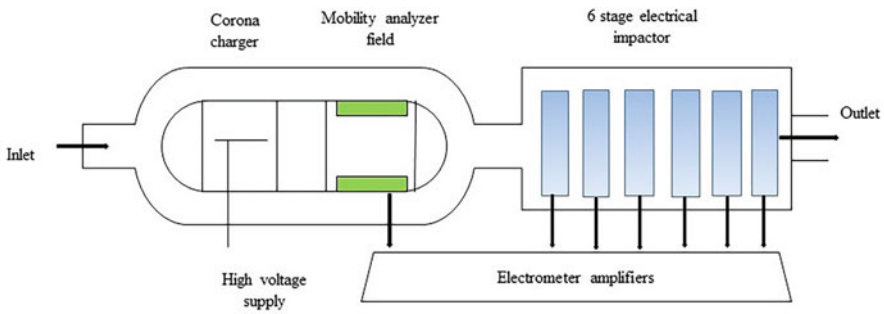

Fig. 9 Schematic of Dekati mass monitor

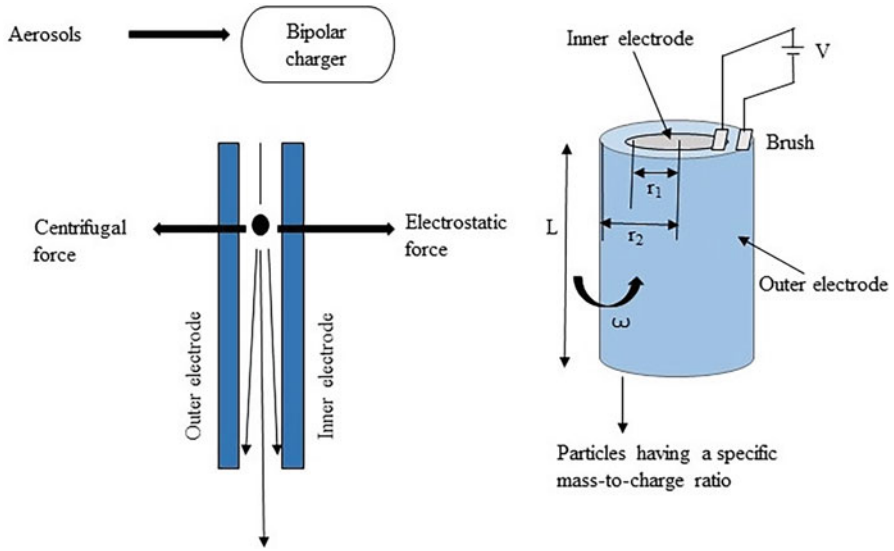

Fig. 10 Operating principle of aerosol particle mass analyzer

angular velocity ω, and q is the electrical charge of particles. The centroid mass, m_c, is derived from balance force as:

$$m_c = \frac{q\,V}{r_c^2\,\omega^2 \ln \frac{r_2}{r_1}} \tag{7}$$

where r_c is the center radius ($r_c = (r_1 + r_2)/2$) and V is the voltage applied. Two forces work on particle inside annular space, centrifugal and electrostatic force, and those particles for which these two balance each other, travel the entire length of electrode, and exit the annual space. The advantage of this instrument is its ability to measure particle mass without the need for particle collection for weighing.

Optical Methods

The optical property of aerosols and their interaction with light is also useful for measuring aerosol particle size and concentration. Optical methods are extremely sensitive and instantaneous with no requirement of particle collection on filter. Optical instruments, in real-time measurement of particle concentration, are based on principles of scattering, absorption, and light extinction. There are three instruments based on measurement of light scattered at fixed angles: photometers, integrated nephelometers, and optical particle counters. Light scattering instruments are sensitive to minute changes in scattering angle, particle size or shape, and refractive index of particles (Hinds 1999).

Photometers

Photometer measures PM concentration by measuring the intensity of light scattered from many particles in one or more angles reaching the detector. It measures the light scattered in the region of 90°, 45°, or less than 30°. This instrument is sensitive to aerosol composition and particle size distribution. To reduce the effect of particle size and refractive index on measurement by photometers, the precise choice of scattering angles and wavelengths are made. Some photometers studied include DataRam 4 (Costa et al. 2012), UCB-PATS (University of California Berkeley-Particle and Temperature Sensors) (Chowdhury et al. 2013), and DustTrak (Chowdhury et al. 2013; Prado et al. 2012). They showed good correlation with other instruments. UCB-PATS used smoke detector technology combining photoelectric and ionization sensors. It uses light-emitting diode (LED) and photodiode measuring light intensity scattered at an angle of 45°, and cyclone along with photoelectric sensor helps in measuring $PM_{2.5}$, whereas ionization sensor is more sensitive toward PM_1.

DustTrak sampler includes an impaction inlet, laser diode, optics, photodetector, vacuum pump, and electronic control panel. The continuous aerosol is drawn through the impaction inlet where particles with diameter greater than 10 μm, 1 μm, or 2.5 μm are removed depending on type of inlet. Then sample stream pass is intersected by light of 0.78 μm wavelength emitted from laser diode. The light scattered by particles is measured by the photodetector oriented at an angle of 90° to laser and sampler stream which is then converted to mass concentration by electronics. Proportionality constant used is determined by comparing DustTrak against gravimetric instrument with Arizona test dust.

Integrating Nephelometer

The integrating nephelometer measures particle concentration by the light scattered at several wavelengths in visible range. The light scattered at angles from 8 to 170° by particles was measured and used to determine particle scattering coefficient. This scattering coefficient is proportional to the mass of particulate matter and used to determine particle concentration. The nephelometer is used widely for the measurements of light scattering coefficient due to its high accuracy, portability, and moderate cost. Drawback associated with nephelometer are the biases in light scattering caused by different sizes and composition of particles, inlet loss of coarse particles, and inefficiency of optical measurement of light scattered in the near forward direction. Figure 11 shows schematic of nephelometer.

Optical Particle Counter (OPC)

Optical Particle Counter (OPC) measures the light scattered by each particle as the aerosol flow through a tightly focused beam of light. It uses laser diode as light source to excite sample of particle at a specific angle, and the light scattered by particles is collected by 90° lens and then is measured by photodetector as an electric pulse. Schematic of OPC is shown in Fig. 12. Particle size is determined from the magnitude of electric pulse by using a calibration curve obtained by measuring

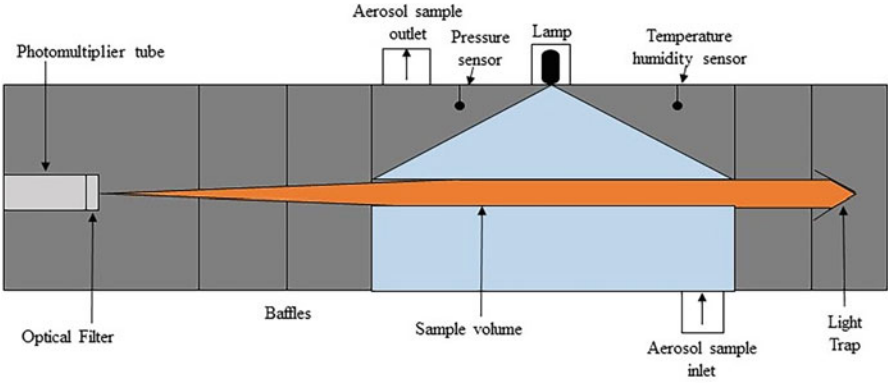

Fig. 11 Schematic of nephelometer

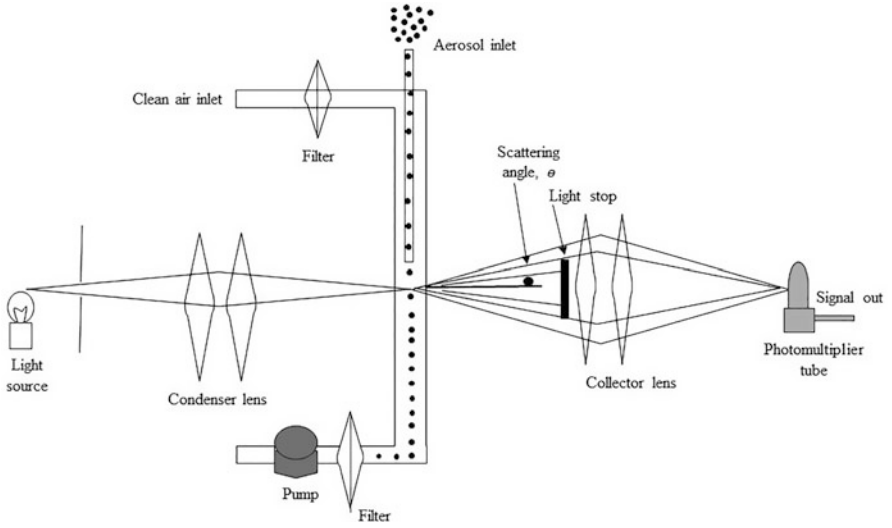

Fig. 12 Schematic of optical particle counter

known particle size and composition. Laser OPC are generally prefer than white light OPC as laser OPC have minimum detection limit of ~0.05 μm particle size and white light OPC cannot detect particle smaller than ~0.3 μm (Gebhart et al. 1976). Also, laser OPC have counting efficiency of 100% for particles greater than 0.1 μm. Its measurement depends on refractive index, shape, and morphology of particles. Varied particle chemical composition causes significant uncertainties in estimating refractive index. While measuring particle size distribution with OPC, it is necessary to dilute aerosol so that only one particle passes through the beam at a time for unbiased measurement.

Electrical Mobility Analyzers

Electrical mobility analyzers classify charged particles based on their mobility in an electric field. Generally, an electrical mobility analyzer consists of two oppositely charged plates parallel to each other having specific voltage with aerosol particles entering through the space between plates. Particles with mobility higher than specified voltage will get trapped to the plates, and particles with low mobility will pass through and get collected on filter (Fig. 13). The comparison of mass sampled in the absence of voltage on the plate to that for different voltages will give the particle distribution. Particles get classified based on their electrical mobility denoted by Z and for spherical particles based on Stokes drag, Z is given by (Hinds 1999):

$$Z = \frac{\mathrm{neC}}{3\pi\mu D_P} \tag{8}$$

where n is the number of charges carried by the particle, e is the magnitude of charge, C is the slip correction factor, μ is the viscosity of air, and D_p is the diameter of particle. This electrical mobility is based on Stokes drag, and if Reynolds number (Re) of particle is greater than 1, the true mobility will be greater. Mobility analyzer are able to measure much smaller particles and are not sensitive to differences in refractive index as optical technique but are sensitive to particle shape.

The following section includes commonly used electrical mobility analyzers for aerosol studies.

Electrical Aerosol Analyzer (EAA)

Electrical Aerosol Analyzer (EAA) is the first electrical mobility analyzer developed by Whitby and Clark (1966). In the EAA, aerosols flow at 5 lpm through a unipolar ion diffusion charger, where before entering into classifier, they get charged by small positive ions. The duration of particle stay in the charger and ion concentration are kept fixed to ensure the predictable charge number exposure to the specific size of particles. Particles having mobility greater than a cutoff mobility value (predetermined by flow rates and voltages) are precipitated in the concentric cylindrical classifier, while the particles with less mobility pass out of the analyzer and get collected on filter where the current produced by the capturing of charged particles is continuously monitored by an electrometer. The difference in current generated by the analyzer's two voltage settings is then related to the number of particles in the size range defined by the two voltage setting's set cutoff sizes. EAA measures size distribution in the 0.003–1 μm diameter range.

Differential Mobility Analyzer (DMA)

The differential mobility analyzer (DMA) is used as a monodisperse aerosol generator to produce sub-micrometer-sized aerosols for testing and calibration purpose and to measure particle size distribution in sub-micrometer size range. In DMA, aerosol first pass through bipolar ion diffusion charger, where it achieves Boltzmann charge equilibrium before entering into classifier. DMA consists of a cylinder and a

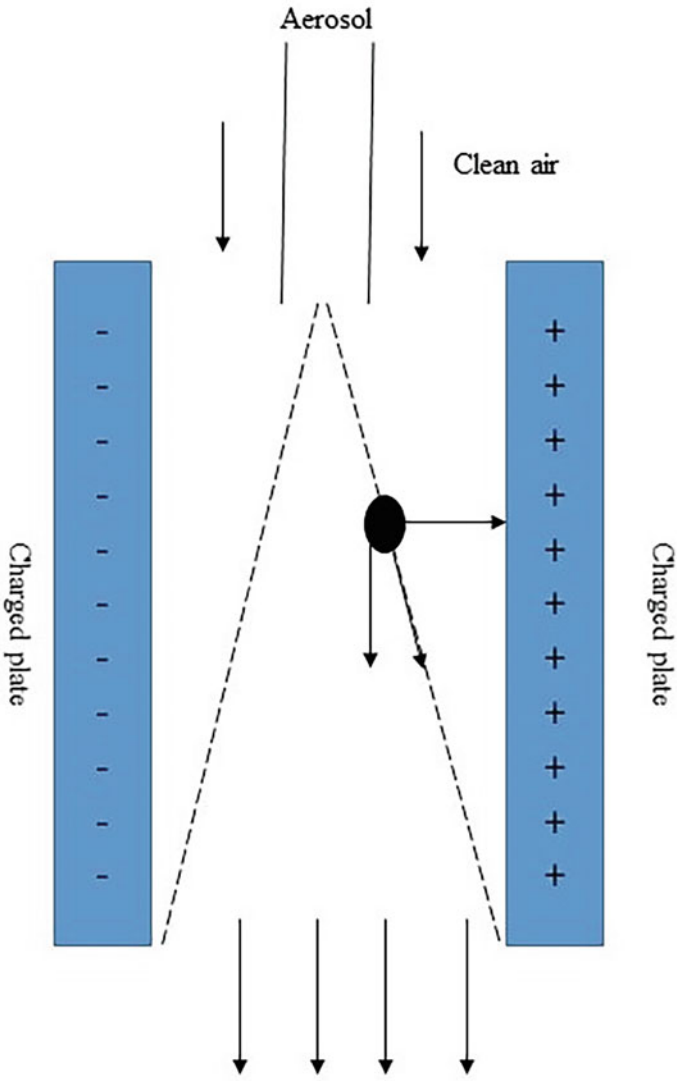

Fig. 13 Schematic of electrical mobility analyzer

charged central rod creating electric field in the space between the cylinder walls and the rod. Particle free clean air and particles through sample inlet move toward the central rod at a velocity determined by their electrical mobility. The particles then may exit through slit or through exhaust or get deposited on the central rod. The exiting aerosol are singly charged and nearly monodisperse whose size is controlled by adjusting the voltage on the central rod. Particles with narrow range of mobility get separated from the main flow by varied voltages and then delivered to detector or

counter for particle size and number concentration measurement. The complete particle size distribution can be determined by continuously scanning through voltage range. DMA measures size distribution in the 0.005 to 1.0 μm diameter range.

Aerodynamic Particle Sizer (APS)

Aerodynamic Particle Sizer (APS) determine particle size distribution ranging from 0.5 to 20 μm by measuring particle velocity relative to the air velocity within an accelerating airflow. It counts and sizes particle by an aerodynamic property time-of-flight (TOF) and an optical property (light scattering intensity). It is based on the principle of inertia. Aerosol accelerates through nozzle with particles lagging behind the carrier gas due to inertia (Wilson and Liu 1980). The difference between particle and gas speed tends to increase with increase in size and density of particles. APS operates at a flow rate of 5 lpm, with 4 lpm removed by passing through filter and re-introduced upstream of the acceleration nozzle as sheath flow and recombining remaining 1 lpm aerosol flow entering through nozzle. The combined aerosol and sheath flow accelerates through final outer nozzle and enters detector region (Fig. 14). The TOF of each particle is detected and converted to aerodynamic particle size using a pre-programmed calibration. Also, the scattered light intensity is measured by analyzing magnitude of pulses of scattered light from the laser. APS is widely used for the characterization of aerosols and evaluation of particle samplers due to its accurate and precise measurement of particle size and concentration. The gas velocity U_g in the nozzle can be determined from the Bernoulli equation of compressible flow:

$$U_g = \left\lfloor \frac{2RT}{M} \ln\left(\frac{P}{P-\Delta P}\right) \right\rfloor^{1/2} \tag{9}$$

where R is the universal gas constant, T is the absolute temperature, M is the gas molecular weight, P is the ambient pressure, and ΔP is the pressure drop across the nozzle. The velocity of particle V_p can be determined from:

$$V_P = \frac{U_g t_{min}}{t} \tag{10}$$

where t_{min} is the minimum transit time or time-of-flight (TOF) for particles and t is the transit time of particles. TOF is the time interval between two pulses of light scattered by particles as they pass through two beams of light, and it is proportional to particle velocity and thus aerodynamic diameter. As the particle size increase, the TOF increases because particle lags behind the air velocity. A calibration curve between aerodynamic diameter and TOF data stored in an accumulator in bins is

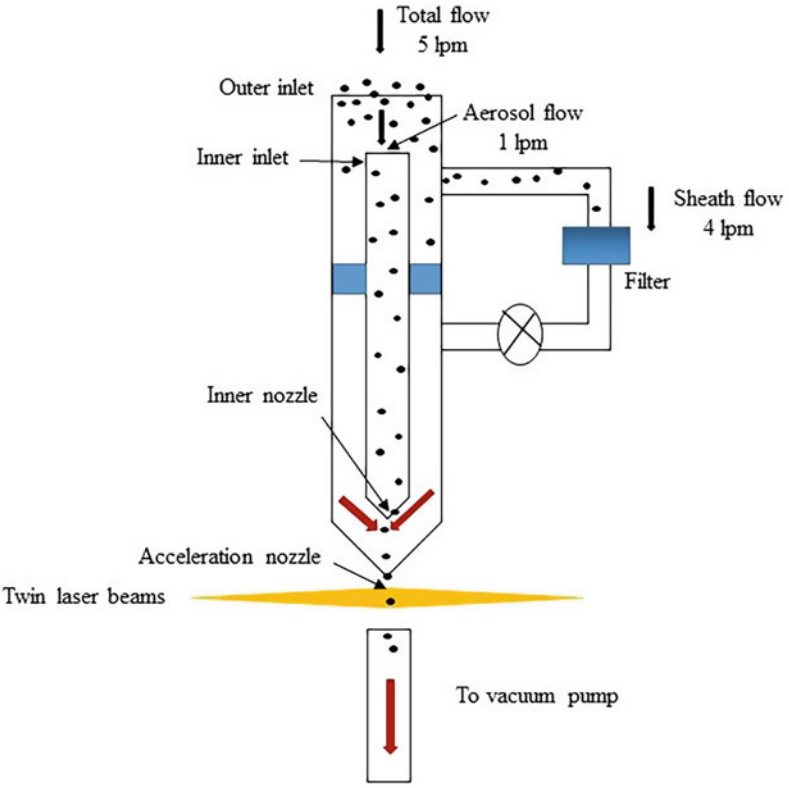

Fig. 14 Schematic of aerodynamic particle sizer

done for each instrument individually using monodisperse test particles with known density. This curve is based on the fact that for a given acceleration nozzle and light detection arrangement, the ratio of V_p/U_g as a function of Stokes number is unique. The counting efficiency η of the APS is the number of particles of a given size counted divided by the number sampled:

$$\eta = \frac{N_{\text{counted}}}{N_{\text{sampled}}} \tag{11}$$

Unlike optical counters, APS measurements are not compromised by Mie resonances. But if more than one particle is involved in the analysis of particle transit time, then APS give rise to coincidence effects resulting in phantom particle generation. It underestimates liquid droplets as they flatten and get greater velocities than spherical particles.

Electrical Low Pressure Impactor (ELPI)

Cascade impactors are widely used for PM measurements. Conventional impactors cover a size range from 0.3 to 10 μm. Impactor-based PM sampling requires long sampling duration to collect measurable particle mass on each stage and a sensitive microbalance. Therefore, to overcome limited number of sample collection in a day and to avoid errors associated with man-handling of filters during sampling and weighing, real-time automatic impactor-based Electrical Low Pressure Impactor (ELPI) were introduced (Keskinen et al. 1992). It determines particle size distributions by combining electrical detection of charged particles and the impactor collection technique. Its mass sensitivity for sub-micrometer range is better than QCM and comparable to EAA. Figure 15 depicts the operating principle and main components of ELPI. Briefly, ELPI generally consist of three components: a unipolar charger, a cascade impactor, and a multichannel electrometer. The aerosol is introduced into unipolar charger at flow rate of 10 lpm. The charged particles then pass through cascade impactor classifying the aerosol into 12 size fractions, and multichannel electrometer simultaneously measures the charge carried by the particles from each stage. The measured current signals are then converted to number concentration at different particle sizes. It also contains flush pump used to zero the electrometers by pumping clean air. ELPI measures size distribution in the range

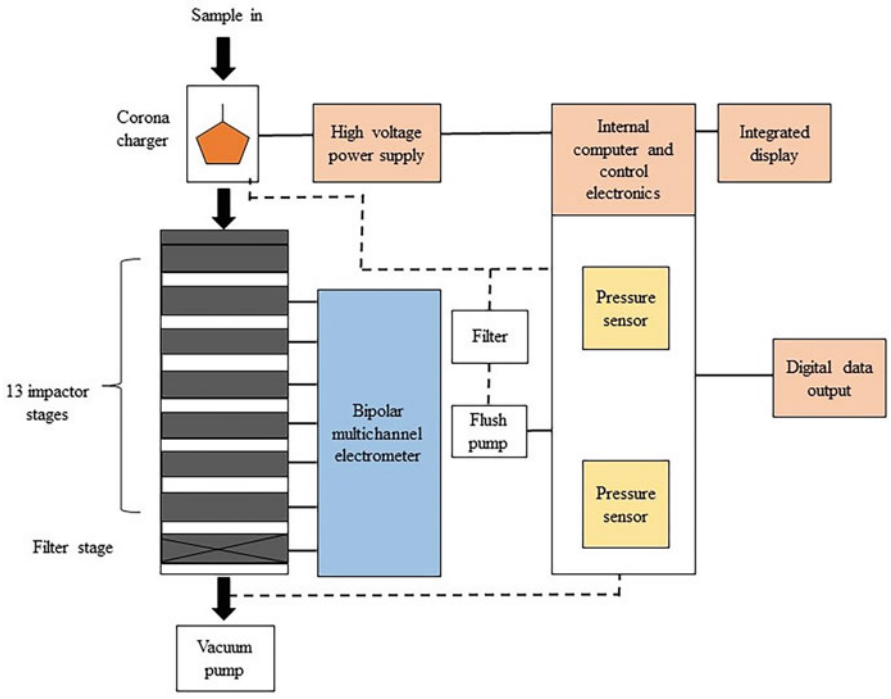

Fig. 15 Schematic of electrical low pressure impactor (ELPI+)

30 nm–10 μm. Dekati Ltd. in 2010 introduced conventional ELPI as ELPI+ with impactor stages increased to 15 stages (14 impactor stages + filter stage) allowing real-time particle size distribution measurement.

PM Chemical Composition Measurement Techniques

Aerosols interact with earth radiation budget and climate directly as well as indirectly. In a direct way, aerosols scatter or absorb solar radiation. Indirectly, aerosols modify the size of clouds affecting the cloud albedo. Size distribution and chemical composition of PM affects cloud condensation and nucleation activities. Therefore, it is important to know the chemical composition of PM using precise and accurate measurement techniques. The choice of measuring techniques depends on chemical compound that requires to be identified, the need to preserve the sample, if quantification is needed or information needed on morphology or size of particles. The major chemical components of PM which are analyzed include anions (sulfate, nitrates, sometimes chloride, and organic acids), cations (NH_4^+, water soluble potassium, sodium, calcium, and magnesium), carbons (OC and EC), and trace elements. A variety of methods and instruments are available ranging from filter-based sample collection for off-line analysis to on-line instruments which detects the chemical compositions of particles in real time (Aggarwal 2010), which are discussed in the following sections.

Off-Line PM Analysis Techniques

Off-line technique involves the prior collection of PM on filter, transportation procedures, and analysis to determine the chemical composition of PM. It provides detailed, specific chemical information about PM composition. However, there are positive and negative artifacts affecting off-line technique: evaporative losses during sampling, storage, and transport of samples, high particle loading causes some sample to bounce or be blown off the filter, and gases can be adsorbed onto filters and react with the surface. Off-line techniques can be divided into atomic spectrometry-based techniques, X-ray-based, and surface analysis techniques.

Atomic spectrometry is the widely used technique for elemental characterization of PM with Inductively Coupled Plasma (ICP) accounting for highest use in research. ICP is based on the ionization of sample under argon plasma atmosphere. ICP-Mass Spectrometry (MS) and ICP- Optical Emission Spectrometry (OES) provide quick and multi-elemental analysis with high sensitivity and low detection limit (ppb). Therefore, this technique is preferred for trace element analysis but the greatest disadvantage is that it is a destructive technique as it requires complete extraction and digestion of sample in acid medium. Another traditional technique for chemical analysis of aerosols is Atomic Absorption Spectrophotometry (AAS) based on the atomization or ionization of element at high temperature and detection at a specific wavelength by a monochromator. There are three variants of AAS: Flame

AAS (FAAS), Graphite Furnace (GFAAS), and Cold Vapor AAS (CVAAS). The difference among these variants lies in the ionization method. FAAS uses flame reaching 300 K, GFAAS uses atomization temperature over 3000 K, and CVAAS uses no vaporization system (Brown and Milton 2005; Wilson et al. 2002). AAS instruments are less costly in comparison to ICP but it is a single element analysis technique, thereby increasing the time of analysis.

X-ray-based techniques used a focused beam of charged particles which excite electrons in the samples with a wavelength characteristic of the element. Among X-ray-based techniques, the most applied ones are energy dispersive X-ray fluorescence (EDXRF) and particle-induced X-ray emission (PIXE). Both EDXRF and PIXE are non-destructive techniques. For EDXRF, there is minimal sample preparation required which reduces the risk of contamination, and it can possibly analyze liquid samples also. PIXE is an ion beam method based on detection of X-rays induced by a particle beam from electrostatic accelerators (Wilson et al. 2002). In contrary to EDXRF, PIXE has higher sensitivity for light elements such as Na, and it is less expensive.

Surface analysis techniques investigate chemical structure of a shallow layer of solid surfaces. Techniques commonly used for surface characterization of atmospheric particulates are X-ray photoelectron spectroscopy (XPS) (Gilham et al. 2008); X-ray diffraction (XRD) (Cienfuegos and Vaitsman 2000); secondary ion mass spectrometry (SIMS) (Janssens 2013); and scanning electron microscope equipped with EDX (SEM-EDX) (Janssens 2013; Sobanska et al. 2003).

On-Line PM Analysis Techniques

On-line techniques provide a real-time chemical characterization of the atmosphere with high temporal resolution of less than 1 hour. The mass spectrometers have been developed to determine the composition of particles in real time and a continuous manner. On-line mass spectrometry measures chemical changes in atmospheric particulate matter over a short period of time and can either determine the chemical composition of particulate assemblages, i.e., bulk analysis or single particles.

Aerodyne aerosol mass spectrometer (AMS) provide real-time information on mass distribution and chemical composition of volatile and semi-volatile component in PM combining standard vacuum and mass spectrometric technique. It detects only non-refractory compounds such as sulfate, nitrate, ammonium, chloride, and organics. It involves thermal ultra-high vacuum vaporization of PM inside tungsten vaporizer (400–600 °C) followed by vapor molecules ionization by a 70 eV electron impact ionization source. The AMS consists of three components: a sampling section, a section for particle sizing, and particle composition detection section. A schematic of AMS is presented in Fig. 16. Each section is pumped deferentially and separated by small apertures. The inlet samples a flow of 1.46 cm^3 s^{-1} focusing particles into narrow beam as they enter into vacuum with nearly 100% transmission efficiency to the detector for particle size ranging from 70 to 500 nm and substantial transmission for particles ranging from 30 to 70 nm and 500 nm to 2.5 μm. AMS

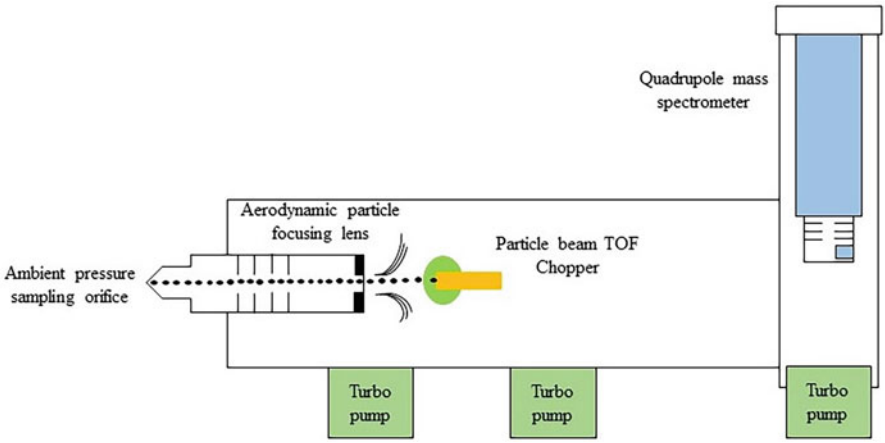

Fig. 16 Schematic of aerodyne aerosol mass spectrometer

alternates between two modes, mass spectrum and TOF with mass spectrum giving the average mass concentration of non-refractory species and TOF used to monitor mass distribution associated with a specific chemical compound as a function of aerodynamic diameter. Limitations associated with AMS are that it can only detect non-refractive particles; it cannot detect refractory particles such as soot, fly ash, metal oxides, and sea salt (Canagaratna et al. 2007); and it cannot provide complete mass spectra of single particle (Allan et al. 2003). Other versions of AMS available vary only based on the type of mass spectrometric detector: quadrupole (Q-AMS), time-of-flight (TOF-AMS), and high resolution TOF (HF-TOF-AMS).

In contrast to AMS that is based on thermal vaporization for characterizing the particles in bulk, aerosol mass spectrometry based on laser vaporization provides mass spectra for individual particles. Single-particle mass spectrometer (SPMS) involves the use of a high-power laser to vaporize and ionize the aerosol particles followed by mass spectrometric analysis. It provides qualitative or semi-quantitative information of chemical composition of individual particles. Several versions of SPMS instruments include aerosol time-of-flight mass spectrometer (ATOFMS) (Prather et al. 1994); laser mass analyzer for particles in the airborne state (LAMPAS) (Hinz et al. 1994); particle analysis by laser mass spectrometry (PALMS) (Murphy and Thomson 1995); laser-induced breakdown spectroscopy (LIBS) (Hahn and Lunden 2000); rapid single particle mass spectrometer (RSMS) (McKeown et al. 1991); nanoaerosol mass spectrometer (NAMS) (Wang et al. 2006); single particle laser ablation time-of-flight mass spectrometer (SPLAT) (Kamphus et al. 2008); and single particle aerosol mass spectrometer (SPAMS) (Li et al. 2011). The difference among the various versions of SPMS is in the laser wavelength used to perform the desorption and ionization and the method used to determine particle size (Sullivan and Prather 2005). Generally, SMPS uses specially designed inlets to transport particles from air into the vacuum and detected by optical light scattering.

Both off-line and on-line techniques are complementary in nature with on-line technique showing improvement in temporal resolution of PM characterization by providing data in 1 hour or less, and off-line technique being non-destructive allows the usage of same sample to analysis by other techniques. The combined use of both on-line and off-line technique can provide better understanding of particulate matter as per research requirement.

Abstract

Medical measurements are present in the everyday life of people and are fundamental processes in the prevention, diagnosis, and treatment of diseases. A growing interest lies in the role of metrological decisions and conformity assessment, where measurements are in support of health. Due to the inherent danger of life involved during the diagnosis and treatment of the patient, it is critical to

measure amounts as precisely and reliably as possible. Such measures and measuring tools are common in people's daily lives and play a very important role in illness prevention, diagnosis, and treatment. Although medical measures (measurements that are important to medical diagnosis) are simply pieces in the larger puzzle of medical decision-making, they make a significant contribution.

Introduction

Over the last few decades, quality evaluation methodologies have become more sophisticated, allowing for meaningful comparisons between healthcare institutions or health plans. However, as they are now utilized, these approaches cannot be used to enhance healthcare quality to the maximum feasible degree since metrics that rely on data acquired for administrative purposes unavoidably contain measurement flaws at the individual patient level. Patients may be incorrectly declared fit or unfit for a wrong or incorrect measurement, or the data taken was not collected properly, or the measurement was not appropriate for them for other reasons, such as exclusion requirements that the measurement system missed. Precise measuring system technician assists with modeling validation and production by employing precision measurement instruments such as hand-help, bench, or vision system.

This chapter focuses on the use of medical devices to improve their metrological traceability, emphasizing the specific role of metrology in the field of health care and the impact of legal control within the framework of the medical device regulation with a measuring function.

Medical decisions are frequently based on statistical analysis and clinical study findings. These studies include medical measurements that are correlated with other medical findings. Assuming that medical measurements are related to International System of Units (SI) of quantities such as mass, temperature, length, and so on, it appears that the main concepts of industrial metrology can be adapted and used fairly easily in the medical field. Following this logic, it is obvious that the metrological traceability of measuring instruments must be improved for them to be usable (reproducibility and repeatability conditions). Metrological tools such as calibrations, legal metrological control, and reference measurement methods should be used to ensure measurement quality.

Measurement is essential in the medical, biomedical, and healthcare fields because it serves as the foundation for medical diagnosis, prognosis, and evaluation. Indeed, "measurement is the foundation of medical research and clinical practice." To make the best decision for their patient, medical professionals such as doctors and clinical laboratory scientists must have faith in the results reported by their instruments or measurement methods. In many industries, incorrect measurements would simply results in customer dissatisfaction or a loss of money; however, incorrect measurements in biomedical could be fatal and result in a loss of life. The proper instrumentation and measurement (I&M) is critical in the medical field. I&M is primarily concerned with the measurement, detection, monitoring, and recording of

a phenomenon known as the measurand, as well as the calibration, uncertainty, tools, and applications that go with it. The fundamentals of I&M apply to any type of instrument or measurement, including medical instruments and measurements.

In this chapter, an overview of the complete range of I&M aspects in the medical field: measurement accuracy, uncertainty, instrument reliability, calibration against the gold standard, and complying with various regional, national, or international medical regulations, has been covered. Measurements of physiological, biochemical, physical, and other patient-related variables are not only common in intensive care medicine and beyond, but the results of such measurements also provide critical information for clinical decision-making as well as research and technology development. Erroneous measurements can jeopardize patient safety and expose the most critically ill patients to serious risks.

In this handbook, chapters based on metrological aspects for blood pressure measurement, SEMG signal acquisition, cognition advances in EEG and fNIRS, tremor measurement during surgery, artificial intelligence techniques for disease predictions in soft tissue organs, and iris-based diagnosis have been discussed.

In recent years, the technological revolution has created opportunities for bringing medical services to everyone's door. This is accomplished not only through the numerous applications available for smartphones but also through specialized devices that are available in a portable format. For such devices, the I&M community faces two major open concerns, i.e., clinical quality measurements to be obtained in the home using low-cost measurement equipment and their operation by a layperson.

Improving signal quality is the most important key to answering these questions. Because the cost of specialized equipment is so high, low-cost equipment can be equipped with inexpensive advanced signal processing tools. Furthermore, specialized sensors can be replaced by less expensive sensors or measurement devices that can be operated by a layperson and have a dedicated mathematical model or data analysis technique that can compute the physiological parameter of interest from the acquired measurements.

Blood Pressure Measurement

The correct measurement of blood pressure (BP) is essential for the diagnosis and management of hypertension. An intra-arterial evaluation is required for direct BP measurement. This is impractical in clinical practice, as blood pressure is measured noninvasively. For clarity, we refer to noninvasive blood pressure measurements as BP measurements. BP determination for hypertension diagnosis has traditionally depended on readings obtained on the arm above the brachial artery during healthcare appointments, often referred to as office BP.

Before the twenty-first century, office blood pressure was measured by an observer listening to noises with a stethoscope while observing a sphygmomanometer (i.e., auscultation). Blood pressure (BP) is an important physiological measure utilized in the diagnosis of many life-threatening disorders such as heart attack,

ischemic stroke, hypertension, vascular disease, hypotension, and many others. As it is closely tied to human life, it plays a significant role in the diagnosis and monitoring of many health conditions. Reliable and exact BP measurement is always a priority for both researchers and medical practitioners (Kumar et al., 2020, 2021b). With recent technological advancements, the issue of precise measurements, standardization of methodologies, and efforts toward adopting certain universal methods remain disputed, particularly traceability in dynamic mode. There are several types of BP measurement equipment in the market. The accuracy of these instruments is an unresolved issue for academics, medical practitioners, and metrologists. Several national and international standards prescribe procedures for calibrating these devices; however, relatively few technologies/systems/instruments are available to calibrate these devices in SI traceable units convincingly. In this chapter, an exhaustive review is presented explaining various noninvasive BP measuring techniques and available national and international standards. ISO standard of simulator is also described, which is used for the calibration and testing of oscillometric-type BP devices. Insight on some of the recent advancements in BP measurement and challenges ahead in their calibration are also provided.

Metrological Aspects of SEMG Signal Acquisition, Processing, and Application Design

Surface electromyography (sEMG) is a complex interference pattern of electrical activity during muscle contraction. It is directly connected to muscular activity and fitness level. Its amplitude ranges from 0.01 mV to 10 mV, with the majority of its energy focused between the frequencies of 0 Hz and 500 Hz. The detection of sEMG signals using noninvasive technology is extremely useful in clinical diagnostics, rehabilitative medicine, and intelligent prosthesis control. EMG has been utilized in the identification of sign language gestures, gaming control, and wearable devices in recent years (Gupta & Agarwal 2021, Gupta et al., 2020). Over the last few decades, there has been significant growth in SEMG-based applications. It is mostly because of advancements in electronic manufacturing and computing capabilities. However, the difficulties related to metrological standards remain unaddressed and must be solved urgently. This chapter tries to put together suggestions, standards, and criteria for such systems, as well as a case study of a SEMG-operated lower limb prosthetic design. The SENIAM recommendations are extensively reviewed and included in the application design. To construct a biologically inspired control structure, high-level and low-level control modules are used. The high-level control module provides activity intention, whereas the low-level control module determines the required angular position of the joints. The SEMG signal is used differently by each control module. The high-level control module problem is written as a classification problem, whereas the low-level control module problem is written as a classification problem for knee angle prediction and a continuous value estimation problem for ankle angle estimation. SVM, LDA, and NN classifiers with time domain feature vectors were observed to be appropriate for the high-level control

module. SVMQ proved to be superior for knee angle prediction. The autoregressive exogenous neural network (NARX) model incorporating SEMG and knee angle information performs well across all locomotion modes for estimating ankle angle. The framework and techniques are presented here for the design and control of SEMG-based active lower limb prostheses, exoskeletons, and orthoses.

A Survey on Advancement in Measuring Cognition Using EEG and fNIRS

Mental workload (MWL) impacts persons who continuously interact with computers and other devices. The usage of technology in everyday life may place substantial cognitive demands on users as they traverse complicated interfaces. Mental overload can affect users' performance and sometimes their safety by raising mistake rates and causing weariness, loss of motivation, longer response, and disregard of essential information (cognitive tunneling). Taking into consideration the users' cognitive qualities and limits is therefore crucial in enhancing the design of human-machine interfaces (BMI) and running them efficiently by installing adaptive elements that can respond to changes in the MWL. It is simple to get an early assessment of a patient's cognitive functions by comparing the patient's score reference standards using appropriately validated cognitive impairment screening tests (Andrianopoulos et al., 2017, Uchitel et al., 2021). This provides for a more accurate diagnosis and treatment strategy. The three basic methods for testing everyday cognitive functions are self-report, informant report, and performance-based screening evaluations. Human cognition is the basic building block of human intelligence, and it is what defines us as individuals. Cognition is described as the ability to recognize and respond effectively to environmental events based on one's beliefs, actions, experiences, and senses. It is one of the most fundamental reasons for human life and one of the most significant features of the brain. Human cognitive processes are constantly growing and developing during childhood, adolescence, and maturity. Although some of these talents begin to decrease as one grows older and reaches elder maturity, others begin to weaken when neurons die and the mechanisms that replenish them become inadequate. Understanding cognition is essential for not only healthy cognitive development and survival but also for treating a wide range of neuropsychological problems, including Alzheimer's disease. Before understanding cognition, one must first investigate the cognitive functions of the human brain. Low-cost ways of monitoring and evaluating cognitive function include fNIRS and electroencephalography (EEG). The use of combined EEG-fNIRS is still in its early stages, but it may be beneficial soon in terms of improving the algorithms and physical system design of hybrid EEG-fNIRS, such as emphasizing spatial and temporal advantages from fNIRS and EEG appropriately by designing advanced feature extraction methodologies and splitting nodes in different targeted cortical functions. This chapter covers the principles of electroencephalography (EEG) and functional near-infrared spectroscopy (fNIRS), as well as numerous ways to

preprocess and analyze EEG and fNIRS data. This chapter also discusses the usage of simultaneous EEG-fNIRS.

Artificial intelligence (AI) is a computer program's capability to perform human intelligence-related functions such as thinking, learning, adaptability, sensory comprehension, and interaction. Artificial intelligence (AI) uses data and algorithms to reach judgments that are on par with, if not better than, those reached by people. AI is now a part of our everyday lives; it powers facial recognition technology, speech recognition in virtual assistants, self-driving cars, etc.

Use of Metrological Characteristics in Ultrasound Imaging and Artificial Intelligence Techniques for Disease Prediction in Soft Tissue Organs

Soft tissue organ diseases are causing havoc on the population as a result of lifestyle changes, infections, heredity, and other reasons. A systematic review is carried out in the related chapter to predict diseases of soft tissue organs based on their metrological characteristics associated with ultrasound images and the use of artificial intelligence algorithms. Different soft tissue organs such as the kidney, liver, thyroid, and breast have been considered, and the need for developing computer-aided diagnostic tools for disease prediction of these organs has been highlighted. This is followed by a detailed description of the different disorders affecting the soft tissue organs and their sonographic appearance. This chapter describes the current advancements in the design of CAD systems for the prediction of kidney, liver, thyroid, and breast disorders. The research was carried out on ultrasound images of the breast based on observations acquired from a detailed analysis of related studies. It has been established that some textural properties are better displayed in the transform domain than in the spatial domain for better differentiation of benign and malignant tumors (Kriti et al., 2019, 2020). The non-subsampled contourlet transform (NSCT) has been used to decompose input images into different resolutions to better capture characteristic information. Texture features were calculated from the decomposed image using the GLCM method, and the computed feature set was merged with morphological features to represent the metrological characteristics of the tumors as seen on ultrasound. The resulting feature set has been fed into the adaptive neuro-fuzzy classifier (ANFC) for tumor classification into benign and malignant classes.

Artificial intelligence (AI) has gained in popularity as a technology with enormous potential to enhance many facts of our life besides research in health care. Despite being a trendy issue, the world of artificial intelligence is robust and ever expanding. AI uses computer systems to mimic human intelligence processes. These processes include learning (acquiring knowledge and learning when to use it), reasoning (using rules to reach conclusions), and self-correction. AI works by integrating massive volumes of data with quick processing and sophisticated algorithms, allowing the program to learn automatically from patterns or features in the data. Artificial intelligence in medicine is a potential technology. Recent research

indicates that using artificial intelligence in medicine can lead to the development of excellent diagnostic and prediction systems for identifying various diseases. Because of advancements in the fields of medical imaging and information technology, computers now play a major role in the diagnostic process for diabetes patients. It is challenging to lower mortality rates to more normal levels by using early and precise detection methods. Data on the frequency and incidence of diabetes and prediabetes are important when trying to identify risk factors for complications, acute and long-term difficulties, mortality, and medical care costs. The International Diabetes Federation estimates diabetes prevalence analysis of the existing prevalence of diabetes globally. Furthermore, additional factors, such as physiological indicators, that may play a role in the development of diabetes are being examined. Early detection and proper treatment can prevent up to 95% of visual impairment.

Glucose Monitoring Techniques and Their Calibration

Over the last two decades, there has been an increase in demand for reliable and noninvasive blood glucose testing. Despite the fact that current blood glucose monitoring techniques, such as the widely available glucometer, are well established. Because of the invasive nature of glucometers, measurement results are frequently inaccurate. This review discusses various glucose testing techniques classified as invasive, minimally invasive, and invasive. The development of the enzyme-based invasive approach is also discussed, with an emphasis on the introduction of portable glucometers (Wei et al., 2022, Alsunaidi et al., 2021). The various minimally invasive and noninvasive glucose measuring methods that have been investigated over the last few decades, as well as their calibrations, are also discussed. Moreover, several techniques have been used for this purpose, but device with accuracies comparable to established glucometers remaining a device with accuracies comparable to established glucometers remains a pipe dream. Despite that various noninvasive devices have been developed, mass-scale commercialization has yet to happen. However, the economic benefits of developing a noninvasive device are significant, and commercialization of such a device may be possible soon.

Artificial Intelligence for Iris-Based Diagnosis in Healthcare

Complementary and alternative medicine, particularly iris-based diagnostics, has made tremendous progress in identifying diabetes and related disorders. Diabetes is the primary cause of renal failure worldwide. It increases the risk of heart and blood vessel disorders. Diabetic kidney disease is a long-term disease. The blood test is used to diagnose diabetic kidney disease, a difficult and stressful therapy for patients. This chapter combines iridology with modern computer-based techniques for diagnosing diabetic kidney disease. Participants were evaluated and classified depending on their health state, such as not having diabetes, having diabetes but not diabetic kidney disease, and having diabetic kidney disease (Atul at al., 2015; Piyush &

Ravinder 2019). Pre-image processing procedures are employed to extract the region of interest from the iris based on the iridology chart's specified regions. The region of interest was evaluated for first-order statistical and second-order textual features. Finally, numerous classification models were tested using various sets of attributes to find the best model. The highest accuracy of 94.4% was attained with the help of a fine Gaussian kernel of the SVM classifier. It has been empirically demonstrated that characteristics of particular parts of the iris are substantially connected with an individual's diabetic kidney disease condition.

Assessment and Elimination of Surgeon Hand Tremor during Robotic Surgery

Two major shortcomings of conventional surgeries are the large size of cuts made by the surgeon in the patient body and the physical discomfort of the surgeon. The large size of the cut leads to many aftereffects like more chances of infection, delayed curing of the wound, more blood loss, more scars (Chen et al., 2020, Patle at al., 2019), and more pain to the patient. A surgeon is physically not at ease because he is supposed to stand for many hours continuously. It is painful as, on average, three to four surgeries are generally performed by a surgeon per day.

Laparoscopic surgery, which revolutionized surgical procedures in the mid-1970s after endoscopy reached a satisfactory level of performance, overcame the first of the above shortcoming by using thin, long nose instruments to reach the site of surgery. The small camera of the endoscope, along with fiber-optic light source and surgical tools, only needed around a 1 cm diameter hole on the patient's body. The surgical procedure was aptly named minimally invasive surgery (MIS). The surgical tool was manipulated by the surgeon manually according to the image of the surgical site sent by the camera, which was displayed on a 2-D monitor in front of the surgeon. Till date, this is the most prominent method to teach surgical skills to the interns of surgery by expert senior surgeons in the hospitals. However, the drawback regarding physical fatigue of the surgeon persisted. Then came robotic surgery in the last decade of the last century.

Robotic surgery is that minimally invasive surgery that takes care of this very issue. Here, the surgeon sits comfortably on a chair and guides the surgical arms of the robot, which perform the surgery. Robotic surgery has many attractive features. It allows precision delicate surgeries that were till now thought to be impossible. The robot arms can reach those critical locations in the body where the surgeon's hands cannot reach. However, the real advantage of this technique lies in the fact that the tremor generated in the hands of the surgeon does not affect the precision of surgery as it can be filtered out before it reaches the surgical arms of the robot.

The related chapter of the book discusses the technique to detect and sense the surgeon's hand tremor during surgery and prevent it from reaching surgical tools. The hand tremor was simulated in the lab using an experimental setup and suitable signal processing of the acquired signal. High-order digital filters were designed and tested on the composite signal consisting of volunteer hand motion signal and

undesired tremor signal. The obtained results indicate that tremor was suppressed successfully to allow required precision in surgery.

Conclusion

Biomedical metrology is the application of electronics and measurement principles and techniques to develop devices used in diagnostic and therapeutic applications.

The various chapters of the book have been selected in such a manner that they not only describe an important device or procedure to measure a biological parameter but also lead to the solution of a medical problem in the most innovative manner. Chapters have been written by the authors in a manner that integrates the engineering principles and design concepts to medicine and biology for healthcare purposes. The chapters cover vast spectrum of biomedical measurement area – blood pressure, brain functioning, and medical imaging to surgery. All the metrology techniques have been applied with Artificial Intelligence at the center, which promises complete mitigation of human misery one day. At the same time, the described techniques indicate that biomedical devices of the future will have to conform more to applicable governmental regulations, which set standards for not only metrology but efficacy and safety of humans also.

lead to harmful results. Robotic surgery makes it possible to filter out the tremor before it is passed on to the surgical arms of the robot actually performing the surgery. In order to eliminate the effect of tremor, it is to be sensed and measured well before time. The research work reported in this chapter pertains to characterization and sensing of tremor by different methods in general and by electromyography (sEMG) in particular. SEMG signal was picked up from the tremor arm, processed, and applied to a classifier to detect the tremor and remove it. Total 14 subjects belonging to different age groups were included in the study. Seven features viz Mean, Standard Deviation, Skewness, Kurtosis, Mean Absolute Value, Zero-Crossing, and Slope Sign Change were extracted and fed to the classifier. Four classifier models viz Support Vector Machine, Logistic Regression, K-Nearest Neighbor, and Random Forest were compared. A decrease in median frequency and increase in power during tremor were observed. Classification accuracy was found as 99.5% with Random Forest model.

Introduction

In the conventional surgery, a surgeon operating on the patient belly has to make a cut that is 6-to-12 inches long. It gives him the required space to reach the organ which he has to work on and to see what he is doing. Right from the beginning of twentieth century, efforts in laparoscopic surgery started changing this scene inside operation rooms in hospitals. For laparoscopic surgery, also called keyhole surgery, several small cuts are made by the surgeon (of average size half-inch). The name of the process has been derived from laparoscope, a thin and long tool that has a small video camera along with light at its tip. A tube is inserted through each port or opening (Fig. 1). The laparoscope and surgical tools enter into the body through this tube. Then the surgeon starts the operation. The camera image is displayed on a video monitor. Surgeon keeps looking at the monitor to see what is happening inside the body. Due to long nose instruments (Fig. 2), the surgeon does not need to reach into the patient's body. This is also the prevalent method to train surgery interns in the operation theater.

The laparoscopic evolution was initially slow largely because of the limitations of technology and partly by nonacceptance of the procedure by the medical fraternity. The early laparoscopic surgeons were subject of ridicule for conventional surgeons. During the mid-1960s and 1970s, gynecologists contributed greatly to laparoscopic technology and its safety aspects. Video technology was in the developing stages then; camera and monitor had poor resolution; and it was difficult to carry out operative laparoscopy. Moreover, the technology was thought to be used for teaching purpose. The video system adequate for surgery was developed by a surgeon (not an

Fig. 1 Incision in Laparoscopic surgery

Fig. 2 Surgical tool used in laparoscopy

engineer!) in the early 1980s, and it became possible for a group of surgeons to work as a team. Mr. John Wicker, an English urologist, named the procedure as "minimally invasive surgery." It proved to be a revolution in general surgery, specially in urology and gynecology, because of its numerous advantages: small cut size, early healing and consequent saving on hospital expenses, less infection possibility, etc. Patients were happy with this new method of surgery and instrument companies were quick to develop and manufacture long nose surgical tools required for this surgery. Very soon, laparoscopic technique was being used for virtually every abdominal operation (Fig. 3).

Laparoscopic surgery changed the face of surgery from the view point of both surgeon and patient; nonetheless, it has many shortcomings. The biggest difficulty is that there is a requirement of tear minimization at the incision point and, therefore, laparoscopic tools have inherent kinematic constraint. Available laparoscopic instruments have limited degrees of freedom – generally 4 – whereas in conventional surgery, the surgeon has the liberty to exercise 7 degrees of motion. Second point is that two-dimensional vision of the system is no substitute to the natural vision of surgeon. It demands a high hand-eye coordination and dexterity on the part of surgeon. Third, there being no haptic feedback, the surgeon does not have the psychological feeling of accomplishment of his task. The small sense of touch also

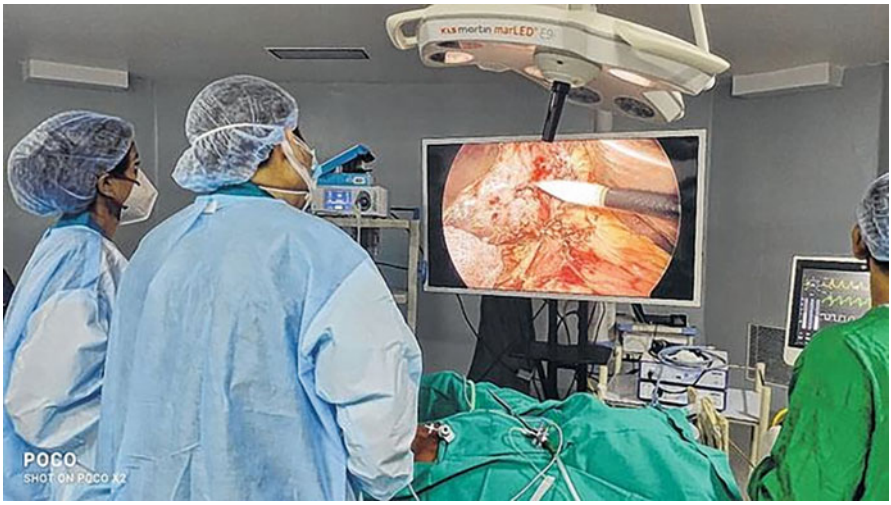

Fig. 3 A typical scene of laparoscopic surgery in an operation theater

makes surgeon's decisions more dependent on his monitor visualization. Finally, physiological tremors in the surgeon's hands due to fatigue cannot be prevented from reaching the surgical tools which can cause harm to the patient when it comes to precise surgeries. Due to these limitations, many complex procedures (e.g., pancreatectomy) have proved difficult to perform laparoscopically. For example, the surgeon needed to adopt awkward positions due to the 2-dimensional vision of the field (Sabiston 2004). Research continued in the field of surgery by both doctors and engineers as it seemed that only a new technology could lead to further development.

Robotic Surgical Systems

The dawn of the twenty-first century brought further advances in the area of minimal invasive surgery. These were the robotic surgery and telepresence surgery which, to a large extent, removed the limitations of laparoscopic procedures (Sabiston 2004; Ballantyne 2002).

The robotic instruments entered the operation theater of the hospital in late 1990s (Camarillo et al. 2004). Before that, PUMA 560 industrial robot arm, which was successfully being used for industrial applications like welding and spray painting, was deployed for a neurosurgical procedure in 1985. A voice-operated robotic system for endoscopic surgery, AESOP® Endoscope Positioner developed by Computer Motion Inc. Intuitive Surgery Inc. (earlier Integrated Surgical Systems), brought out the da Vinci Surgical System® which had two motion subsystems: One was called master handles manipulated by surgeon while the other was a pair of robot arms to execute surgical tasks. It was said to possess master-slave configuration. It was approved by FDA for abdominal surgery in the year 2000 and for

mitral valve repair in 2002. This led to an upsurge in the usage of robotic systems in different types of surgeries like urology, cardiac, pelvic, and neurological. While the robotic technology makes it possible to carry out precise surgery from the surgeon's point of view, it results in less blood loss, faster recovery, less chances of infection, and lesser complications on the part of patient. This surgery allows the surgeon to do the surgery while sitting comfortably while he can rest his hands for few seconds when he feels tired. The vision system of these robots is three-dimensional which shows the depth information related to the movement of the robotic arms and the surgical site. The motion controller of the robot is quite advanced. It performs the necessary motion scaling of the surgeon's hands who moves the master handles in inches while the motion transferred to the surgical arms may be in millimeters in a precision surgery. This allows the surgeon to be natural and look after other tasks related to the procedure. The motion controller also detects incorrect paths of surgical arms and allows their motion only through safe areas. Newer researches are adding advance features in the area of robotic surgery, making the systems more and more cost effective and ensuring more frequent usage of this technology in times to come (Hashizume and Tsugawa 2004).

The main drawback of manual or laparoscopic surgery is inducement of tremor in the hands of the surgeon with time. This tremor is an involuntary, undesirable repetitive movement generated by fatigue (Bhagwath 2001) which causes inaccuracy in microsurgery (Patkin 1977). The biggest advantage of robotic surgery – precision – may be lost due to tremor in the hands of surgeon. Suppression of fatigue-generated tremor is necessary to prevent in microsurgery. Consider the cannulation of retinal vein for injecting anticoagulants to treat occlusions. These occlusions lead to blindness. According to one estimate, about 1.6% of persons of 49 years or more get affected by this disease (Mitchell et al. 1996). The precision needed in this surgery can neither be achieved in conventional surgery nor in laparoscopic procedure (Weiss 1998) as the position accuracy of surgical tool required is of the order of 10 μm (Charles 1996). Another example is ophthalmologic arteriovenous sheathotomy, which is considered as a possible treatment for branch retinal vein occlusion (Opremcak and Bruce 1999), but nearly infeasible with precision available without the robotic surgery (Tang and Han 2000). Similar examples exist in otorhinolaryngological, neurological, and microvascular surgeries (Taylor et al. 1999).

Let us now look at the techniques to reduce the magnitude of physiological tremor during microsurgery. These include both technology- and nontechnology-based methods. At the lower end of the ladder, there are wrist rests and other mechanical supports. Controlling of sleep, the caffeine consumption by surgeon before the surgery also decreases tremor (Humayun et al. 1997). Similarly, beta-blockers have shown reduction of tremor amplitude (Elman et al. 1998). On the technology front, it is the robotic surgery which promises the kind of accuracy required in precise operations. Teleoperation in robotic procedure is the most effective provision to minimize tremor (Das et al. 1999; Jensen et al. 1997; Hunter et al. 1993). This is due to the physical distance between master handles and surgical arms that allows tremor filtering. Simultaneously, it is helpful in implementing

motion scaling. However, the initial cost of a teleoperating robot is very high. Also, there is hindrance to the free movement of persons within the operation theater which may be menacing if these persons have been working in the environment of conventional surgery and have not been trained for robotic surgery. Apart from a surgeon trained on surgical robot for years together, robotic surgery also requires stringent safety measures to be adopted. By combining robotic surgery with communication technology, its usefulness has increased manifold. First, telerobotic surgery was performed between politecnico di Milan, tele-robotics laboratory, Italy, and jet propulsion laboratory, Pasadena, on 7 July 1993 (Rovetta et al. 1993). Advancement was achieved for path planning with the combination of collision avoidance technique and geometric algorithms in the late 1990s (Patle et al. 2019). After some time, three-dimensional technique, planning, and motion flexibility was achieved with good dexterity. Today, success rate of robotic surgery is 94–100% (Robotic surgery). Common robotic surgeries are the following: cardiovascular, head and neck, gynecologic, knee replacement, abdominal colon, rectal, and urology. Some typical cases of oncology take up to 14 h for surgery. In India, presently, there are 8 hospitals where robotic surgery is being done on regular basis. In USA, about 1200 hospitals conduct robotic surgery.

The Surgical Robot Architectures

The ROBODOC® (Fig. 4) was introduced by Integrated Surgical Systems in the early 1990s.

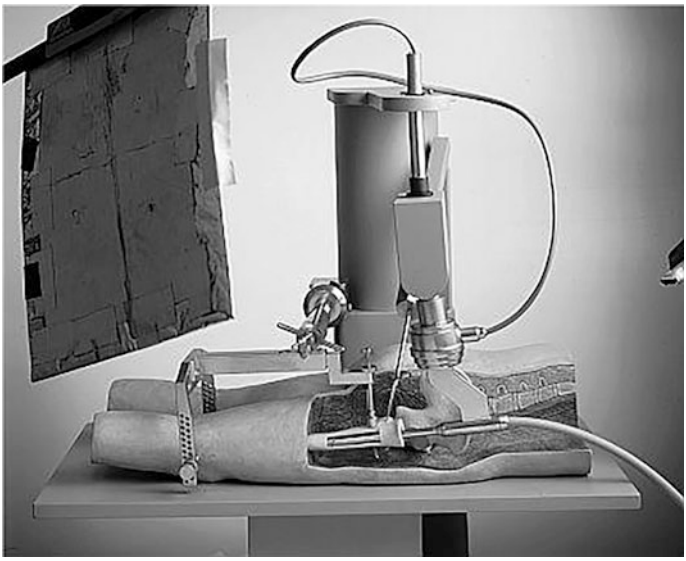

Fig. 4 ROBODOC performing surgery. (Source: www.avrasurgical.com)

For performing surgery by ROBODOC, the surgeon has to first make a choice of the required implant and its appropriate position in the patient's body by looking at the CT images of that area. The robot controller does the path planning, and the surgical tools move accordingly. Registration of the images is done before the surgery. Surgeon marks the surgical tie points so that CT images and patient are in synchronization.

Automated Endoscopic System for Optimal Positioning (AESOP) is an autonomous robot having the capability of imaging only. It is controlled by simple voice commands. It was developed by Computer Motion Inc. in 1994. Its prime function was to position an endoscope at the desired place during surgery. Endoscope is held by a 2-DOF wrist joint. The robot base is clamped to a rail on the operation table. The design of the robot is such that the endoscope may be placed very close to the organ under surgery. The robot is capable of storing three anatomical positions in its memory, and one voice command is enough to recall them (Nathan et al. 2006). The device became quite popular among surgeons because the endoscope supported by robot produced stable images. When the system was compared with manually supported endoscope, it was found that the average operative time was lesser with AESOP (213 min) than with a human assistant (235 min) (Berkelman and Ma 2009) (Fig. 5).

Zeus system has three robotic arms – two of them perform the surgery while the third is an endoscopic arm. The surgeon sits comfortably upright with a control console consisting of video monitor (Fig. 6). The robotic arms execute surgery by mimicking the movement of the surgeon. The endoscopic arm is voice-operated. Surgeon maneuvers the instrument handles which are positioned to maximize his comfort. The surgical arms have 7 degrees of freedom.

Fig. 5 AESOP robotic arm. (Source: http://www.spineuniverse.com)

Fig. 6 Zeus system setup. (Source: Ann Surg© 2004 Lippincott Williams & Wilkins)

Natural Orifice Transluminal Endoscopic Surgery (NOTES) has a master slave configuration where robotic arm enters the body through an orifice (Nakamura 2010). An articulating tube helps the movement of robotic arm in such a way that fulcrum effect is negligible. This makes the manipulations inside the body quit easily. Robotic arm is equipped with three end effectors – the first is a gripper, the second holds scissors, while the third is a clamp whose function is to place the tools at the point where surgery is to be performed. Depending on the surgical task, the electromechanical tool-changing mechanism of the system selects the appropriate tool. The surgical tool is controlled from remote by a joystick. The tool changer (Fig. 7) not only minimizes the operation time by optimizing the process of tool exchanges, but also reduces the tissue trauma during exchanges. Placing the actuators at site increases the effectiveness of robot as the end effectors can apply high force during operation. Kinematics of the robot does not pose restrictions in movement as the robot arm is quite far from the articulating tube.

The da Vinci system (Fig. 8) has 4 subassemblies: (1) a vision cart consisting of endoscopic arm having a pair of light source and a pair of cameras, (2) a 3-D visualization console where the operating surgeon sits, (3) a moveable patient cart consisting of two surgical robotic arms and one manually operated manipulating arm, and (4) surgical tools which are to be changed during surgery; these are fitted to the grippers of surgical arms depending on the surgical task to be done.

The endoscopic arm has a pair of cameras mounted at the tip. Each camera generates a 2D image from which 3D image is reconstructed. The 3D video console

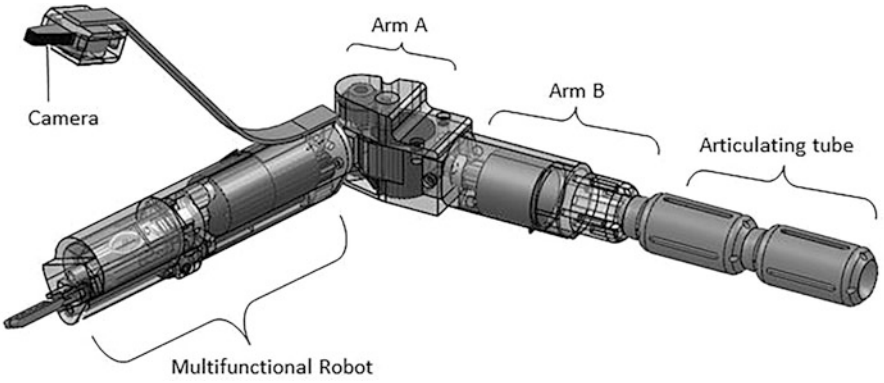

Fig. 7 NOTES multifunctional robot

Fig. 8 da Vinci system set up. (Source: http://www.intuitivesurgical.com)

shows a true three-dimensional image which has the depth information of the surgical site. It also has foot pedals by which endoscopic arm is controlled by the surgeon. The foot pedals also control electrocautery. The surgeon console is equipped with encoders or master handles whose motion is captured by the motion controller and transferred to the surgical robot arms after scaling down. The robotic arm grippers are operated through motion transfer by cables driven by motors at the other end. The gripper has a total of 7 degrees of freedom – three body motions, three wrist motions, and one open-close operation.

Advantages of Robotic Surgery

Robotic surgery overcomes many shortcomings of the conventional and laparoscopic surgery. Difficult surgeries become feasible because:

(i) In robotic surgery, surgeon has more flexibility in execution of surgical tasks.
(ii) Tremor in the surgeon's hand can be prevented from reaching the end-effecter by filtering the encoder signals using appropriate filters.
(iii) Large movements made by surgeon with encoders are scaled down into motions of mm size or less by motion controller.
(iv) The clarity of surgical site through 3D vision results in excellent hand-eye coordination.
(v) Surgeon is in the most comfortable position, and his body does not have to go through twists and turns to carry out surgical tasks.

Robotic surgery is most suitable for eye surgery, prostate surgery, and knee and hip replacement which demand high precision and accuracy. According to an estimation, by 2035, surgeons will be replaced by robots considering the dexterity in suturing and accuracy.

Challenges and Future of Robotic Surgery

The challenges to robotic surgery systems are as follows:

(i) Robotic surgery is a relatively new technique, and its propriety is yet to be established. Critics claim that the duration of robotic surgery is more as compared to corresponding conventional or laparoscopic surgery. It has been observed that on average, robotic surgery takes about 50 min more than laparoscopic surgery. Supporters of robotic surgery argue that this is mostly due to lack of training of persons associated with this surgery.
(ii) Initial cost of surgical robot is prohibitive. Only big hospitals can afford it.
(iii) Operation theaters are already congested having a large number of equipment. Robotic surgical system is voluminous and occupies substantial floor space. Accommodating the robot in the existing operating room along with the personnel is quite difficult. Future surgical rooms may be constructed bigger to overcome this disadvantage.
(iv) At present, nurse changes the surgical tool manually. This results in longer operating time. In future, this task may be made automatic so that tool changing time decreases substantially (Reuvekamp 2009).
(v) Robotic surgery requires massive training of surgeon and nurses. According to one estimate, minimum 15 complete practice surgeries are a must before the procedure is done on an actual patient.
(vi) A high-power back up supply is to be ensured because failure of electricity may put the patient's life in danger.

One requirement of successful robotic surgery is that patient and surgeon must not be at large distance away from each other so that surgeon's commands can be followed by surgical arms in real time. If it is required to keep this distance large, the commands to the arms may be communicated through optic fiber cables to maintain accuracy, but this results in two disadvantages. One, system's cost increases, and second, time lag between issuing of commands from master stage and their execution at slave stage may be so high that the patient is ultimately harmed. The development of wireless commands for robots may be the solution to this problem. With advances in communication technologies, robotic surgery of future is expected to possess wireless control (Electronic devices). Control of surgical arms using voice commands will result in lesser supporting staff in the operating room.

One point to be kept in mind is that due to expansion of robotic surgery, human beings will not be laid off but their skill set will undergo a change. They will be more competent than their present counterparts.

The main requirement of surgical robot is that it should possess good computational capabilities. The artificial intelligence (AI) is integrated in the design of this surgery. Surgeon takes the training, performs the procedures, and gets the experience even though the mistakes are committed. Main motive to implement AI in the field of medicine is to keep the surgeons alert while performing the surgery. The base for AI is heuristic knowledge by which the machine learns with real life experiences. Genetic algorithm (GA) and neuromorphic engineering are mostly used in AI. The meaning of neuromorphic engineering is to transform the microcircuitry in analog computing medium which can mimic the neural tissue. The structure requires the equivalent of neurons in hardware like resistors, capacitors, and silicon chip which can store the acquired signal. Latest research is to determine and copy the interconnections of neurons of brain. AI maintains the population of chromosomes and coding for control architecture. There are three requirements for robot to meet: learn, remember, and evolve. Surgeons are being trained on computer virtually for surgery based on preoperative or intraoperative imaging data of structures. With this process, the risk of mistakes during surgery can be avoided.

The integration between an unsolved problem and new approach to solve the problem is a challenge in robotic surgery. One solution is that the surgical tool should be designed in such a way that it may be used in some advanced way or the result should be better, i.e., mortality should be decreased. In surgical system, the imaging and manipulation should be enhanced. For development of surgery, the input and the guidance from the clinical area are required. The role of surgeons is there in two ways: first to collaborate with research team of technology developers and then to utilize the developed technology in their specialities. Institutional programs should be organized frequently on surgical innovations.

Ethical and Safety Considerations

Robotic surgery is technology-intensive electromechanical device, and therefore, any mishap may take place within the operation theater during surgery. It may even

put the life of patient in danger. Therefore, this surgery needs the presence of technically trained person in the operation room who can tackle any emergency related to the robot and who can help the surgeon during surgery. This surgery involves many legal and ethical issues also that require attention of medical, technical, and administrative authorities. Following are some of these issues:

(i) Is it ethically correct to charge the cost of robotic surgery from patient? He, in fact, never insisted on robotic surgery. It was the surgeon's preference and decision.
(ii) Who is responsible in case robotic surgery fails because of *technical problems* – the surgeon or the robot-manufacturing company?
(iii) If robotic surgery involves teleoperation and the surgeon and patient are located in different countries, how will the ethical and regulatory norms be followed?

Biological Tremor and Its Characteristics

The tremor in humans is a continuous and involuntary shaking of a body part characterized by its frequency, location, and pharmacological response (Smaga 2003; Mansur et al. 2007). The tremor movement may occur either due to neurological disorders or due to natural physiological reasons. Physiological tremor is always present in human beings (Borges and Ferraz 2006) to some extent. An example of neurological disorder tremor is the one during Parkinson disease (Almeida et al. 2010) which is caused by dysfunction of the central nervous system. There are few other, relatively rare, pathological tremors mentioned in the literature (Wyne 2005).

Physiological tremor can be categorized as resting tremor and action tremor (Borges and Ferraz 2006). As the name indicates, resting tremor occurs when the body is in rest position and suddenly the parts of body start shaking due to some disease. During this tremor, the muscles are relaxed, for example, when the hands are resting on the lap. Normally, this tremor affects only the hands or fingers. It happens due to some problem in that part of the brain which governs motor functions in the human body. It may occur due to neurological disorders such as stroke, brain injury, and neurodegenerative diseases, use of medicines especially for asthma, or drugs used for neurological disorders, alcohol withdrawal, thyroid problem, liver or kidney problem, anxiety, or panic (Rocon et al. 2007). Parkinson tremor is a type of resting tremor.

The action tremor comes to fore when a person contracts his muscles (Borges and Ferraz 2006). It occurs due to excessive force experienced by the muscles, mainly due to fatigue. Time domain behavior of tremor shows that the tremor increases with time.

Tremor can be classified into three categories on the basis of its frequency. Low-frequency tremor is less than 4 Hz, middle-frequency tremor is between 4 and 7 Hz, and high-frequency tremor has frequency components more than 7 Hz

(Borges and Ferraz 2006). To cover full range, frequency of physiological tremor may be taken as 3–15 Hz (Latt et al. 2011).

From the view point of location, tremor is most visible in the arms, legs, and the head. Most affected part of the body due to tremor is hand where it manifests itself by difficulty experienced in the tasks performed by hand such as writing or drawing or grasping of objects. It may sometimes be seen in periodic shaking of head or legs or as a shaky voice.

Tremor is a nonstationary phenomenon (Deuschl et al. 2001). Tremor is observed more when a person is in stress, physically exhausted, occupies certain posture or movements. Amplitude of tremor increases with fatigue or stress and disappears after taking some rest (Adhikari et al. 2016). Tremor increases with aging, and mostly it occurs after the age of 50 years, but people may suffer due to tremor at any age (Moghadam et al. 2018). Men and women are affected equally with tremor.

Tremor is not life-threatening but affects day-to-day routine work. During a typical surgical procedure, tremor is to be taken on priority. By holding the surgical tool for a long time with controlled movements, the muscles get tired and the resultant trembling of hand may erroneously lead to the cutting of some tissues other than the intended ones (Taylor et al. 1995). It has been observed that hand tremor increases continuously with the duration of surgery (Slack et al. 2008).

Techniques for Detection and Measurement of Tremor

Human tremor can be estimated by many methods. The most popular method in the clinic is by severity scales (Ramaker et al. 2002; Greffard et al. 2006). Here, the patients draw various drawing patterns which include geometrical figures, letters, and numerals (Fig. 9). Neurologists evaluate the deviation of drawn pattern from the reference and assign a numeric scale 0–5. Here, 0 means no visible tremor while 5 is severe disabling tremor. It is clear that this type of classification is subjective. Second, parameters characterizing the tremor – frequency, amplitude, and speed – cannot be determined from this method.

Clinical evaluation does not give much information about the characteristics of tremor or its genesis as it is not patient-specific. To overcome these shortcomings, electronic techniques have been developed for the assessment and analysis of tremor. These include digitization, accelerometry, position encoding using magnetic tracking system or active optical markers, spirography, and electromyography (EMG) (Almeida et al. 2010).

Digitizers promise the measurement of tremor quantitatively directly on the computer. The digitizing tablet is able to record the coordinates of the tip of the pen held by the patient on the digitizer surface. This device can detect the movement of a subject following standard drawing patterns placed on it (Elble 2003).

Spirography makes use of digitizing tablets (Almeida et al. 2010). In this method, patient is asked to reproduce the standard Archimedes' spiral. The tablet surface contains the reference image of this spiral, and the patient is required to trace the

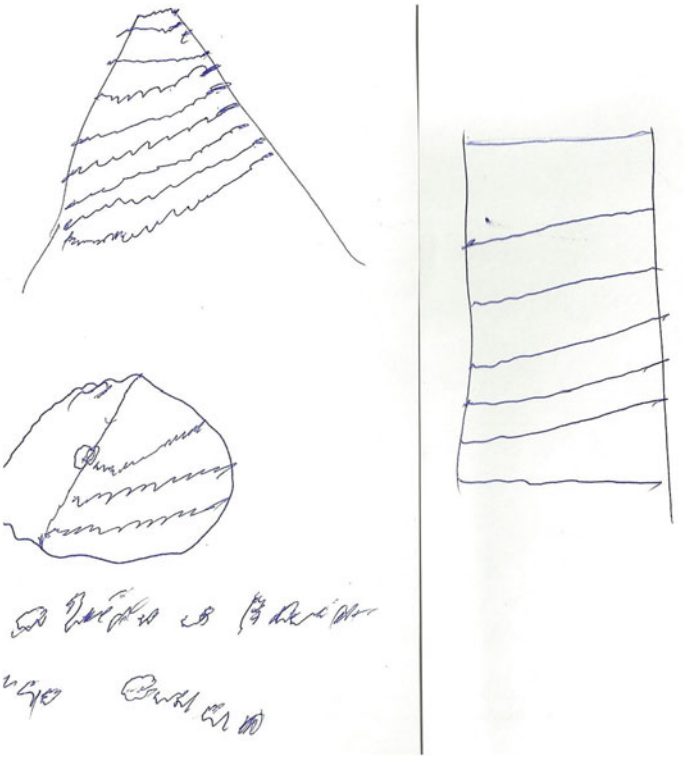

Fig. 9 Drawing patterns drawn by tremor patients

spiral image as accurately as possible. Archimedes spiral has several features which make it a popular method of tremor assessment:

- Its design is straightforward, and patients can easily understand it.
- There are no sudden changes in the shape, and it allows smooth movements.
- Digital spirography provides quantitative estimation of the movement control (Pullman 1998).
- The signals can be stored in a computer for later reference and analysis.

The analysis of patient signal can be done by image processing. Geometric transformations may be applied to the patient drawing image to extract relevant features (Saunders-Pullman et al. 2007). Statistical analysis can be done using advanced tools algorithms for data evaluation (Haubenberger et al. 2011; Bajaj et al. 2011).

Position encoders have also been used in the assessment of tremor (Gopal et al. 2013). Encoders provide a position feedback signal of an object. They are available with analog (0–5 V, 0–10 V, or 4–20 mA) or digital output. Both linear and rotary encoders may be used to measure tremor depending upon the attachment of sensor

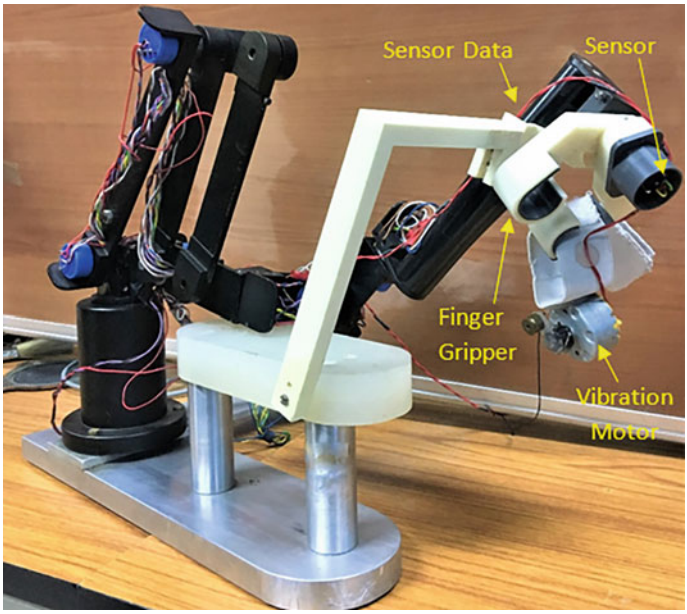

Fig. 10 Prototype of two Degree of Freedom (DoF) tremor generation and measurement arrangement

with the object under tremor. A prototype system of two degree of freedom (DoF) developed by authors of this chapter for generation and measurement of tremor by displacement sensor is shown in Fig. 10.

To simulate tremor, 12 V DC vibration motor was attached to a fabricated finger gripper. An analog rotary encoder with 12-bits resolution was mounted on the gripper joint to sense the tremor. The encoder output was a signal which was a total of surgeon's voluntary hand motion and involuntary tremor motion. The position was achieved with precise linearity by doing numerical integration of output signal of encoder. The calibration for sensor is not required as its rotational life (shaft revolutions) is 100 million. The advantages of using this sensor in over accelerometer are the following: noncontacting magnetic technology, highly resistant to vibrations, programmability at factory for zero position, highly repeatable, extremely long life, stability, linearity, programmable electrical angle, minimal sensitivity to environment parameters, and ability to withstand side load on arm. The output signal of sensor was amplified by a factor of 2. The output voltage was digitized by NI 9205, a 16-bit data acquisition system @ 1 kHz. Tremor was determined in both vertical and horizontal directions and its peak frequency displayed.

Artificial tremor in the range of 3–15 Hz was generated using vibration motor. Figure 11 shows the composite analog signal – high-frequency component tremor superimposed on low-frequency voluntary motion signal. The data was acquired and analyzed at various tremor frequencies. Figure 12 shows the Fourier Transform (FFT) of signal at 10 Hz tremor.

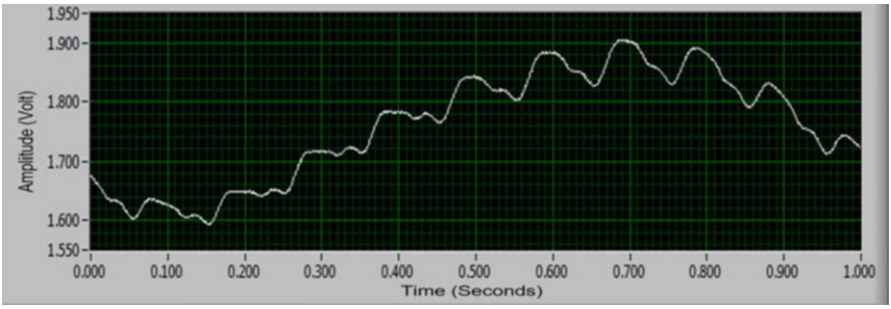

Fig. 11 Recorded raw signal having voluntary and involuntary motions

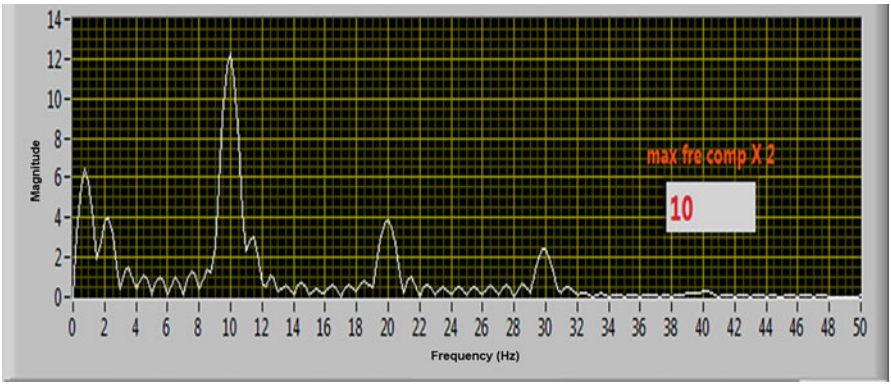

Fig. 12 FFT of raw signal having peaks of voluntary and involuntary motions

From the FFT diagram, it can be observed that peak power exists in the tremor signal of 10 Hz and then in the volunteer signal which is around 1 Hz. The other peaks exist at 20 Hz and 30 Hz which are the harmonic frequencies of the fundamental tremor frequency of 10 Hz. To keep only the volunteer frequency and tremor frequency and eliminate high frequencies, a low pass filter with cutoff frequency $f_c = 20$ Hz was designed. The composite signal was filtered by this filter. The output of filter now had only volunteer signal and fundamental tremor frequency.

To eliminate tremor, it was required to notch 10 Hz. A Butterworth filter having stopband from 8 to 12.5 Hz and passband frequencies of 4 and 18 Hz and of order 5 was realized which removed the tremor component. It was an adaptive filter which adjusted its notch frequency according to the change in the frequency of tremor signal. For this purpose, peak frequency of tremor signal is monitored continuously in real time throughout the duration of the experiment.

Accelerometry is another popular method of tremor determination. In this method, accelerometer monitors the vibrations produced by the tremors (Elble 2003; Raethjen et al. 2000). The principle of accelerometer is based on Newton's second law of motion. It measures linear acceleration along three orthogonal

directions. The sensor inside an accelerometer is an electromechanical device which makes use of either the piezoelectric phenomenon or the variation of capacitance caused due to vibrations. Accelerometer outputs the instantaneous value of the vibration of the body part to which it has been physically attached as a function of time. These values are logged in and can be analyzed later.

Tremor can be detected and measured quite easily by electromyography (EMG). The electromyogram signal is generated when a muscle undergoes contraction and relaxation. Neuromuscular disorders can easily be diagnosed by analyzing EMG of such patients. Two types of electrodes are used to acquire EMG. Needle or wire electrodes are inserted into the muscle if activity of a particular muscle is to be recorded (Elble 2003; Raethjen et al. 2000). If the signal is to be acquired from a group of muscles, it can be accomplished by placing electrodes on the skin surface. The parameters of EMG signal which characterize tremor include frequency (Hz), mean amplitude (mV), and pattern (synchronous or alternating) (Milanov 2001).

During acquisition of EMG signal, ECG signal generated by heart acts as an interfering signal. The effect of heartbeats on acquired EMG can be minimized if EMG is recorded with muscles carrying some weight. For tremor analysis using EMG also, some task is chosen which involves weights.

Yet another method to measure tremor is by gyroscope. While accelerometers measure linear acceleration, gyroscopes measure angular acceleration. Their output is expressed as degrees per second (°/s). Accelerometers measure inertial forces, and therefore, they provide a frame of reference in relation to gravity. Problem occurs when the accelerometer is also vibrating. In this situation, reference of accelerometer becomes difficult to maintain. An accelerometer can provide a false frame of reference if it is subjected to sustained static accelerations. Gyroscopes do not suffer from this drawback. They provide a stable, oriented, and accurate frame of reference. Thus, the gyroscope provides true course of motion. Gyroscopes are not usually used alone for vibration measurement, but when paired with accelerometers, they offer a much more complete picture of the vibrating environment. Currently, there are wireless devices that integrate accelerometers and gyroscopes for movement capture (Giuffrida et al. 2009).

There are some lesser used techniques that measure displacement and can be used to measure tremor. One such method is the magnetic tracker system which gives information about the linear movement along Cartesian coordinates (x, y, and z) and orientation in spherical coordinates (pitch, roll, and yaw) of an object (Ghassemi et al. 2006). Acceleration can also be measured using active optical markers, and the application of trigonometry makes it possible to describe the vector orientation and the estimation of posture (Albert and Kording 2011).

Measurement methods have been combined with advanced communication techniques to make tremor evaluation results available remotely. For example, tremor is done through videos (Uhríková et al. 2011). There are tools that use tremor sensor and transmit information through Internet and Bluetooth technology (Barroso Júnior et al. 2011).

After acquiring the tremor signal, it is to be processed to extract useful information carrying features. Usually, the signal processing is done in frequency domain for

which Fast Fourier Transform (FFT) of the signal is taken (Giuffrida et al. 2009; Barroso Júnior et al. 2011). There are some applied variants of FFT which are more effective when signal fulfills certain conditions. For example, its version Weighted Fourier Linear Combiner (WFLC) (Riviere et al. 1997) is more suitable for periodic or quasi-periodic estimation of motion with single dominant frequency. Similarly, Band-Limited Multiple Fourier Linear Combiner (BMFLC) (Veluvolu and Ang 2011a) is better when the tremor signal is band-limited signals and it contains multiple frequency components. Statistical tools may be used for extraction of parameters which may be used for classification of tremor. Other algorithms may also be applied depending upon the objective (Latt et al. 2011; Popovi et al. 2010). It is very difficult to pinpoint the best method of analysis as tremor is a random or quasi-random signal (Mansur et al. 2007).

It may be observed that any tremor sensor provides a composite signal in which hand tremor of surgeon is superimposed on voluntary motion corresponding to the surgical tool movement. Hence the signal processing is to be done first to separate the two motions before extracting the characterizing features of tremor to analyze it. Researchers have suggested some methods to accomplish this task and estimate the tremor. An Extended Kalman filter (EKF) was proposed to assess tremor in the presence of associated noise (Bó et al. 2009). An auto-regressive moving average (ARMA) model has been described in (Becker et al. 2008). Literature survey indicates that the solution to this problem has also been attempted using stochastic filters (Becker et al. 2008).

Summarily, the different methods of tremor estimation are based on sensing the displacement, velocity, acceleration, gyroscopic parameters, and electromyography (Bridgeman and Arsham 2017; Veluvolu and Ang 2011b; Teskey et al. 2012). Mostly, accelerometer is used for tremor measurement for the purpose of kinematic and dynamic studies of hand (Kim et al. 2009a; Zhang et al. 2011). However, accelerometer, being an inertial sensor, cannot predict the fatigue. To measure the muscle fatigue in time and frequency domain, surface electromyography (sEMG) has been suggested as the best technique (Galinsky et al. 1990; Chen and Chen 2020; Cifrek et al. 2009a).

Feature extraction and classification are main tasks to evaluate the tremor. Statistical measures of sEMG spectral parameters have been widely used for characterization of muscle fatigue (Basmajian and Luca 1985; Slack and Ma 2007a). The standard parameter of measurement of fatigue is median frequency (Chandra et al. 2018). Measurement of amplitude of sEMG, i.e., action potential, is also a widely accepted parameter (Bo et al. 2011; Ackmann et al. 1977). Previous researchers have reported attributes like root mean square (rms) (Shenoy et al. 2008), time domain parameters (Fougner et al. 2011), time frequency representation (Wang et al. 2006), auto regressive (AR) coefficients (Graupe and Cline 1975), multivariate AR model (Hu and Nenov 2004), sequential feedforward selection (Hargrove et al. 2009), etc. To reduce the vector dimensions of EMG features, various tools like discriminant analysis, prediction probability, and principal component analysis (PCA) (Englehart et al. 1999) have been used.

For suppression of hand tremor, the use of bandpass and high pass filters is a good approach as explained in (Zhang and Ang 2006). Some authors have used the fuzzy

logic proportional derivative controller to suppress the tremor (Bó et al. 2011). Tremor can be suppressed with proportional integral controller by means of functional electrical stimulation (FES) (Gallego et al. 2013). Tremor can also be suppressed with impedance-based approach in addition to FES by increasing the viscosity of muscles (Bó et al. 2014). With repetitive control (RC), the tremor is suppressed. With this approach, one need not modify the joint dynamics (Freeman et al. 2015). RC scheme is structurally efficient though it is not considered having a general form. Since distal joints are stronger than proximal joints, FES-based tremor suppression was found better for tremor in wrist (Bain 2002). Surface electromyography (sEMG) was used for measuring muscle fatigue and was found a faithful measure for assessment in both time and frequency domain (Cifrek et al. 2009b). Though accelerometer was used for dynamic and kinematic study of hand tremor, the tremor cannot be assessed with accelerometer alone as inertial sensors cannot capture the induced tremor (Kim et al. 2009b).

EMG-Based Tremor Sensing and Elimination

Spectral measure of sEMG provides the most used metric for physiological tremor (Slack and Ma 2007b). A decrement of the mean and median frequency of sEMG is certainly a standard measure of fatigue level; sometimes amplitude of the raw sEMG signal is also added in this list (Kallenberg et al. 2007). If proper feature extraction and classification techniques are used for sEMG signal, it can provide good results to predict the tremor. K-nearest neighbor and SVM are popular classifiers for EMG signal (Oskoei and Hu 2008). Combination of different neural and fuzzy techniques for classification also provides good results (Kim et al. 2004). Many researchers have used feed-forward backpropagation neural network and Fuzzy-based classifiers (Ajiboye and Weir 2005). Some researchers have used wavelet neural network to classify the sEMG (Subasi et al. 2006). The accuracy obtained was 90.7%. By decoding the ten individual finger flexion and extension with 32 channel surface sEMG signal for transradial amputees, the accuracy obtained was 90% (Tenore et al. 2008).

An EMG-based tremor sensing, signal processing, separation from volunteer motion, and elimination have been described in this section. Further, analysis of the separated tremor motion was done by extracting its characterizing features and subsequent classification. The remaining volunteer motion corresponding to surgical action may be transmitted to the surgical arms of the slave robot after necessary kinematics and inverse kinematics algorithms in the motion controller module of the surgical robot.

EMG Signal Acquisition

Total 14 subjects were recruited (eight males, six females, weight 58–74 kg, and height 154–180 cm). The demographic details of subjects are given in Table 1. Data was collected using in-house developed active electrodes (Fig. 13). Process of recording and handling of phantom was explained to subjects, and written consent

Table 1 Subject details

S. no.	Age (years)	Weight (kg.)	Height (cm.)
1.	26	58	154
2.	25	63	163
3.	24	59	163
4.	23	70	170
5.	29	70	166
6.	26	72	177
7.	26	58	165
8.	24	62	167
9.	19	50	170
10.	28	65	180
11.	44	64	162
12.	70	68	165
13.	68	72	169
14.	49	74	170

Fig. 13 Active electrode used for sEMG signal acquisition

was taken from all the subjects before the data collection. Ethical principles of medical research were followed during the whole process of signal acquisition (World Medical Association 2013).

During recording, the subjects were kept warm as cool limbs slow down the nerve conduction (Naik et al. 2016; Chang 2019). Electrode site was cleaned with mild soap and water. 4-channel raw EMG signal was acquired in two different trial conditions. During first trial, subjects were instructed to be in relaxed state as in Fig. 14 and the sEMG data was recorded by operating the phantom handle. The movement of phantom handle was kept similar to standard surgical hand movement. No fatigue was, thus, developed during this phase.

During the second set of trials of sEMG acquisition (Fig. 15), a weight of 2.7 Kg was placed on the subject's forearm in sagittal plane followed by hand exercise with hand gripper for about 4 min because of which sufficient fatigue and tremor was developed.

Four electrodes were placed on the muscles to acquire the sEMG signal (Haris et al. 2015) at the positions of Flexor carpi ulnaris and Palmaris longus and at Extensor carpi ulnaris and Extensor carpi radius. Between trials, sufficient time was given to subjects to get normalized. These electrodes were put as per the norms of

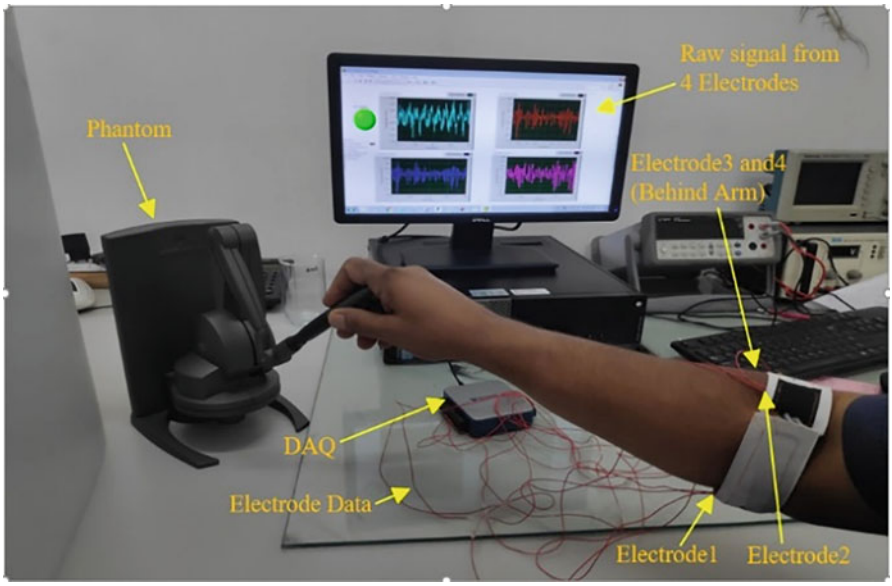

Fig. 14 Experimental setup for signal acquisition in relax mode

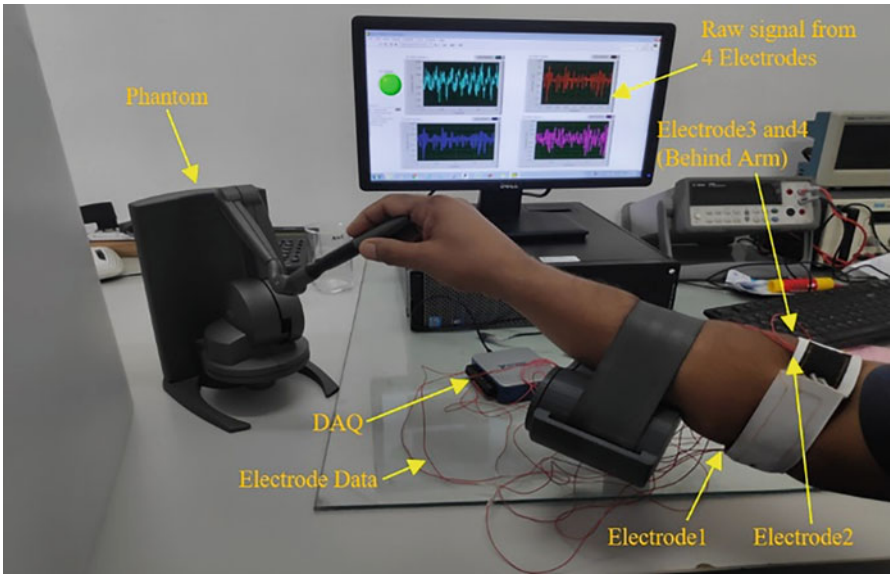

Fig. 15 Experimental setup for signal acquisition in tremor mode

Surface Electromyography for the Non-Invasive Assessment of Muscles (SENIAM) (Hermens et al. 2000). The sampling rate was set at 512 samples/sec and recording time 30 s. Amplification of the EMG signal was adjusted so that maximum output

voltage of active electrode was in the medium range of about 2.5 volts rms (approx.) during full contraction of muscles. sEMG signal was acquired with data acquisition card NI USB 6210 of National Instruments, UK.

EMG Signal Processing

Figure 16 shows the plot of 4-channel raw sEMG signal in relaxed state, and Fig. 17 is the raw signal obtained in tremor mode. In order to remove the power line interference of 50 Hz, the recorded raw signal was passed through a Butterworth bandstop filter of order 9. For this filter, passband ripple was selected as −2 dB and stop band attenuation as −50 dB. The edge frequencies were taken at 1, 3, 50, and 100 Hz. The transfer function of this filter was calculated as:

$$H_a(s) = \frac{1.31}{s^9 + 1.13s^8 + 4.34s^7 + 4.68s^6 + 7.07s^5 + 7.28s^4 + 5.1s^3 + 7.31s^2 + 3.74s + 1.3} \quad (1)$$

Another bandpass filter of 7th order with bandpass frequency of 3–15 Hz was used to remove the signals other than tremor. This Butterworth filter was designed for passband ripples of 1 dB and stop band attenuation of 40 dB. The transfer function of this was obtained as:

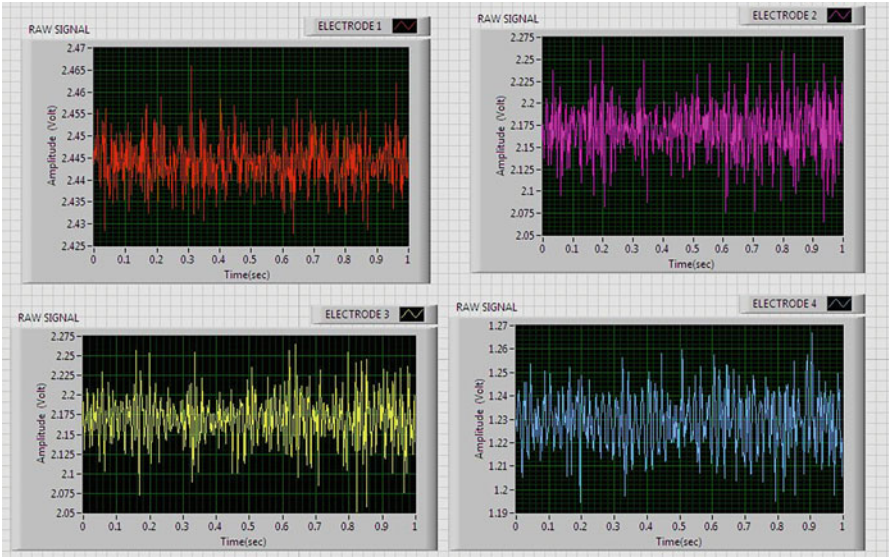

Fig. 16 Raw signal of electrodes in relax mode

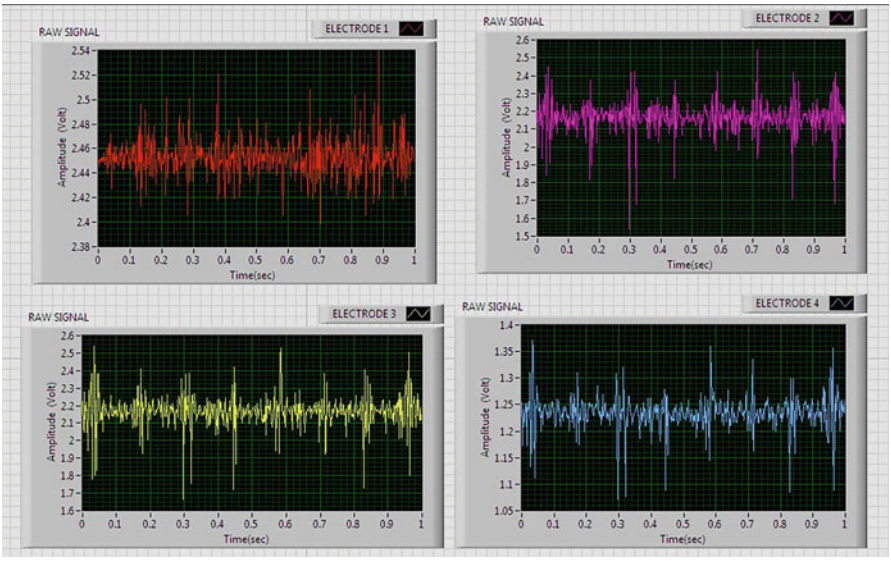

Fig. 17 Raw signal of electrodes in tremor mode

$$H_a(s) = \frac{1.32}{s^7 + 4.66s^6 + 11.53s^5 + 14.97s^4 + 14.87s^3 + 10.03s^2 + 4.09s + 1.31} \tag{2}$$

The filtered sEMG signal for both relax and tremor state is shown in Figs. 18 and 19. After filtering, the signal is ready for further analysis and tremor classification.

Feature Extraction

The 4-channel sEMG signals were analyzed with 1 s epoch without overlapping. Six linear features were extracted. These features are Mean, Standard Deviation, Skewness, Kurtosis, Zero-Crossing, and Slope Sign Change (Duan et al. 2016). The features were selected such that they have a significant relationship with tremor intensity (Das et al. 2001). To differentiate tremor from relaxed state, data was arranged in the tabular format required for classification. Since four electrodes were used, there would be 24 columns (6 × 4). One additional column for class, i.e., "tremor" or "relaxed," was kept. Data was acquired in four different time slots of 30 s each for two different hand movements (relaxed and tremor). Thus, 120 feature vectors of 30 s for relaxed and 120 feature vectors of 30 s for tremor state were generated. Hence, the dimension of the feature dataset was 6000 (240 rows × 25 columns). The model output determines the severity of tremor. The description of selected features is as below:

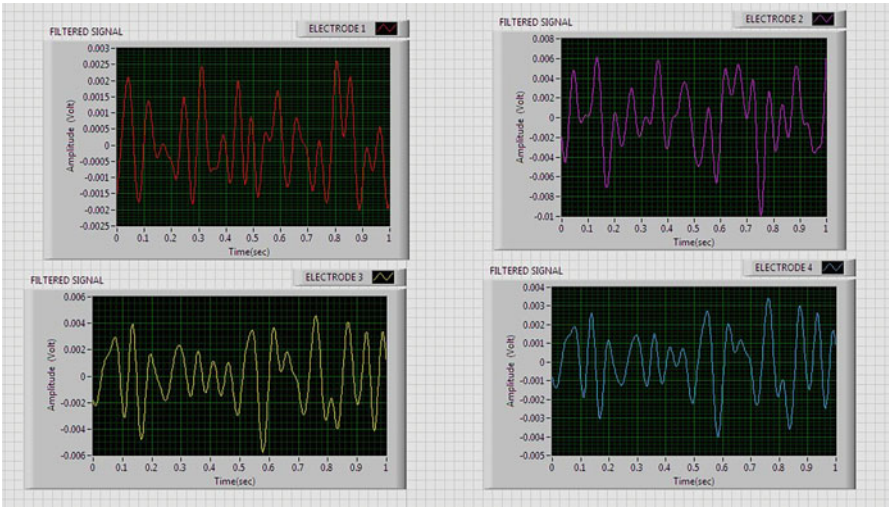

Fig. 18 Filtered signal of electrodes in relax mode

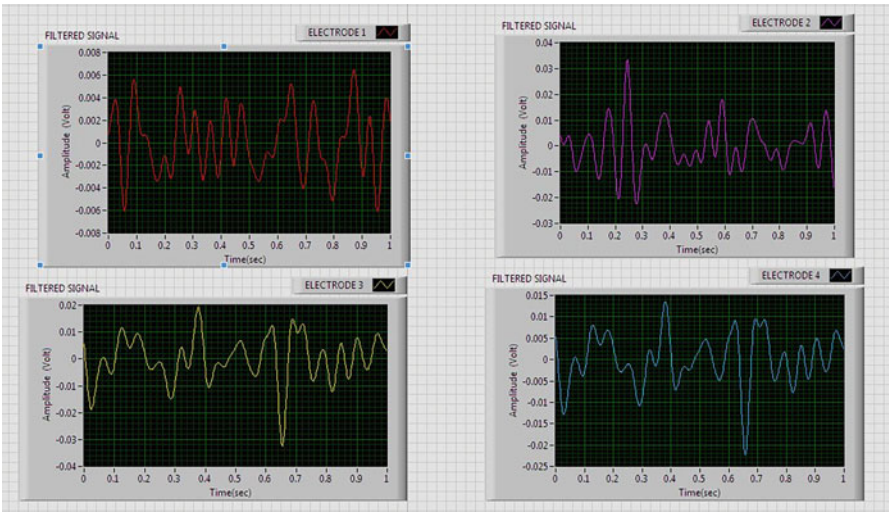

Fig. 19 Filtered signal of electrodes in tremor mode

Mean

Mean is a measure of central tendency which is calculated by aggregating all the values of the dataset by sum operation and then dividing it by the size of dataset. Mathematically, it is defined as:

$$\text{Mean of Dataset } \mu = \frac{x_1 + x_2 + \ldots + x_n}{n} = \frac{\sum_{i=1}^{N} x_i}{n} \tag{3}$$

Standard Deviation

It measures the amount of variation in the dataset from the mean value. If it is low, dataset values are close to one another and very close to the mean, and if it is large, it represents the values are far apart from one another and far from mean. Mathematically, it is represented as:

$$\sigma = \sqrt{\frac{\sum (x_i - \mu)^2}{N}} \tag{4}$$

where σ: population standard deviation; N: size of the population; x_i: each value from the population; μ: The population mean

Skewness

Skewness is a measure of the asymmetry of the probability distribution of a real-valued random variable about its mean. It may be +ve or –ve. In case of positive skew, tail of the probability distribution at the right side is longer as shown in Fig. 20a. It shows that maximum mass is concentrated toward the left of figure. In negative skew, the left tail is longer (Fig. 20b). Mathematically, Pearson's moment as coefficient of skewness is represented as:

$$\mu_3 = E\left[\left(\frac{X - \mu}{\sigma}\right)^3\right] = \frac{\mu_3}{\sigma_3} = \frac{E\left[(X - \mu)^3\right]}{\left(E\left[(X - \mu)^2\right]\right)^{3/2}} \tag{5}$$

Kurtosis

Kurtosis is a statistical measure that defines how heavily the tails of a distribution differ from the tails of a normal distribution. In other words, kurtosis identifies whether the tails of a given distribution contain extreme values. For univariate data, kurtosis is mathematically defined as:

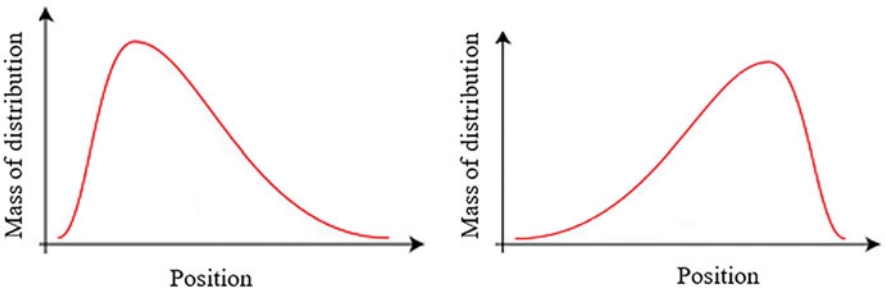

Fig. 20 (**a**) Positive skew. (**b**) Negative skew

$$\frac{\sum_{i=1}^{N}\left(Y_i-\overline{Y}\right)^4/N}{\sigma^4} \tag{6}$$

where Y_i's are the data points and σ is the standard deviation of the data. Since kurtosis is often compared with normal distribution and kurtosis value for normal distribution is 3, alternatively kurtosis is represented as:

$$\frac{\sum_{i=1}^{N}\left(Y_i-\overline{Y}\right)^4/N}{\sigma^4}-3 \tag{7}$$

Reason for calculating the kurtosis is to assess the sharpness of the input SEMG signal.

Zero-Crossing

A zero-crossing is a point where the sign of a mathematical function changes, represented by an intercept of the axis in the graph of the function. In image processing, zero-crossing represents the detection of an edge and is thus useful for finding contours.

Slope-Sign Change

This feature detects the change in mathematical sign of the derivative of the function. It is important because it processes the information whether a function is increasing or decreasing which helps to model the underlying data-generating function.

Principal Component Analysis

Principal Component Analysis (PCA) is used to reduce the dimensionality of the feature vector space. In this approach, the feature vector z (x_1, x_2, x_3. . .x_n), where x_n is the nth extracted feature for each subject, is decomposed into orthogonal basis vectors. First 3 principal components have been taken with maximum variance. Output of this stage was fed to the classification model.

Classification

Tremor is classified by acquiring the signal and then extracting features from it. Classification was done to differentiate between the physiological tremor in resting and contraction conditions of sEMG. Accuracy of classification was compared among four methods viz K-Nearest Neighbor (KNN), Logistic Regression, Support Vector Machine (SVM), and Random Forest.

K-Nearest Neighbor

K-Nearest Neighbor (KNN) is a supervised learning approach where the class of the respective feature vector is known for the training data set. Whole dataset was split into training and testing sets. The ratio of data was kept as 75:25. Selection of data for the two sets was random. The two output classes – "tremor" and "relax" – were considered. In KNN method, according to the number of nearest epochs selected for the system (value of K), output class is assigned to the test epoch by majority voting among the nearest epochs. Assigning the class to the respective testing data is done by calculating the distance of the testing feature vector with all training feature vectors. The various steps for KNN classification are as follows:

1. Choose the value of K.
2. Calculate distance of present testing dataset from all the training dataset.
3. Sort the calculated distance.
4. Find out the number of different classes for the first K nearest distance data.
5. Assign that class to the present testing data whose number is maximum.
6. Continue steps 2–5 for the complete test dataset.

Logistic Regression

It is a probabilistic supervised learning technique in which, primarily, maximum likelihood estimation is done given the parameter vectors. The parameter vector should be selected such that the probability of all the observed targets is maximized. Since the data points are identically and independently distributed, product of each predicted data point can be taken, and after taking logarithm of this product, the log sum can be maximized.

Support Vector Machine

It is a binary classification algorithm which assigns either 1 or -1 to the data points. Given the data points ($x_1, x_2 \ldots x_n$) and the corresponding label values ($y_1, y_2 \ldots y_n$), optimal margin classifier is trained to find a hyperplane which is at the farthest distance from the support vector(s). Support vector(s) are the data points which are at the minimum distance from the hyperplane, and our objective then becomes to select a hyperplane which is at maximum distance from the data points.

Random Forest

Random Forest is an aggregate predictor of decision trees. Decision trees greedily choose a feature split based on the impurity function score. Two impurity functions are used, viz Entropy and Gini Index. The feature which gives the maximum difference in impurity before and after applying the feature split is chosen for splitting. However, decision trees are prone to overfitting, and to deal with this problem, random forests are used as bagging bootstrap aggregator in which many decision trees are trained and each decision tree is supplied with a random subset of total features, and at the prediction time, voting is used for classification. This also deals with missing features problem in the dataset.

Results and Analysis

All the trials were conducted successfully, and subjects were healthy after trials. All the 14 subjects participated in the study for sample collection, and the analysis was carried out in three steps, i.e., time domain analysis, frequency domain analysis, and classification to know the total behavior of tremor signal.

Time Domain Analysis

Accuracy of voluntary signal depends upon the filtering of signal from raw signal. It was very much required to develop the optimized filter to get the tremor signal free from noise. The signals presented in Figs. 4 and 5 clearly demonstrate the change in amplitude from relaxed state to tremor state. In time domain, estimation of tremor becomes visible with the change in shape of signal. Figure 7 demonstrates the filtered tremor signal with different values of amplitude. Table 2 shows the increase in tremor values during fatigue.

Frequency Domain Analysis

Frequency domain analysis of tremor involves the calculation of median frequency and power contained in the sEMG signal. The sEMG median frequency was determined for all the subjects for different actions during surgery, and the results are presented in Fig. 21. These plots show decrease in median frequency for all four electrode signals during tremor. The decrement of median frequency indicates the existence of tremor due to fatigue. The power of sEMG signal is depicted in Fig. 22 for both tremor and relax states. It is clear that the power contained in the signal increases during tremor.

Classification

PCA was carried out, and the components of maximum variance were obtained. Two, three, four, and five components were evaluated one by one. All four classifier models were fed the PCA data to classify the tremor in relaxed and tremor states. Classification accuracy measures the ratio of correct predictions to the total number of cases evaluated. Table 3 shows the classification accuracy for PCA components 2, 3, 4, and 5 for all the classifiers. For KNN classifier, different values of K ranging from 4 to 7 have been considered. It can be seen from the obtained result that the accuracy increases for every classifier when the number of PCA components increases from 2 to 4. However, it does not change with further increase of PCA components to 5. The number of PCA components was finally selected as 4 (PC_1 to PC_4).

Table 2 Amplitude of filtered signal in relax and tremor mode of 4 electrodes

Mode	Electrode 1	Electrode 2	Electrode 3	Electrode 4
Relax	0.0038	0.008	0.008	0.006
Tremor	0.006	0.029	0.028	0.018
Increased amplitude (times)	**1.58**	**3.6**	**3.5**	**3**

Bold data are the increased amplitude (times) of tremor signal

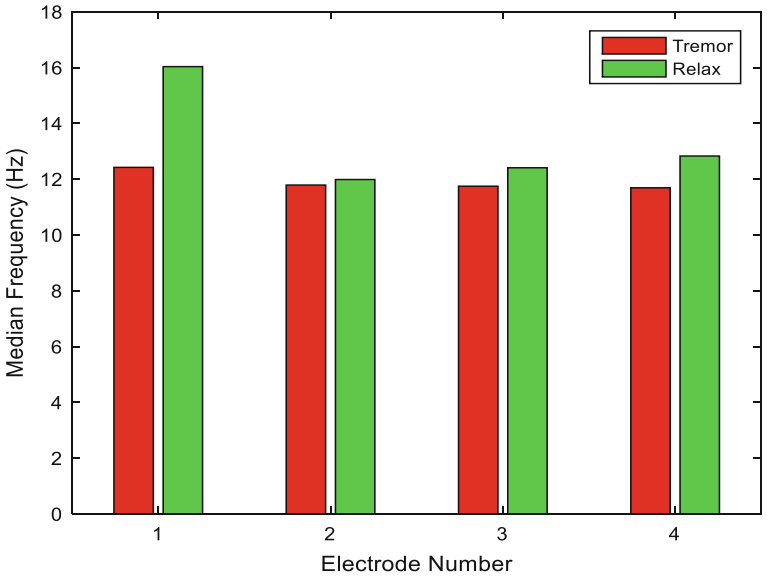

Fig. 21 Median frequency of sEMG signal in relaxed and tremor states

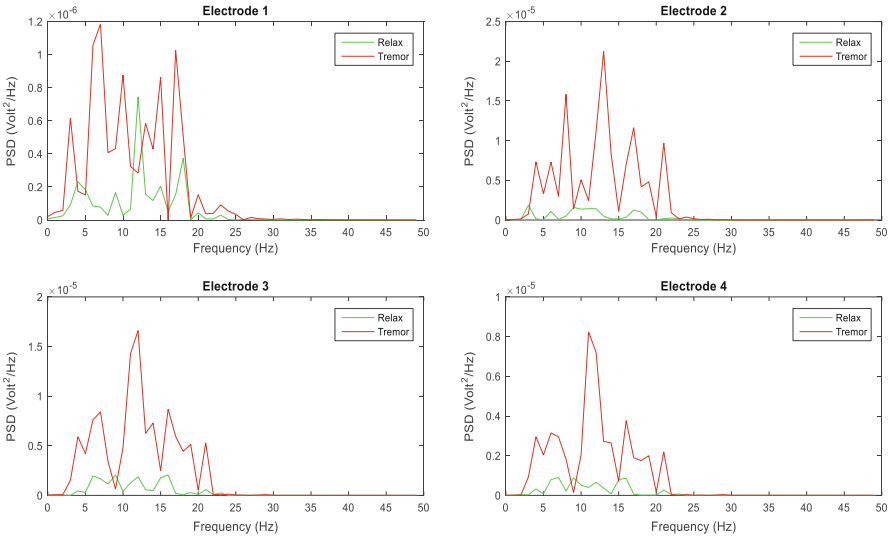

Fig. 22 Power of 4 electrodes in relax and tremor mode

Another conclusion that can be drawn is that for KNN classifier, the increase in size of neighborhood beyond 5 does not increase the accuracy. So, if KNN is to be used for classification, K may be taken as 5.

Table 3 Accuracy of different classifiers (in %) for various number of PCA components

No. of PCA components	Accuracy of KNN classifier with different values of K				Logistic regression	SVM	Random forest
	$K = 4$	$K = 5$	$K = 6$	$K = 7$			
2	96.5	97.2	97.3	97.3	98.4	99.2	100
3	97.7	98.0	98.0	98.0	99.5	99.3	100
4	98.2	98.4	98.4	98.4	99.6	99.5	100
5	98.2	98.4	98.4	98.4	99.6	99.5	100

The third observation is that different classifiers can be ranked from KNN to be the least accurate to Random Forest to be the most accurate. For KNN classifier, the maximum accuracy obtained was 98.4% for $K \geq 5$ and PCA components $\geq$4. For the second classifier – Logistic regression, the maximum accuracy was 99.6%, and for third classifier – Support Vector Machine, the maximum accuracy obtained was 99.5%. Fourth classifier (Random Forest) gave an accuracy of 100% for all components of PCA. From these values, it can be said that Random Forest classifier is the best for classification of tremor signal.

Conclusion

Researchers have worked since long to predict tremor in human arm so that it can be stopped. Present system has been designed, developed, and validated by using sEMG for measurement, analysis, and classification of tremor. Analysis was performed on relax and tremor data of subjects to identify the generated tremor. This method ensures that the tremor component is fully extracted without any damage or distortion to the rest of the sEMG signal. The sEMG signal, with muscle fatigue, was filtered with efficient Butterworth filters of 9th and 7th order which allow bare minimum ripples in the pass band and maximum attenuation in the stop band. Six features viz Mean, Standard Deviation, Skewness, Kurtosis, Zero-Crossing, and Slope Sign Change were extracted. Principal Component Analysis was done to prune the number of features. First, four PCA components were fed to the classifier. The classification of the fatigue was implemented on 14 subjects. Results show the decrease in median frequency of muscle signal and increase in sEMG signal power during tremor compared to relaxed state. Classification was performed with four classifiers viz K-Nearest Neighbor, Logistic Regression, Support Vector Machine, and Random Forest. Random Forest Classifier was found to be the best as the accuracy obtained with this was highest.

Abstract

Blood pressure (BP) is an important physiological parameter used in the diagnosis of many life-threatening diseases such as heart attack, ischemic stroke, hypertension, vascular disease, hypotension, and many others. It is directly connected to human life, it plays an important role in the diagnosis and monitoring of various health ailments. Accurate and precise BP measurement is always a priority for both researchers and medical practitioners. With recent technological advancements, the issue of accurate measurements, standardization of techniques, and efforts toward adopting some uniform methods remain debatable, particularly traceability in dynamic mode. There are numerous types of BP measuring devices in the market. The accuracy of these devices is always an unresolved issue for researchers, medical practitioners, and metrologists. Several national and international standards recommend methods for calibrating these devices, but very few devices/systems/instruments are available to calibrate these devices convincingly in SI traceable units. This chapter provides an in-depth explanation of various noninvasive BP measuring techniques as well as available national and international standards. Some recent advances in BP measurement, as well as challenges addressed and challenges ahead in their calibration, are also discussed.

Blood pressure · Calibration · Testing · Accurate · Instruments · Techniques

Introduction

Regular blood pressure (BP) measurement is required for monitoring the health of the heart and its associated illnesses. BP measurement is commonly used to diagnose high blood pressure (HBP), hypertension, cardiovascular disease, heart attack, chronic renal disease, kidney failure, stroke, dementia, and peripheral vascular disease (Landry et al. 2022; Avolio et al. 2022; Kitagawa et al. 2022; Kovell et al. 2022; Kim et al. 2020; Liu et al. 2012; Chen et al. 2012; Schutte et al. 2022). HBP affected approximately 1.13 billion people in 2015, accounting for 19% of all fatalities (NCD Risk Factor Collaboration (NCD-RisC) 2017; Forouzanfar et al. 2017). Uncontrolled blood pressure affects up to 80% of people with HBP, putting them at a higher risk of morbidity and death (Egan et al. 2019). Thirty percent of people have HBP or have an increase in BMI and age. With an aging population and

rising obesity rates, it is becoming increasingly important to diagnose, treat, and control hypertension (Leenen et al. 2010; Franklin et al. 1997; Kumar et al. 2021a, b; Lubin et al. 2020). An international study of more than 1.5 million people discovered that more than 70% of those taking HBP medication had frenzied BP (>130/80 mmHg) (Beaney et al. 2020; Gakidou et al. 2017). According to the World Health Organization (WHO), over 17.90 million people died worldwide in 2016, with cardiovascular disease being the leading cause. The global prevalence of high BP in people over the age of 18 is defined as systolic and diastolic pressures greater than or equal to 140 and 90 mmHg, respectively. The number of adults with high blood pressure nearly doubled from 594 million in 1975 to 1.13 billion in 2015, with low- and middle-income countries (LMICs) accounting for the majority of the increase. Only LMICs account for more than 75% of cardiovascular disease deaths (https://www.who.int/en/news-room/fact-sheets/detail/cardiovascular-diseases-(cvds). Accessed 02 Apr 2022; https://www.who.int/health-topics/cardiovascular-diseases/#tab=tab_1. Accessed 02 Apr 2022; https://newsroom.heart.org/news/acc-aha-hfsa-issue-heart-failure-guideline. Accessed 02 Apr 2022). Statistics clearly reveals that BP measurements are extremely important in everyone's life.

Blood pressure measurement was made by the great scientist Stephan Hales, which is still regarded as a remarkable discovery of the eighteenth century (Booth 1977). The significance of BP measurements can also be understood by the famous statement of the great physiologist Johannes Mülle on the discovery of BP, which states that "the discovery of the blood pressure was more important than the discovery of the blood" (Booth 1977). Following the discovery of the BP, many researchers continued to focus their attention and efforts on BP, resulting in the development of various noninvasive blood pressure (NIBP) measurement techniques, which are summarizd in this chapter.

There are various NIBP measuring instruments and devices on the market that measure blood pressure using various principles (Kumar et al. 2021b). BP is measured using auscultatory techniques based on Mercury, but Mercury is a toxic element that poses health risks to humans. According to the Minamata Convention recommendations, mercury-based medical devices are either prohibited in medical practices or suggested to be phased out with alternative techniques by 2025 (see www.mercuryconvention.org for Minamata Convention on Mercury, United Nations Environment Programme, September 2017). In contrast, mercury-based sphygmomanometers are still used in some clinical settings as a Gold Standard for blood pressure measurements. The accuracy of blood pressure measurement with a mercury sphygmomanometer is also dependent on the medical practitioners' visibility and hearing ability (Babbs 2015; Mion and Pierin 1998).

NIBP Measuring Techniques

Various noninvasive BP measurement techniques thus developed, commercially available, and in use are depicted in Fig. 1.

Fig. 1 Various noninvasive blood pressure measuring techniques

Auscultatory Technique

One of the most widely used methods for measuring blood pressure is the auscultatory technique. It is a noninvasive method of measuring blood pressure. Despite being based on mercury and having been invented in 1896, it is still commonly referred to as the "Golden Standard." Because mercury is hazardous to human health, its use is prohibited in all public places, including medical facilities, research facilities, and laboratories. The use of mercury in sphygmomanometers is no longer as common as it once was in clinical practice (Penaz 1973). The auscultatory method of measuring blood pressure necessitates the use of skilled personnel. Moreover, the operator's capability of hearing and vision plays an important role in determining the BP readings. A typical traditional mercury sphygmomanometer is shown in Fig. 2.

The auscultatory method entails wrapping a cuff around the patient's upper arm of the hand and inflating it to a pressure of approximately 160–180 mmHg until the artery is not completely closed, resulting in the closure of blood flow through the artery. There is no audible sound in these circumstances. The sound produced when the cuff pressure is deflated is known as the Korotkoff sound. The frequency of the generated sound is so low that it cannot be heard by the human ear. A stethoscope is used by the medical practitioner or operator to listen to this Korotkoff sound. Korotkoff sound changes during the very short duration of cuff pressure deflation, which is classified into five different phases as shown in Fig. 3.

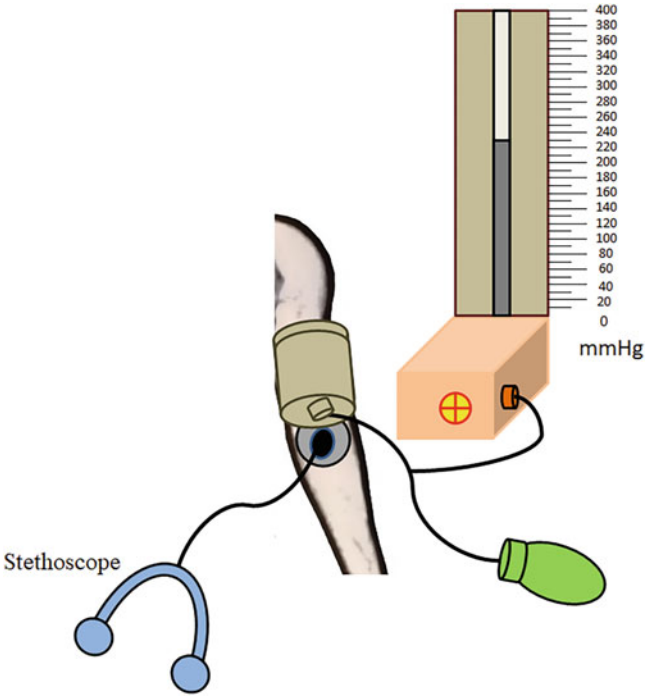

Fig. 2 Pictorial view of the traditional mercury sphygmomanometer

Phase	Korotkoff Sound	Pressure (in mmHg)
1	Thud	120 (Systolic)
2	A blowing noise	110
3	A softer thud	100
4	A disappearing noise	90
5	Nothing	80 (Diastolic)

Fig. 3 Different phases of the korotkoff sound generated during the deflation of the cuff pressure at the time of BP measurement using the auscultatory techniques

Phase 1 begins when the cuff pressure first begins to inflate to the point where blood can flow. A thud (clear tapping) sound is produced in Phase 1 to represent systolic blood pressure (SBP), and a blowing noise (softening of the tapping and a swishing element) is produced in Phase 2. A softer thud is associated with phase

3. Figure 3 shows the Phase 4, the Korotkoff sound begins to disappear (abrupt muffling), and in Phase 5, there is no sound available, which is known as diastolic blood pressure (DBP). When the artery just begins to open and the artery pressure rises above the cuff pressure, a phase Korotkoff sound is produced, which is referred to as SBP. When this happens, the blood in the artery has a turbulent flow as it travels through the partially compressed artery with the cuff pressure, and this sound does not stop even as the cuff pressure decreases. When the phase 5 Korotkoff sound (nothing or no sound) is produced, the pressure is considered to be in the DBP. In the century since its invention, the mercury sphygmomanometer has undergone no significant design changes. Mercury sphygmomanometers have a very simple design and basic operating principle, which means that there are very few points that could go wrong with them in comparison to other BP devices. This is the reason why they were/are so popular. One other glaring issue is the widespread utilization of mercury, which is inherently dangerous (see www.mercuryconvention.org for Minamata Convention on Mercury, United Nations Environment Programme, September 2017; Babbs 2015; Mion and Pierin 1998; Bailey and Bauer 1993).

Oscillometric Technique

In the year 1876, Marey was the first person to propose using the oscillometric approach (Marey 1876). Marey noticed the pressure oscillations in the cuff and recorded them for the period of the cuff pressure deflation, at the point of maximum oscillations corresponding to the arterial pressure. This was the first time that the oscillometric method had been used. When the pressure in the cuff rose above the SBP, the oscillations began. They continued even when the DBP dropped below the SBP.

One of the most common types of automatic NIBP approaches is known as the oscillometric technique. It is not necessary to wrap the cuff around the brachial artery when utilizing this method. In the oscillometric method, a microcontroller is utilized to perform the functions of controlling the motor, reading the analogue signal from the pressure sensor, converting the analogue signal to its digital equivalent, and estimating the SBP and DBP values on the logic that has been programmed. The amplitude of the pressure sensor's fluctuations is extremely minimal (approximate in the order of μV to mV). Therefore, it is necessary to increase the strength of the amplitude before transmitting the results to the microcontroller. Because the sensor's output is at a low level and is susceptible to noise from the environment, a filter is utilized to minimize the noise in the signal. Furthermore, the SBP and DBP are determined through the use of empirically derived algorithm. A pictorial view of the oscillometric method for BP measurement technique is shown in Fig. 4 (Mauck et al. 1980; Amoore et al. 2008; Zheng et al. 2011).

The most significant advantage of this method over the others is that the cuff position has no effect on the BP measurement. Another potential advantage of the method is that it is less susceptible to outside noises, with the exception of mechanical motion-induced low-frequency vibrations. The procedure is more convenient for patients, particularly in terms of making the cuff placement and removal easier.

Fig. 4 Photograph of the oscillometric method-based BP device during the BP measurement

Another advantage of this method over the auscultatory technique is that no stethoscope is required. The most significant disadvantage of using this method is that the algorithm used to estimate the SBP and DBP varies from device to device (Zheng et al. 2011; Jazbinsek et al. 2010).

Finger Penaz Technique

Continuous noninvasive arterial BP measurements are performed using the Penaz technique, which is a noninvasive (indirect) method for BP measurement. This technique was introduced in 1972 by Jan Penaz. In this technique the arterial pulse in finger was detected by photoplethysmograph (PPG). It is a simple and low-cost optical technique used to detect variations in the microvascular bed of tissue blood volume. It operates on the unloaded artery principle. In this method, a cuff is wrapped around the finger and inflated while the artery is not completely collapsed. An electro manometer attached to a cuff that measures cuff pressure after an artery has collapsed. The Penaz method keeps the finger inside the cuff. Because the close loop control system modulates the cuff pressure, the artery thickness remains constant. When cuff pressure is used, the artery thickness and intra-arterial pressure vary naturally. To maintain a constant transmural pressure, the modulating cuff pressure must be changed at the same rate as the intra-arterial pressure, which is inversely proportional. The closed loop control system is constantly working to maintain a consistent photoplethysmographic output at a constant nonzero transmural pressure. When the artery reached a zero transmural pressure state, the cuff pressure remained constant for arterial pressure and BP was recorded in a continuous and indirect manner. The plethysmograph output is used to operate a servo-loop, which quickly changes the cuff pressure to maintain a steady output while keeping the artery partially open. The oscillations of the cuff pressure are determined and found to resemble the arterial pressure in the majority of cases. This method measures SBP and DBP changes more accurately, but both SBP and DBP may be underestimated at times when compared to brachial artery BP measurements. Due to its inconvenient nature

and erroneous absolute BP measurements, this approach is currently underutilized in clinical settings. Figure 5 depicts a schematic diagram of the fundamental working principle of this technique (Penaz 1973; Van Egmond et al. 1985).

Ultrasound Technique

When the patient's pulse is difficult to detect with a stethoscope and the patient is hemodynamically unstable, the ultrasonic method is used to measure blood pressure. In this method, ultrasonic transducers are used to transmit and detect ultrasound around the artery while it is covered by the cuff, as shown in Fig. 6. Before compressing the artery, the cuff is inflated to obtain an accurate blood pressure reading. When the cuff pressure begins to fall, the reflected ultrasound undergoes a Doppler phase shift, causing the artery wall to begin moving at SBP. The DBP is the pressure measured after the arterial motion has either stopped or reached its end point. Utilizing

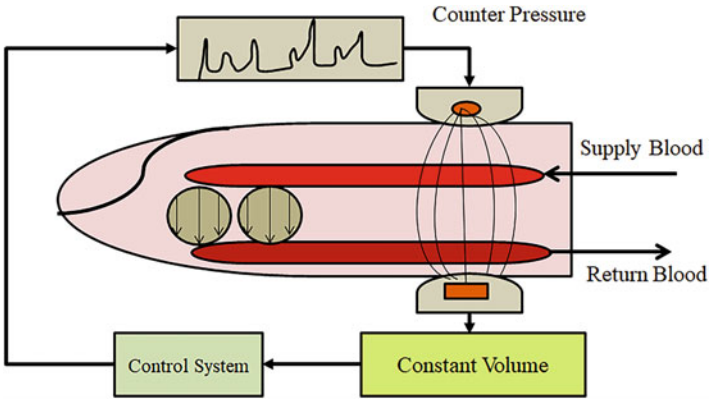

Fig. 5 Block diagram of the working principle of the Finger Penaz technique

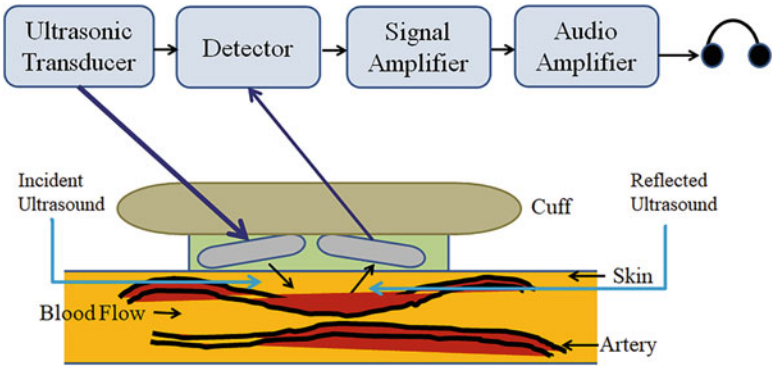

Fig. 6 Block diagram of the working principle of the ultrasonic technique

this technique, the user can also determine the ankle-arm index and blood flow in the infants and children using this method. Additionally, blood flow can also be determined (Elseed et al. 1973; Senador et al. 2022; Zakrzewski et al. 2018).

Tonometry Technique

Tonometry is essentially a noninvasive continuous BP measurement method. It uses a superficial artery waveform splinted (or partially squeezed) against a bone. In this technique, multiple or an array of pressure sensors, similar to cuff pressure, are used directly on the wrist to locate an artery slightly underneath and at the center of the sensor. Although pressure sensors are used to measure the beat-to-beat waveform of patients' wrists in this method, it is still considered the most accurate. Because calibration is required for each individual patient, the device cannot be deemed suitable for regular users. In the critical care unit (ICU), it is typically utilized during surgical procedures, particularly when patients are under the influence of anesthesia (Drzewiecki et al. 1983). The schematic diagram is shown in Fig. 7.

Wearable Sensor-Based Cuffless Technique

Continuous blood pressure measurement using this method is an invasive technique that is painful, uncomfortable, and carries the risk of infection. Given the variability of blood pressure, there is no viable solution for outpatient continuous BP measurement that has been shown to improve patient outcomes. Wearable sensors-based cuffless technique for continuous NIBP measurement is a new option for long-term monitoring and preventative care at home. Traditional cuff-based BP measuring instruments and devices cause discomfort. PTT and PPG are used in the cuffless technique. Commercially available PTT and PPG equipment does not meet the AAMI/ISO guidelines for blood pressure measurements (mean difference 5 mmHg and standard deviation 8 mmHg). Magnetic sensors have been used to measure PTT, vascular transit time (VTT), tonometry, and pulse wave velocity to address these constraints (PWV). The PAT is based on the heartbeat's journey from the heart to the finger's peripheral artery, as determined by the R-wave of the ECG and the peak of

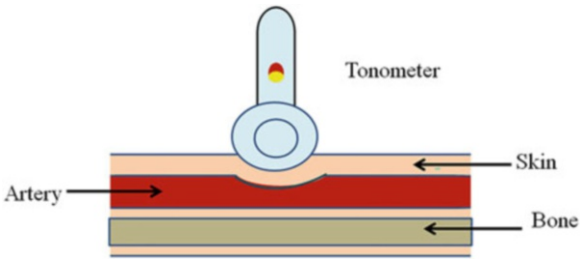

Fig. 7 Schematic diagram of the tonometry technique

the PPG signal. PTT is the interval between the ECG R-wave and the first PPG derivative. The VTT is used in phonocardiography to estimate the delay between the PPG fingertip and the chest. Several recent studies used a mobile phone camera to measure blood pressure, while others used the Windkessel model and neural system (Papadopoulos et al. 1993; Le et al. 2020; Elgendi et al. 2019; Khalid et al. 2020).

This section discusses various NIBP measurement techniques. Figure 8 depicts a comparative description of the benefits (in green) and drawbacks (in blue) associated with these NIBP techniques.

Location for BP Measurements

The location of the BP measurement is one of the important issues in BP measurement techniques. Several locations of the body being used for BP measurement are shown in Fig. 9.

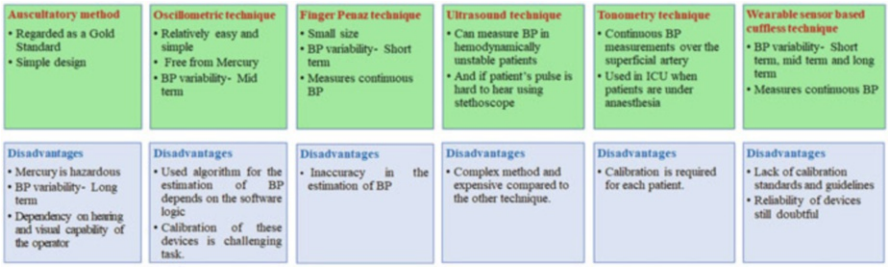

Fig. 8 Advantages and disadvantages of NIBP measuring techniques

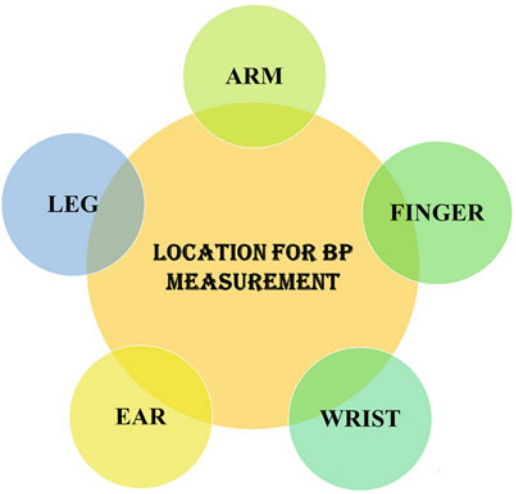

Fig. 9 Various sites for the blood pressure measurement

Arm

The majority of blood pressure measurements are taken on the upper left and right arms. To the best of our knowledge, there is no technique for determining which part of the body is best suited for accurate blood pressure measurement. However, an observational study was conducted in the neuroscience intensive care unit (NSICU), a comprehensive stroke academic center, to examine blood pressure measurements in extremely ill patients with nervous diagnoses. Data from 82 patients was collected and documented over the course of 4 months. All of the patients' blood pressure (BP) was measured in four different locations at the same time, including the left upper arm (LUA), right upper arm (RUA), right wrist, and left wrist, with specially designed wrist cuffs. Wrist sites are not commonly used in regular blood pressure measurements. When other measurement sites are inconveniently unavailable, the wrist is used, but it is included in the inter-site comparison. Forty-one of the 80 participants in this study were men. According to reports, the LA and RA are the most commonly used NIBP measurement sites. Based on the literature, the mean difference between the LA and RA in the total pressure range of 0–30 mmHg was determined to be 7.877.23 mmHg, which is very significant because a 5 mmHg variation in the SBP makes a difference in opinion when deciding whether to intervene or withhold treatment (Siaron et al. 2020; O'Rourke 2002).

Leg

The leg is an important site of the human body for blood pressure measurement. P. Sareen et al. studied 250 patients who required anesthesia for surgery and compared their blood pressure levels in the legs and arms as part of the study. The average SBP in the arm was found to be 127.72 ± 15.65 mmHg while the average SBP in the leg was found to be 142.97 ± 22.18 mmHg. The BP in the arm was 80.67 mmHg as compared to 75.66 mmHg in the leg. The MBP of 96.34 ± 11.71 mmHg was observed in the arm while it was 98.24 ± 13.94 mmHg in the leg. When it comes to SBP readings, the calf measurement was found to be 15.25 mmHg higher as compared to hand measurement for an individual. It varied from a 25 mmHg in the arm compared to an 80 mmHg in the leg. The upper limb DBP was 5 mmHg higher than the lower limb DBP on an average (Sareen et al. 2012).

Finger

The blood pressure is measured on the patients' fingertips. There are numerous devices on the market for measuring blood pressure with the finger, but the accuracy of these devices is questionable. Blood pressure measurement on the finger is often less reliable, but it is still used in clinical settings. The benefits of measuring blood pressure on the finger include the ability to continuously monitor blood pressure

without discomfort and the ability to simply detect the patient's hypertensive tendency after surgery in the intensive care unit due to continuous BP pulse measurement as well as long-term BP recording and monitoring. The reading of the finger BP measurement is less reliable than the brachial artery (Stergiou et al. 2018; Sesler et al. 1991; Molhoek et al. 1984).

Wrist

BP is sometimes measured at the wrist using specialized devices. Because of their smaller size than arm devices, wrist devices can be used by obese people. When using wrist monitors, a systematic inaccuracy is introduced into BP measurements due to the hydrostatic effect of wrist position changes with regard to the heart. To reduce the possibility of systematic errors, keep the wrist level with the heart when taking blood pressure readings. While a series of readings are examined, it is impossible to know whether this was done retroactively. Wearable blood pressure monitors have the potential to provide highly reliable blood pressure readings, but more research is required (Sareen et al. 2012; Mitchell et al. 1964).

Ear

In a recent study, Xing et al. used a PPG-based technique to measure blood pressure at the ear site. A multi-Gaussian decomposition PPG for the in-ear was performed to reduce noises caused by the extraction process. A four-element Windkessel model was applied to PPG data to generate BP estimation algorithms. To validate this new strategy, 53 patients were enrolled for a 1-month follow-up and 17 for a 2-month follow-up, and it was discovered that SBP estimation accuracy improved using inertance-based pre-classification, while DBP showed less improvement (Xing et al. 2021).

Sources of Errors in the BP Measurements

Various sources of errors identified in the BP measurements are depicted in Fig. 10 and described in detail in this section.

Body Position

The position of the arm is one of the most crucial elements to consider. As the arm moves from the up to the down position, there exist variation of 5–6 mmHg in the pressure. This shift in pressure is attributed due to increase in the hydrostatic pressure. During the BP measurements, it is recommended that patients take the measurements while seated in a chair that has a back support (Mitchell et al. 1964; Netea et al. 2002, 2003; Webster et al. 1984; Pickering 1993; Verberk and Mieke 2016).

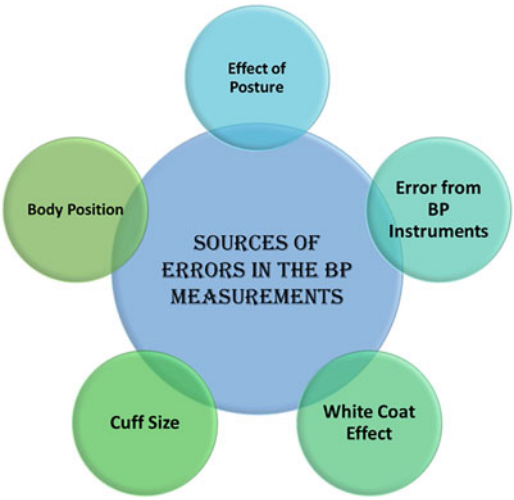

Fig. 10 Different types of sources of errors in blood pressure measurement

Cuff Size

The size of the cuff influences BP measurement and is the most common cause of BP overestimation and underestimation. The cuff should be chosen based on the patient's arm diameter. Except for the slimmest arms, properly sized cuffs reduce error. The British Hypertension Society (BHS) recommends a cuff size of 12.5–13 cm and a length of 35 cm for adults with an arm circumference greater than 33 cm (Pickering 1993; Maxwell et al. 1982; Van Montfrans et al. 1987).

Effect of Posture

The American Heart Association (AHA) recommends sitting as the best posture for measuring blood pressure (Pickering et al. 2005). According to Netea et al.'s study on 245 people of various ages, SBP was the same in both seated and supine postures, but there was a difference in DBP at the age of 30. The DBP in the seated position was approximately 10 mmHg higher than in the supine position; however, at age 70, the difference was only 2 mmHg. According to the research, BP measurements should be taken when the patient is calm and the arm is at heart level. Patients should thus choose the supine position for accurate blood pressure measurements (Netea et al. 1998).

White Coat Effect

When blood pressure is measured in a doctor's office, clinic, or hospital, it is found to be higher than in another location

shortly afterward. Recent research has established that when blood pressure is measured by operators wearing a white coat, this can cause anxiety, which is known

as the white coat effect (Jhalani et al. 2005). The white coat effect is observed to a greater or lesser extent in hypertension patients, but it is much less or absent in normotensive individuals. The distinction between clinics and ambulatory BP is reached. White coat hypertension refers to people whose clinic blood pressure is hypertensive but who are normotensive elsewhere (Verdecchia et al. 1995).

Error from BP Instruments

The key factor that determines the accuracy of the assessment of human BP is the measurement accuracy of the BP measuring instrument itself. The basic accuracy of the device is affected by a number of different phenomena, all of which are discussed above and contribute to the general decline in measurement accuracy. The measurement apparatus itself contains several errors, each of which is unique to a particular measurement technique. For instance, in a sphygmomanometer that uses mercury, the accuracy of the device is affected by factors such as the quality of the mercury and the diameter of the capillary. When it comes to aneroid sphygmomanometers, the precision of the pressure dial gauge that is utilized makes a significant contribution to the instrument's accuracy. The precision of the sensor, the accuracy of the bridge arrangement, and the quality of the excitation source are all potential causes of inaccuracy in oscillometric approaches. In addition to these major contributors, the software logic that is used to estimate SBP and DBP also contribute significantly (Cluett et al. 2021; Hwang et al. 2018).

International Standards and Recommendations for BP Devices

Indian Standards

The BP measuring devices for humans are covered by two Indian standards: IS 3390: 1988 and IS 7652: 1988. The first standard describes the mercurial sphygmomanometer's requirements, while the second specifies the aneroid sphygmomanometer's dimensions and other standards. According to IS 3390: 1988, all calibration must be completed against a standardized and validated reference mercury sphygmomanometer, starting with the highest pressure and then in decreasing orders of pressures at the rate of 2 mmHg per second without tapping. The IS 7652: 1988 stipulates that the three calibrations are required without tapping and with dropping pressures falling at a rate of about 2 mmHg per second. Calibrations are advised to be performed with the gauge in a vertical position and only after at least 24 h have been passed since the device was last used. It is recommended that observations be made sequentially, starting with the greatest pressure and working down in multiples of 30 mmHg. After the initial calibration has been completed for 6 h, a second calibration has to be done in the same manner, but with the gauge angled 45° toward the back (Indian Standard IS 3390 1988; Indian Standard IS 7652 1988).

World Health Organization (WHO) Guidelines

The WHO guidelines (2020) is the revised document of WHO guidelines (2005) for BP measurement devices. The revised documents amicably address the major concerns of the developing economies wherein access and availability of the accurate, precise, and high-quality BP devices are not sufficient and adequate. It stipulated the technical specifications for NIBP devices with a cuff, their specific characteristics, procedure for calibration, maintenance, and regulatory requirements. It further stipulates that the mercury-based appliances should be checked to confirm that the column of mercury is undamaged and upright, as well as the mercury meniscus is centered at zero. Calibration of aneroid sphygmomanometers is recommended to be performed by technical professionals half yearly or as suggested by the manufacturer to ensure accuracy within the acceptable limit. For digital devices, it is recommended to be calibrated against a reference manometer with an accuracy of 0.1 mmHg or compared with a well-maintained mercury sphygmomanometer with an accuracy ± 3 mmHg (WHO 2020).

OIML Recommendations

The technical documents on BP instruments recommended by the International Organization of Legal Metrology (OIML) are in two parts; one for noninvasive mechanical sphygmomanometers as OIML R16-1 and another for noninvasive automated sphygmomanometers as OIML R16-2.

According to OIML R16-1 recommendations, noninvasive mechanical sphygmomanometers and their related elements are utilized with an inflated cuff to measure arterial BP noninvasively. This recommendation covers sphygmomanometers with a mechanical pressure sensor and display used with a stethoscope or other manual techniques to detect *Korotkoff* sounds and inflate the cuff. *Korotkoff* sounds are a technique for measuring BP in the adults wherein sounds are heard above and closed artery when occluding pressure is gradually released, with the appearance of sounds that correspond to SBP, and the disappearance of sounds that correspond to DBP. To verify the first time, the maximum permissible error for measuring cuff pressure is 0.4 kPa (3 mmHg), and 0.5 kPa (4 mmHg) for using sphygmomanometers in the range of 15–25 °C and relative humidity of 20–85%. The sphygmomanometer must meet the maximum permissible error after 24 h at −20 °C and 70 °C with 85% relative humidity (International Recommendation OIML R 16-1 2002).

As per the scope of OIML R 16-2, the recommendations are specifically applicable to BP devices, which measures BP at the wrist, upper arm, and thigh. According to OIML R 16-2 recommendations, the NIBP system should have at least one cuff that is connected with the pneumatic system, one electromechanical transducer for measuring the cuff pressure, and a display to show the user the measured value of the pressure. Additionally, the system should have a pneumatic system that is connected with the cuff. During BP readings, the apparatus needs to have a deflation valve so that the air may be let out of the pneumatic system.

Kilopascals (kPa) or mmHg are the units of measurement that are suggested for use when referring to BP. The greatest amount of error that is acceptable in the cuff pressure indicator at any position along the scale range is ±0.4 kPa, which is equivalent to ±3 mmHg. It is advised that it be within ±4 mmHg in the event that it is being confirmed for the first time.

It is recommended that the observations conducted in the environmental conditions should be within 15–25 °C for ambient temperature and 20–85% RH for relative humidity. It is recommended to assess the performance of the BP measuring device by placing it in the climatic chamber at 5 °C for 24 h, followed by 24 h at 50 °C. Within the goal range of SBP and DBP, the air leakage must not exceed a pressure drop of 6 mmHg/min, and the deflation rate of the programmed deflation valve must be in the range 2–3 mmHg/s. The pressure should be released from the device at a rate of 260–15 mmHg within 10 s, and in the case of neonatal or new-born patients, the rate of pressure release should be less than 5 s at 20–0.7 kPa or 150–5 mmHg. There should be a provision for automated zero settings, and the device should have the capability to perform zero settings at the necessary interval. The device needs to be compatible with electromagnetic waves. After going through 10,000 simulated measurement cycles, the change in the cuff pressure indication should not be greater than 3 mmHg. This applies to the entire pressure range. On the display unit, the precision of the pressure value must be 1 mmHg (International Recommendation OIML R 16-1 2002).

Some Other Important Standards

The IEEE Standard 1708 defines wearable cuffless BP devices (WCBD) and evaluation processes. The authorization of the BP measuring instrument for performance evaluation, as recommended by the ESH standard (I.S. Association 2014; O'Brien et al. 2002), requires at least two trained observers. The procedure for calibrating WCBD is extremely difficult and varies from device to device. The observers must be familiar with the manufacturer's recommended operating instructions for each item; otherwise, an engineer from the manufacturer should be part of the evaluation team. The utilized sphygmomanometer must conform to ISO 81060-2:2013 or ANSI/AAMI SP10. Adult testing must include a minimum of 45 individuals, including at least 22 females and 22 men between the ages of 18 and 65, in accordance with ISO standards. Due to its complexity and length, the validation process is suggested by the ESH protocol to be divided into two parts. Twenty people are recruited in the first level, and any device that fails during this level is removed from the testing phase. After validating 20 participants, the data collected from various tests (e.g., static test, test with BP change from calibration point, test after a specific period of time after calibration) are individually analyzed and should be within 7 mmHg for both SBP and DBP measurements (I.S. Association 2014; O'Brien et al. 2002).

The above discussed various standards are summarized in concise form in Table 1.

Table 1 National and international standards for various BP devices

S.No.	National and international standard	Type of BP device	Some of the recommendations/ guidelines
1.	Indian standards: IS 3390: 1988 (63)	Mercury sphygmomanometer	1. All calibration shall be accomplished properly standardized and certified mercurial manometer. One calibration shall be made without tapping and with decreasing pressure only. Reading shall be taken at the highest point of scale and at all other points, which are multiples of 20 mm. The reading shall be taken with the pressure falling at a rate of 2 mm/s approximately **2. Leak test:** When the cuff of each completely assembled sphygmomanometer is tied around a rigid bar of appropriate diameter and each valve shall be subjected to an internal air pressure of 50, 150, and 300 mmHg. The instrument or the valve shall then be cut off from the air supply. The leakage rate of the completely assembled sphygmomanometer shall not exceed 10 mmHg per minute
2.	Indian standards: IS 7652: 1988 (64)	Aneroid sphygmomanometer	1. Three calibrations shall be made without tapping and with falling pressures only. The pressure shall be made to fall at a rate of approximately two millimeters per second. The first calibration shall be made only after at least 24 h have elapsed since the last application of the pressure to the instrument. The gauge shall be in vertical position. Readings shall be taken with decreasing pressure at the highest point of the scale and at all other points which are multiples of 30 millimeters. The pointer of the instrument shall be brought to an even division and the pressure read on the calibrating manometer and instrument under test are recorded. The second calibration shall be done not less than 6 h after the completion of the first, in the same manner as the first except that the gauge shall be inclined backward at an angle of 45” to the vertical

Table 1 (continued)

S.No.	National and international standard	Type of BP device	Some of the recommendations/ guidelines
			2. Each completely assembled sphygmomanometer and its valve shall be subjected to internal air pressure of 50,150, and 300 mmHg. The leakage shall not exceed 10 mm of mercury per minute when the sphygmomanometer or its valve is cut off from the air supply
3.	WHO (65)	Automated non-invasive blood pressure measuring devices with cuff	**1. Efficacy measure:** Threshold for accepting accuracy of BP measurement at estimated probability of tolerable error ($\leq$ 10 mm Hg) $\geq$ 85% **2. Sample size:** $\geq$ 85 participants **3. Participating general population study:** Participants aged $\geq$12 years **4. Cuff sizes:** Minimum number of participants per cuff size, depending on number of test device cuffs. Requirement for arm circumference distribution according to range of use of test device **5. Reference BP:** Mercury sphygmomanometers or accurate non-mercury devices **6. Data collection:** Sequential BP measurements on the same arm are preferred **7. Pass criteria:** Average difference in BP and standard deviation criteria 1 and 2 of universal method. Absolute differences in BP $\leq$ 5, 10, and 15 mm Hg and scatterplots presented
4.	OIML R16–1 (66)	Noninvasive mechanical sphygmomanometer	**1. Environmental conditions** The maximum permitted error for measuring cuff pressure is 3 mmHg and 4 mmHg when utilizing sphygmomanometers at 15–25 °C and 20–85% relative humidity. After storage at −20 °C and 70 °C with 85% relative humidity for 24 h, the sphygmomanometer must meet the maximum permissible error 2. During rapid exhaust of the pneumatic system, with the valve fully open, the pressure reduction from 260 to 15 mmHg must not exceed 10s

(continued)

Table 1 (continued)

S.No.	National and international standard	Type of BP device	Some of the recommendations/ guidelines
			3. According to the supplier's declaration, mercury must be 99.99% pure 4. The mercury shall exhibit a clean meniscus and shall not contain air bubbles
5.	OIML R16–2 (67)	Noninvasive automated sphygmomanometer	1. Replace the cuff with the vessel. Connect the calibrated reference manometer by means of a T-piece connector to the pneumatic system. After disabling the electro-mechanical pump (if fitted), connect the additional pressure generator into the pneumatic system by means of another T-piece connector 2. For each of the following combinations of temperature and humidity, condition the device for at least 3 h in the climatic chamber to allow the device to reach steady conditions: 10 °C ambient temperature, 85% relative humidity (non-condensing) 20 °C ambient temperature, 85% relative humidity (non-condensing) 40 °C ambient temperature, 85% relative humidity (non-condensing) **3. Rapid exhaust:** During the rapid exhaust of the pneumatic system, with the valve fully opened, the time for the pressure reduction from 260 mmHg to 15 mmHg shall not exceed 10 s 4. For blood pressure measuring systems having the capability to measure in a neonatal/infant mode, the time for the pressure reduction from 150 mmHg to 5 mmHg during the rapid exhaust of the pneumatic system with the valve fully opened shall not exceed 5 s **5. Stability of the cuff pressure indication:** The change in the cuff pressure indication shall not be more than 0.4 kPa (3 mmHg) throughout the pressure range after 10,000 simulated measurement cycles

(continued)

Table 1 (continued)

S.No.	National and international standard	Type of BP device	Some of the recommendations/ guidelines
6.	IEEE Standard 1708 (68)	Wearable cuffless blood pressure devices	**1. Observer training and measurement:** Two observers are trained in accurate BP measurement and to get familiar with the data collecting procedure and device operation **2. Subject selection:** Twenty subjects are recruited at Phase 1of the assessment, and devices passing the criteria of this phase will proceed to Phase 2, where an additional 25 subjects are recruited. The characteristic of recruited subjects should follow the requirement stated in this standard **3. Main validation:** The procedure is broken down into three levels: static test, test with BP change from the calibration point, and test after a certain period of time from calibration. Practitioners should properly design their validation protocol to cover the validation from each of the three levels. Observer measurements and test device measurements are conducted with stated validation procedures **4. Data analysis:** The collected data are analyzed and compared to the stated accuracy criteria **5. Data reporting:** The results are presented in recommended format

Calibration of the Oscillometric BP Devices

Accurate blood pressure readings are critical for both diagnostic and therapeutic purposes. An incorrect blood pressure measurement could result in discrepancies between medical practice and clinical trial results. An important challenge for automated oscillometric instruments is assessing and determining the accuracy of the BP measuring device because the manufacturer does not disclose the algorithm used. As a result, various simulators are available on the market for testing and calibrating these devices. Furthermore, an international standard is available to ensure the simulator's quality and accuracy (ISO/TS 81060-5: 2020 standard for NIBP simulators).

There is a widespread usage of automated NIBP measurement devices in the hospitals and at homes. Consequently, a great deal of concentrated work is being expended on the development of calibration methodologies for the NIBP simulator. The International Organization for Standardization (ISO) has also developed a standard, ISO/TS 81060-5: 2020, which specifies the repeatability and reproducibility requirements for NIBP simulators. We have simply summarized a few needs; for more information, please refer to the complete standard mentioned here. It describes the acceptable repeatability and reproducibility limitations for the amplitude and shape of the oscillations produced. The standard specifies that the resolution must be at least 0.1 mmHg. The appropriate testing conditions, e.g., temperature and humidity are 15–25 °C and 15–85% RH, respectively. The variation in temperature over the entire test should be within 1 °C, and the variance in relative humidity should be within 5% RH of these values. The opening and closing of the doors and windows should be avoided during the test to avoid affecting the results (I.T.S. 2020; Kumar et al. 2020). Maximum error in pressure measurement at any location within the nominal measurement range must be less than or equal to ±1 mmHg. At any selectable pulse rate, the maximum error for measuring the pulse rate must be less than or equal to ±1.0/min.

The experimental standard deviation of oscillation amplitude over ten successive oscillations must be less than or equal to 0.05 mmHg in order to assess the repeatability of oscillation amplitude. For the purpose of the reproducibility test, the mean value will serve as the reference value. Calculating the mean value of the oscillation amplitude and comparing it to the reference value is one way to investigate whether or not the oscillation amplitude can be replicated accurately. The difference in each static pressure's two values must be less than or equal to 0.1 mmHg, and this difference must not exceed 0.1 mmHg. There is no additional criterion that must be met in order to test the repeatability and reproducibility of the envelope of the oscillations, as this is not required by the specifications. The measurement data was taken while conducting the reproducibility test and shapes of the oscillations captured and logged for periodic tests and re-tests of the NIBP simulator over the course of time (I.T.S. 2020; Kumar et al. 2020; Hung et al. 2007; Riedel et al. 2011; Amoore et al. 2007).

Future Directions and Confronts

Recently, considerable research attention has been focused on the development of novel, dependable, and portable BP measurement technologies. BP is measured during daily activities using nonlinear autoregressive models, feed forward neural network models, and pulse arrival time models. Multiple one-class support vector machine (OCSVM) models are used in this study to train the data in proportion of outliers. OCSVMs hyper planes assigned new BP estimations to clusters, and prediction intervals (PIs) were computed using BP error standard deviation linked with various clusters. When compared to individual model precision, covariance intersection fusion improved BP and PI predictions by 24%. The used model fusion

demonstrates ability for clinically assessing BP. The PI indicates that approximately 71%, 64%, and 29% of the data acquired from sitting, standing, and walking can yield accurate estimations of BP (Landry et al. 2022).

Holz et al. designed wearable glasses consisting of optical sensor. This technology can measure BP in real time and can run for a whole day after charging once. The PPT technique is used to calculate BP. The wearer's PPT on the angular artery, superficial temporal, and occipital is the primary signal. As a result, such gadgets would be particularly useful for continuous BP monitoring. With the help of developed device, the user can also monitor his BP at the time of drinking, moving, or doing any other activity, and record the BP readings (Holz and Wang 2017).

Wang et al. have developed a sophisticated BP measuring device that is based on smart phones. The vibrations caused by the beating of the heart are measured by the system using the accelerometer sensor available in the phone. The camera of the smart phone is used to monitor the pulse on the fingertip. Due to the fact that the system measures BP using the camera on a smart phone, the disadvantage is that it is difficult to use when engaging in physical activity (Wang et al. 2018; Liu et al. 2018; Miao et al. 2015).

Andrew Carek and Christian Holz designed and developed a wearable device that was sewn into a pair of shorts. The machine known as Naptics is able to measure blood pressure in patients without waking them up while they are sleeping. Naptics detects the optical reflections of the pulse as it travels down the leg of the wearer and records the micro vibrations of the patients that are caused by the heartbeat. This allows Naptics to determine where the beat wave is located in the wearer's leg (Carek and Holz 2018).

Automation based on the internet of things (IoT) and artificial intelligence (AI) is the primary emphasis of the current industry 4.0 age as well as also important component for the industrial revolution 5.0. Consequently, IoT-based BP measuring devices and remote BP measurement would be a significant improvement in the industry for convenient and continuous wireless monitoring and measurement. The recent literature survey on BP devices clearly reveals an uptrend in research, commercial, and clinical activity wherein increased use of wearable BP devices by the consumers and also adherence to certain standards and regulations for wearable BP devices. In-spite of well-known inherent difficulties with cuffless BP measuring devices, the discussions and research to use or not to use or some reliable replacement of the arterial cuff sphygmomanometer in the diagnosis and treatment of BP related ailments are still in focus (Wu et al. 2020; Avolio et al. 2022).

Conclusions

Because of the direct impact on the heart, blood pressure measurement, recording, and monitoring are vital for human health. It is a major cause of kidney failure, coronary heart disease, heart strokes, and the majority of other fatal diseases. We discussed various noninvasive blood pressure measurement techniques, as well as their benefits and drawbacks, in this chapter. The various types of errors caused by

posture, position, white coat effect, and devices, among other things, are thoroughly discussed. Various national and international BP standards are elaborated, and an ISO standard of simulator, which is used for calibrating and testing oscillometric type BP devices, is also described. We are confident that this comprehensive review, which includes information on BP measuring devices ranging from basic to advanced, will be very useful and will pave the way for researchers, students, metrologists, and academics who want to work in this challenging area of medical science.

Abstract

In the last two decades, there has been an increasing demand for accurate and non-invasive blood glucose tests. Despite that current blood glucose monitoring techniques, such as the widely available glucometer, are well established. Inaccuracies in measurement results are common, because of the invasive nature of glucometers. This review discusses various glucose testing techniques classified as invasive, minimally invasive, and invasive. The development of the enzyme-based invasive approach is also reviewed, with emphasis on the introduction of portable glucometers. The various minimally invasive and non-invasive glucose measuring methods that have been investigated over the last few decades and their calibrations are also discussed.

Glucose measurement · Invasive · Minimally invasive · Non-invasive · Calibration

Introduction

Diabetes is a chronic metabolic syndrome that is characterized by impaired functioning of the insulin hormone, resulting in higher glucose concentration in the blood (Asmat et al. 2016). According to the World Health Organization, it has been stated that there are about 420 million diabetes patients worldwide and this number is increasing alarmingly day by day (WHO 2022). The chances of complications like cardiovascular disease, retinopathy, neuropathy, etc. are higher in diabetic individuals. Therefore, it is advisable to monitor the levels of glucose at regular intervals. In addition, this is critically required for regulating the insulin dose (Lawand et al. 2015). The conventional method used for the monitoring of blood glucose levels uses electrochemical enzyme-based detection. However, sampling involves needle-based finger pricking and collection of blood on a strip immobilized with the glucose oxidase enzyme. This approach is painful and may also lead to infection (Paul et al. 2012). Other invasive glucose measurement method includes the hexokinase assay which is widely used in hospitals and laboratories. The history of glucose biosensors dates back to the 1950s, and since then different generations of glucose biosensors have come to the forefront (Nikhil et al. 2016). Even though all these methods are well established and accepted, the painful procedure of testing limits their frequency. Therefore, these days other minimally invasive and non-invasive methods are being extensively explored as an alternative that may have the potential to replace the conventional invasive approach. In this chapter, three major categories of blood glucose measurement, including the invasive, minimally invasive, and non-invasive methodologies, are discussed in detail. The emergence of different glucose measurement devices is also briefly explained. Glucose sensing using the electrochemical method is very popular, paving the way for the development of different generations of biosensors over the years. Even though invasive methods are widely used, measurement errors are common, which may include pre-analytical, analytical, and post-analytical errors. Therefore, certain established standards have been included and briefly discussed. In addition, the calibration approach for different glucose monitoring techniques is also explained.

Glucose Measurement Techniques

The timely management of diabetes is a critical parameter for preventing further diabetes-related complications. Regular monitoring of glucose levels helps in managing the disease. The popular glucose measurement devices are invasive in nature and may not be suitable for frequent monitoring. Therefore, a lot of research is being carried out toward the development of techniques that are non-invasive in nature. Glucose measurement devices can be divided into three categories:

(a) *Invasive glucose devices*: The conventional glucose measurement devices are based on the electrochemical method which involves puncturing the skin with the help of needles. This results in the release of blood which is sucked onto a measurement strip through capillary action. This technique provides instant glucose levels, and no technically skilled personnel is required for the measurement. The frequent puncturing can cause discomfort and may lead to infections; therefore, patient compliance becomes difficult (Tonyushkina and Nichols 2009).

(b) *Minimally invasive devices*: These devices allow the real-time continuous measurement of subcutaneous glucose levels. The working principle is based on the enzymatic reaction in the interstitial fluid using the glucose oxidase (GO_x) enzyme (Reddy et al. 2020). However, the prolonged usage of continuous glucose measurement (CGM) devices can cause tissue damage at the site of installation. The advantage of using the minimally invasive device is the availability of real-time variations in the glucose levels occurring throughout the day. This allows the patients to have a greater degree of metabolic control over their sugar levels through an optimized insulin therapy minimizing the risk of diabetes-associated complications (Koschinsky and Heinemann 2001).

(c) *Non-invasive devices*: The main disadvantage of the invasive or minimally invasive device is the probability of low patient compliance. Therefore, the development of a non-invasive device will bring about a paradigm shift due to vast market potential. Some techniques like Raman, NIR, MIR, and impedance spectroscopy and ultrasonics, etc. are being explored for the development of non-invasive devices. A few devices have been developed so far using optical

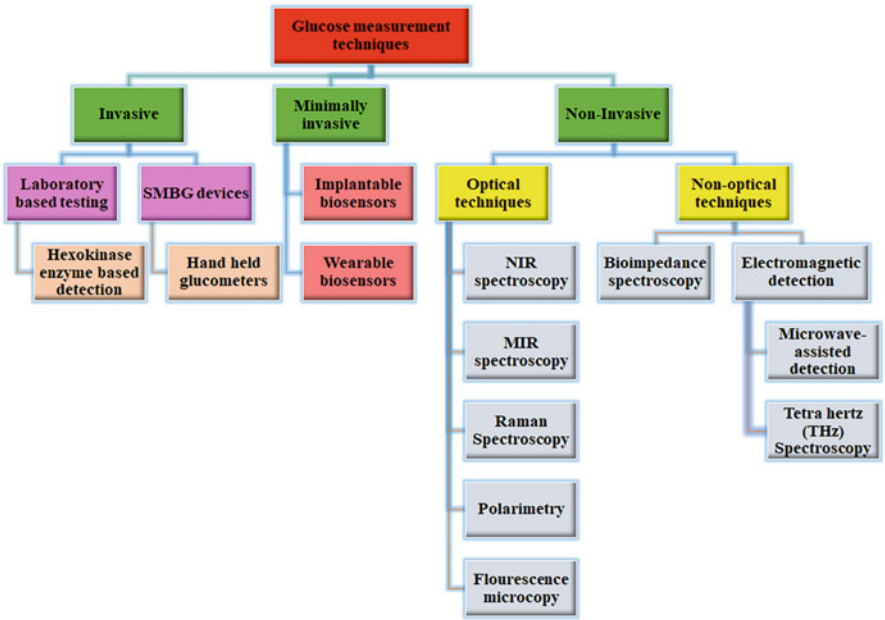

Fig. 1 Different types of glucose measurement techniques

techniques; however, they suffer from poor accuracy (Paul et al. 2012). Figure 1 summarizes the classification of glucose detection techniques (Kottmann et al. 2012).

Invasive Glucose Measurement Technique

Conventional glucose measurement devices allow the self-monitoring of blood glucose levels and are therefore also known as self-monitoring blood glucose (SMBG) devices. The pioneers of this field were Clark and Lyons from the Children's Hospital in Cincinnati. Their device was based on the determination of oxygen consumption, catalyzed by glucose oxidase enzyme. The working electrode consists of a thin layer of the enzyme entrapped over an oxygen electrode using a semipermeable membrane (Chen et al. 2013). This method proved to be a milestone in the measurement of diabetes (Wang 2001). The following set of reactions occurs in this process:

$$\text{Glucose} + O_2 \xrightarrow{GO_x} \text{Gluconic acid} + H_2O_2 \quad (1)$$

$$O_2 + 4H + +4e^- \rightarrow 2H_2O \quad (2)$$

It was only in the early 1970s that the SMBG devices became commercially available when the rights of this device were transferred to Yellow Spring Instrument Company which eventually launched it in 1975 as a 23 YSI analyzer. Since then, several variations in the basic methodology have occurred for the improvement of invasive glucose measurement devices, and several devices have flooded the market. However, the invasive method of detection suffers from multiple limitations like false negative/false positive, due to mishandling or exposure of the sensor to extreme ambient conditions, incorrect coding (leading to >30% measurement errors), interference from biomolecules like uric acid and triglycerides whose concentration is altered in certain diseased conditions like gout, and pancreatitis. Furthermore, the inconvenience of measurement which is not only painful but poses risks of infection

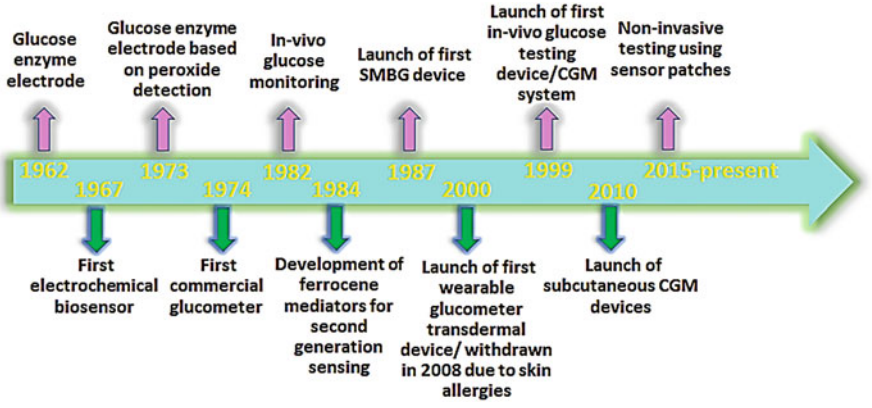

Fig. 2 Timeline of glucose measurement devices

due to frequent monitoring may also cause tissue abrasion (Ginsberg 2009; Erbach et al. 2016). The timeline of the advent of different glucometers is shown in Fig. 2 (Chen et al. 2013; Wang 2001).

The electrochemical method of detection is based on measurements mediated by any one of the three enzymes, namely, hexokinase, glucose oxidase (GO_x), or glucose-1-dehydrogenase (GDH) (Yoo and Lee 2010). The hexokinase assay is a common technique that is used for glucose detection in laboratories (Yoo and Lee 2010; Price 2003). The SMBG devices generally involve glucose oxidase or GDH enzyme for glucose detection. However, glucose oxidase-based biosensors are more frequently used because of their high selectivity for glucose (Yoo and Lee 2010). In addition, the glucose oxidase enzyme is less sensitive to variations in pH and temperature. The GDH-based glucose biosensors are also used, the GDH enzyme is divided into three major subcategories based on the type of cofactor involved, i.e., flavin adenine dinucleotide (FAD), pyrroloquinoline quinone (PQQ), and nicotinamide adenine dinucleotide (NAD), FAD and PQQ cofactors are tightly bound to their enzyme counterpart, whereas NAD is not. Even though GDH enzymes do not require oxygen substrate for their reaction, they still suffer from low specificity toward glucose limiting their applications in glucose biosensing (Teymourian et al. 2020; Lee et al. 2018).

The basic principle of detection in the electrochemical technique involves the oxidation of glucose in the presence of water and oxygen, leading to the formation of gluconic acid and hydrogen peroxide (H_2O_2). The H_2O_2 serves as the signal which is detected at the electrode as a result of its oxidation at the anode (Grieshaber et al. 2008). There are three ways in which glucose may be detected at the electrodes:

(i) Measurement of the oxygen consumption
(ii) Measurement of the total concentration of the H_2O_2 produced at the electrode
(iii) Employing a chemical mediator for the electrons transfer to the electrode interface

The first two approaches are considered the first generation of glucose biosensors, and the third approach is considered the second generation of glucose biosensors. The third generation of biosensors eliminates the need for any toxic mediators for electron transfer to the electrode and involves the direct transfer of electrons to the electrode surface (Dudkaitė and Bagdžiūnas 2022).

Basic Principle of Glucose Biosensing

The basic principle of a glucose biosensor involves the catalytic oxidation of glucose to gluconic acid in the presence of oxygen molecule. The cofactor FAD of GO_x is regenerated during the following reactions:

$$\text{Glucose} + GO_x - FAD+ \rightarrow \text{Gluconolactone} + GO_x - FADH_2 \quad (3)$$

$$GO_x - FADH_2 + O_2 \rightarrow GO_x - FAD + H_2O_2 \quad (4)$$

$$H_2O_2 \rightarrow 2H^+ + O_2 + 2e^- \quad (5)$$

The regeneration step results in the production of H_2O_2 which is electrochemically oxidized at the electrode interface to release the electrons which are directly proportional to the number of glucose molecules in the blood (Yoo and Lee 2010).

First Generation of Glucose Biosensors

In this generation of glucose biosensors, the glucose concentration has been estimated as a result of the measurement of the total amount of hydrogen peroxide released by the glucose oxidase enzyme after catalyzing the reaction leading to the formation of gluconic acid from glucose. The enzyme cofactors provide steric hindrance which limits the electrical interaction between the enzyme and the electrode surface. This interaction is, therefore, mediated by oxygen substrate which helps in shuttling the electrons to the electrode surface. The amount of H_2O_2 is equivalent to the concentration of glucose present. However, problems like deactivation of the enzyme as a result of H_2O_2 production and requirements of high working potentials are encountered which results in interference from other electroactive species like ascorbic acid, uric acid, etc. (Avari et al. 2020).

Second Generation of Glucose Biosensors

In this case, there is no need for a high operating potential; instead, electron acceptors which are commonly known as redox mediators are employed to mediate the electron transfer process. The mediator gets oxidized and reduced at the electrode interface resulting in an amperometric signal. Some examples of these redox mediators include ferrocene, ferricyanide, methylene blue, Os^{2+}/Os^{3+}-based complexes, etc. (Teymourian et al. 2020; Guven et al. 2021; Lin et al. 2019; Bollella et al. 2019).

Third Generation of Glucose Biosensors

In this case, the direct electron transfer takes place from the enzyme to the electrode surface mediated by nanostructured materials and their composites, without the use of any toxic mediators. Over the years, extensive research has been directed toward the synthesis of nanomaterials that possess high electron transfer capabilities for the development of glucose biosensors. This leads to an enhancement in the sensing performance of the bioelectrode because of the efficient coupling of the enzyme with the electrode. Various metal nanoparticles, metal oxide nanoparticles, and nanocomposites have been employed for this purpose (Rahman et al. 2010). Figure 3 shows a schematic representation of the different generations of glucose biosensors (Avari et al. 2020).

Table 1 summarizes multiple glucose sensors based on third-generation sensing.

Minimally Invasive Glucose Measurement Devices

CGM devices can be classified into three types:

(i) Invasive CGM devices: These devices are capable of measuring the fluctuating glucose levels in venous blood. However, they are preferably used in hospitals.

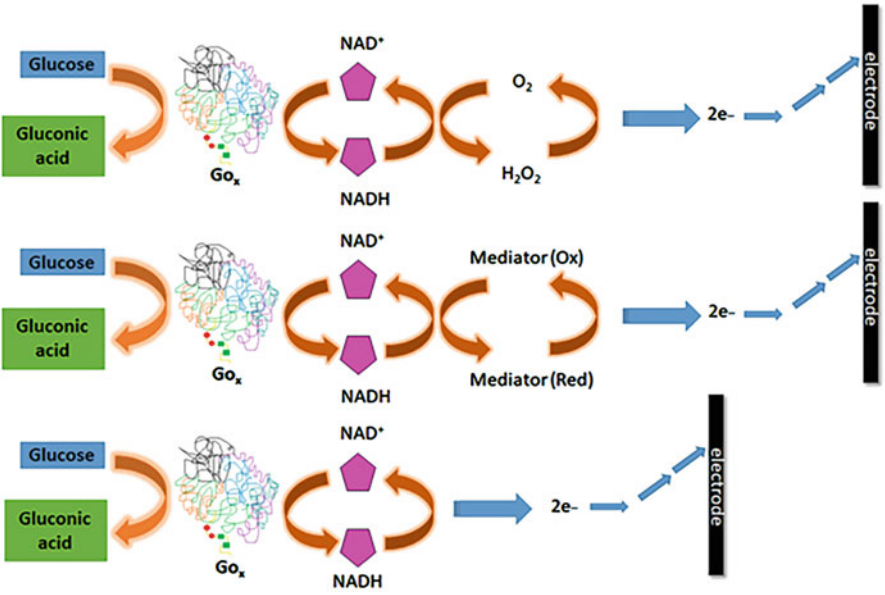

Fig. 3 Different generations of glucose biosensors

(ii) Minimally invasive CGM devices: They may include needlelike or implantable sensors that measure glucose levels in the subcutaneous tissue.
(iii) Non-invasive CGM devices: Such devices are yet to be marketed, and exhaustive research is being carried out in this direction to develop a device based on thermal, acoustical, optical, or electrochemical techniques. This is a popular area of research, and a lot of potential ideas have been introduced that may pave the way for non-invasive CGM devices (Freckmann et al. 2021).

Calibration of CGM Devices

The calibration of the commercially available CGM sensor is critical to ascertain the accuracy of the measurement. The devices are calibrated one 1–2 h after installation known as the warm-up period. It is recommended to calibrate the device every 12–24 h after the completion of the warm-up period. Linear regression techniques are quite popular for calibrating CGM devices (Acciaroli et al. 2018). Some of the commercially available CGM devices are Medtronic Guardian 3, Abbott Freestyle Libre, Dexcom G4 Platinum, Dexcom G5, and Dexcom G6. All of these devices measure the interstitial glucose levels based on the glucose oxidase-based chemical reaction, which is converted into an electrical signal which is proportional to the glucose concentrations. This conversion is mediated by a calibration function. This function must be updated from time to time due to variations that might occur as a result of instrumental drift, biocompatibility issues, etc. Furthermore, these devices may be factory calibrated, but still face challenges like inefficiency to detect sudden blood glucose changes and skin allergies due to the sensor glue (Heise et al. 2021).

Table 1 Third-generation glucose biosensors based on different nanomaterials and their nanocomposites

S. no	Sensor matrix	Detection technique	Linear dynamic range	Limit of detection	Ref
1.	Graphene nanoribbons	Cyclic voltammetry	50–2000 mg/L	20 mg/L	Mehmeti et al. (2017)
2.	ZnO nanorods	Amperometry	0.05–1 mM	0.06 mM	Ridhuan et al. (2018)
3.	PEC complex (chitosan/kappa-carrageenan) doped with gold nanoparticles (AuNPs)	Square wave voltammetry	10 μM–7 mM	5 μM	Rassas et al. (2019)
4.	Chitosan-supported mesoporous carbon nanocomposite	Amperometry	250 μM–3 mM	4.1 μM	Barathi et al. (2019)
5.	(3-Aminopropyl) triethoxysilane (APTES) stabilized titanium dioxide nanoparticles cross-linked to carboxylic graphene	Electrical impedance spectroscopy	50–1000 μM	24 μM	Ognjanović et al. (2020)
6.	Poly(vinyl alcohol) and poly (ethyleneimine) blend nanofibers activated by glutaraldehyde	Differential pulse voltammetry	2–8 and 10–30 mM/L	0.3 mM	Temoçin (2021)
7.	Mesoporous carbon nanostructure, lignin-based carbon nanofibers	Cyclic voltammetry	0.15–2.7 mM	89 μM	Beaucamp et al. (2021)
8.	Nanoporous copper oxides embedded into graphitic carbon layers (MOP-CO)		0–4000 μM	26 nM	Wei et al. (2022)
9.	Platinum nanoparticles electrodeposited on poly(azure A)	Amperometry	20 μM–2.3 mM	7.6 μM	Jiménez-Fiérrez et al. (2020)
10.	Single-walled carbon nanotubes (SWCNTs)	Amperometry	0.1–30 mM	0.05 mM	Tasca et al. (2011)

Metrological Issues Related to SMBG Measurements

All the laboratory tests including the lab-based glucose measurement technique are prone to erroneous results. The diagnostic efficacy of a test is largely influenced by abundantly large test errors irrespective of the origin of the error. Therefore, a

parameter known as the total error is important to the clinician as it includes all the different sources of errors that influence the overall measurement (Krouwer and Cembrowski 2010):

$$\text{Total error} = \text{Observed value} \sim \text{true value of glucose} \quad (6)$$

The various sources of errors affecting the overall glucose estimation are tabulated in Table 2.

Standards for SMBG Monitoring

The allowable limit for analytical errors associated with SMBG measurements is still a debatable issue. The American Diabetes Association (ADA) recommends that the total error of glucometers should be $<5\%$. Other organizations like the National Committee of Clinical Laboratory Standards (NCCLS) are a little lenient, with the allowable error limit set at $\pm 20\%$ for blood glucose >100 mg/dl and ± 10 mg/dl for glycemia ≤ 100 mg/dl (Solnica and Naskalski 2007). Furthermore, the International Organization for Standardization (ISO) recommends that ninety-five percent (95%) of the individual glucose results shall fall within ± 15 mg/dl of the results of the manufacturer's measurement procedure at glucose concentrations ≤ 75 mg/dl and within $\pm 20\%$ at glucose concentrations >75 mg/dl. Furthermore, ISO 15197 uses metrology terminology for accuracy "closeness of agreement between a test result and the accepted reference value" (Krouwer and Cembrowski 2010).

Non-invasive Glucose Sensing

Considering the importance of regular glucose monitoring, for the optimization of diabetes therapy, non-invasive glucose sensing is a popular research area. Given the need for measuring glucose levels at least five to six times a day, the invasive techniques are not fit for regular use. Different non-invasive techniques are being

Table 2 Various sources of error in SMBG measurement

Error type	Definition	Sources
Pre-analytical errors	Errors which may occur before testing	Lack of proper cleaning of test surface (finger) Blood sample from a hypotensive patient Dilution of blood specimen as a result of manipulation of puncture site (Krouwer and Cembrowski 2010)
Analytical errors	These include errors which may occur during analysis	Usage of expired test strips Untrained test personnel performing the test Temperature variations that may cause denaturation of bio-recognition elements (Nichols 2011)
Post-analytical errors	Errors which occur after the measurement	Delayed reporting Reporting of wrong information to the clinician (Krouwer and Cembrowski 2010)

explored, including optical techniques like Raman, fluorescence, NIR and MIR spectroscopy, polarimetry, etc., and other nonoptical techniques like bio-impedance spectroscopy, photoacoustic spectroscopy, microwave assisted detection, and electromagnetic detection. However, optical techniques are known to demonstrate the best results (Alsunaidi et al. 2021).

Raman Spectroscopy

In this technique a laser is used to induce molecular vibrations in the body fluids; the scattering of light which is influenced by the molecular vibrations is detected which gives an estimate of the concentration of glucose in the blood (So et al. 2012). The NIR laser is the preferred source of excitation because of its good penetration depth and less risk of photochemical and thermal damage (Pandey et al. 2017). Raman spectroscopy is highly sensitive to several molecular vibrations including the C–O, C–C, C–OH, C–O–H, and CH_2 stretching and C–O–H bending frequencies, which are specific to glucose (Wróbel 2016).

Raman spectroscopy is a popular technique in terms of the deep tissue analysis of the human body courtesy of the development of the spatially offset Raman spectroscopy (SORS) technique. This technique enabled the probing of the human tissues from several micrometers to several millimeters and in certain special cases up to several centimeters as well. Nowadays, it is possible to use SORS in association with surface-enhanced Raman spectroscopy (SERS) to exploit the advantages of both techniques. This allows for the in-depth analysis of diffusely scattering media especially tissues, enabling the detection of those biomolecules which exist in extremely low physiological concentrations like glucose. In a recent study, glucose levels were successfully monitored in the interstitial fluid, by SORS technique which detects the spectra generated using a SERS-based implant in vivo (Matousek and Stone 2013).

A Raman-based prototype GlucoBeam, RSP Systems A/S, Denmark, was tested in a study, on patients suffering from type I diabetes. The objective of the study was to develop calibration models and to test the efficacy of the device in real time. The study comprised 15 adults, and was conducted over a span of 25 days at home and in the clinic, where each subject underwent at least six measurements per day, two measurements were performed using capillary blood glucometers, another two using a CGM device, and another two using the GlucoBeam, RSP Systems A/S prototype being tested. Calibrations models were developed using data from 19 to 24 days, and the leftover 3–8 days were used for independent validation. The device demonstrated a good practical ability with around 94% of the values falling in zones A and B of the Clark error grid. These findings suggest the potential of the prototype in the development of a real-time Raman-based non-invasive glucose measurement device (Pleus et al. 2021).

In another study, the transcutaneous measurement of blood analyte, i.e., glucose was demonstrated, using Raman spectroscopy on a total of 17 human subjects. The calibration was performed using capillary blood glucose measurements. Calibration models were developed using partial least squares regression (PLSR) and were validated using leave-one-out cross-validation utilizing spectrally preprocessed

data using Savitzky-Golay filter using 13 window points smoothing to improve the signal-to-noise ratio. The raw data consisted of overlapping backgrounds, obscuring the Raman features. Two strategies were employed to preprocess the spectral data. In the first strategy, least square fitting was performed allowing the Raman features to be resolved, and in the second strategy, the background subtraction was not carried out and the spectra were analyzed in their raw form (Enejder et al. 2005). This report suggests that the spectral features of the glucose are an integral part of the calibrations.

Near-Infrared and Mid-Infrared Spectroscopy

This technique utilizes radiation in the NIR region of the electromagnetic spectrum. Owing to the high penetration depth of the NIR light, NIR spectroscopy has been extensively applied in the field of biology for deep tissue analysis. The NIR region is categorized into three main bands, the combination overtone band (2000–2500 nm), the first overtone band (1400–2000 nm), and the second or higher overtone band (750–1400 nm) (Zhang et al. 2016).

The overtones and combination bands represent the forbidden frequencies, resulting in weak signal intensities. This also results in overlapping spectral features, giving rise to the problem of multicollinearity in the NIR region which makes the specific detection of glucose a major concern. To solve this problem, chemometrics techniques are used for deriving maximal chemical information about the target analyte (Ozaki et al. 2018). Within the NIR region, two optical windows exist, one window from 650 to 950 nm and another from 950 to 2200 nm which also represents the short-wave NIR region (SW-NIR). The first window has been extensively explored; however, the exploratory analysis of the second window calls for specialized instrumentation. The SW-NIR region pertains to the electronic transitions which are responsible for the high permeability, making it particularly interesting to biologists.

For the non-invasive detection of glucose, both absorption and reflectance-based techniques have been utilized. The sites of measurement usually include fingers, lips, palms, and webbing between the fingers. However, obtaining glucose-specific information is quite challenging because of the interference from other NIR-active biological compounds like fats, hemoglobin, and proteins. Furthermore, the measurements are influenced by ambient factors like temporal variations, machine drift, time drift, etc. (Yang et al. 2018).

The SW-NIR region has been probed for non-invasive glucose detection. In a study by Jain et al., absorption and reflectance spectroscopy in the SW-NIR region were employed for the design of a non-invasive blood glucose monitoring system. The design of the system was such that it involved both absorption and reflectance measurements mediated by infrared emitters of 1300 and 940 nm in 25 subjects. The model has been validated against reference blood glucose measurements using an SD check invasive glucometer.

One of the common obstacles in glucose detection using NIR spectroscopy is the significant absorption by water. Therefore, identification of those bands in the NIR which are transparent to water is a prerequisite for glucose detection (Jain et al.

2019). The water-specific peaks in the NIR region fall between 1350 and 1520 nm and 1790 and 2000 nm. Therefore, the NIR band from 700 to 1100 nm is an important window for the non-invasive detection of glucose (Shokrekhodaei and Quinones 2020). Several glucose-specific peaks fall in this region, owing to the CH and OH vibrations. Golic et al. have pointed out the influence of H bonding and temporal variations on the CH and OH vibrations, respectively. Therefore, it is important to calibrate the glucose concentrations for the CH and OH features, to minimize the effect of H bonding and temperature. The major spectral features which correspond to the CH, CH_2 and OH stretching vibrations are located at 910 nm, 930 nm, and 970 nm respectively (Golic et al. 2003).

MIR spectroscopy technique follows the same principles of absorption as NIR spectroscopy. Here, the light in the MIR region from 2500 to 10,000 nm of the electromagnetic spectrum is employed for analysis. The absorption features corresponding to glucose in the MIR region are much sharper in comparison with those in the NIR region. However, the practical applications of this technique for non-invasive device development are challenging as a result of the poor penetration depth of the MIR light (Vashist 2012). Therefore, MIR-based technique can only be adopted in the reflective mode. The absorption feature of glucose in the MIR region occurs between 6250 and 11,110 nm. Water has a much more prominent absorption in the MIR range in comparison with the NIR range (Tang et al. 2020).

In a study, a combination of the quantum cascade radiation and photoacoustic detection of absorption was used. The in vitro data suggests that the usage of less number of IR wavelengths allows for better prediction; in addition, the accurate selection of glucose variant and invariant wavelengths is also critical. They have also shown that by using the MIR technique in conjunction with the photoacoustic method, the glucose-containing layer of the skin can be easily accessed, so resolving the issue of MIR light's shallow penetration depth. Also, by introducing a time delay of 10 min, it is possible to obtain a higher degree of correlation between blood glucose and the photoacoustic signal. All these results indicate the potential of MIR spectroscopy in the development of an in vivo blood glucose measurement system (von Lilienfeld-Toal et al. 2005).

Polarimetry

This technique has been adopted for non-invasive glucose monitoring for a long time. This is based on the principle that when a plane-polarized light is incident on a chiral molecule, the plane of the light gets rotated. Glucose is a chiral molecule that is optically active and can rotate the plane of polarized light. The polarization direction will form a deflection angle with the original incident direction, which is proportional to the glucose concentration. The technique enables direct estimation of glucose concentration, and is easy to operate and simple, but suffers from multiple limitations like interference from other optically active molecules, and scattering effects. The human body is a scattering medium and this may cause the polarized light to lose its polarization. Furthermore, the aqueous humor of the eye is the site of glucose measurement, but the measurement is largely affected by the motion artifacts, because of the variations in the corneal infringement (Tang et al. 2020). In a

study, a differential Mueller matrix polarimetry technique has been used. The estimation of glucose concentrations from aqueous glucose samples by measuring the optical rotation values (γ) and depolarization index (δ) in tissue phantom samples consisting of 0–500 mg/dl glucose and 2% Lipofundin with a limit of detection of 20 mg/dl was accomplished. The γ and δ values have also been obtained from the fingertips of healthy volunteers. The γ and δ values obtained from the fingertips of human volunteers were found to have a good correlation with those of the tissue phantom samples (Phan and Lo 2017).

Fluorescence Spectroscopy

When an electron absorbs a photon, it gets excited from its singlet ground state (S_o) to an excited state (S_n, $n > 1$). The electron then decays back to S_1, the lowest excited state, by dissipating a part of its energy in the environment. This process is known as internal conversion. When the electron returns to the ground state (S_o) with the emission of a photon having a radiative rate constant K_r, this phenomenon is known as fluorescence (Albani 2008). Glucose emits a fluorescent signal when exposed to visible or UV light. But the signal is weak and affected by other fluorescent interferants. For this purpose, glucose is usually coupled to other fluorescent probes known as receptors, which enhance the fluorescent intensity significantly. However, the measurement may be affected by several factors like scattering, skin pigmentation, the thickness of the epidermis, etc. (Alsunaidi et al. 2021). A variety of receptors have been employed for this purpose, including enzymes, glucose-binding proteins like concanavalin A and glucose galactose-binding proteins, nanostructured materials like carbon nanotubes (CNTs), quantum dots, etc. Fluorescent resonant energy transfer is a popular technique which is based on the interaction between a fluorophore (donor) molecule and the acceptor molecule (receptor). In the presence of glucose molecule, this link between the donor and the acceptor is broken which disrupts the electron sharing between the two and improves the fluorescent signal. This bond stays intact in the absence of glucose enabling electron transfer between the two and reducing the fluorescent intensity (Villena Gonzales et al. 2019; Klonoff 2012). Nowadays, CNTs are being extensively utilized for glucose detection. The technique involves the adsorption of glucose receptors onto carbon nanotubes. Here, the receptor molecules are absorbed by single-walled CNTs, and post the binding of glucose molecules to their receptors, the nanotubes' fluorescence gets altered because in the presence of glucose, this binding between the CNTs and the receptor is disrupted. The change in fluorescence is then relative to the glucose concentration (Klonoff 2012).

Bio-Impedance Spectroscopy

This technique comes under the broad term bioelectrical impedance analysis (BIA). BIA is a practical tool that is used to analyze the composition of the body in terms of fat content and water. In this technique, painless currents of low amplitude are passed through the human body using cables connected to electrodes or other conductive surfaces. This allows the measurement of resistance (R) and reactance (Xc). Both these parameters are used for estimating the impedance (Z), and the total water

content of the body, in addition to the extracellular and intracellular water. Based on this data, other parameters like fat-free mass (FFM), fat mass (FM), and body cell mass (BCM) are calculated (Mialich et al. 2014; Lukaski et al. 1985). This technique is also used for analyzing the compounds in the blood. The changes in the parameters discussed above reflect the changes in the dielectric/dimensions of the target (Losoya-Leal et al. 2012). In another version of this technique, known as dielectric spectroscopy, the variations in frequency are measured concerning the variations in the dielectric properties of the target matrix. A study has shown the potential of using bio-impedance spectroscopy, for the non-invasive detection of glucose. A wristwatch was used for the sensing purpose in healthy human subjects for clinical-experimental studies. The sensing system is composed of an open circuit that is coupled to the skin and another circuit that performs the impedance measurements. The sensor uses electromagnetic waves in the frequency range of 1–200 MHz. These waves then interact with the skin to monitor any changes in the electrical properties of the tissue underneath. The results showed a good correlation between the actual glucose levels and the sensor readings. However, environmental variations, sweat, and motion artifacts due to the sensor probe are bound to cause measurement errors which must be addressed (Caduff et al. 2003).

Electromagnetic Monitoring

Electromagnetic wave (EM) sensing has an edge over other techniques because of its capability to undergo strong interactions like absorption, scattering, and transmission, with various compounds inside the body. EM waves can be categorized into radio waves, microwaves, terahertz (THz) waves, visible/infrared (IR) light, ultraviolet, X-rays, and gamma rays particularly based on their frequencies or wavelengths. However, the EM waves may broadly be classified into ionizing (X-rays and γ-rays) and nonionizing radiations (THz waves, microwaves, IR waves), and the nonionizing radiation is more suitable for biological testing due to its nondestructive nature and minimal damage to the tissues and organs in the body. The IR-based techniques (NIR and MIR spectroscopy) have already been discussed in the sections above. THz waves have a frequency in the range of 0.3–3 THz, and they fall between microwaves and far-infrared waves. Terahertz time-domain spectroscopy (THz-TDs) is utilized for medical applications (Zhang et al. 2019). In a study, the optical properties of the human skin were characterized using optical THz time-domain spectroscopy. The variations in the attenuated total internal reflection (ATR) spectra were correlated to the changes in the glucose levels after the measurement of ATR spectra consecutively from 0 to 90 min in six volunteers after glucose intake. The ATR amplitude exhibited an increase with rise in glucose concentration (Cherkasova et al. 2016). In another study, THz waves in the frequency range from 0.2 to 0.9 THz were used for the quantification of blood glucose levels using a wave generated from an indium arsenide (InAs) wafer and an 800-nm femtosecond laser in transmission mode. The analysis was performed on 20 blood samples obtained from diabetic patients, and a good correlation with low error rates ($<15\%$) was found between the measurements and a commercial glucose meter (Chen et al. 2018). Furthermore, the principle of measurement through microwaves

involves the interaction between microwaves and matter which is under test. The incident signal may change in terms of velocity, attenuation, or reflection. Furthermore, this interaction manifests as a change in the permittivity of the sample. This is a nondestructive technique and doesn't require direct contact with the test object, assisted by penetrating waves. The nonionizing nature of the waves minimizes any health risks associated with the technique, making it a particularly attractive technology in the healthcare industry. However, temperature, moisture content, density, etc. may affect the measurement (Korostynska et al. 2014). The dielectric coefficient of blood is dependent on glucose levels. Based on this fact, for the non-invasive measurement of glucose levels, microwaves of a frequency most sensitive to glucose are incident on a tissue, and the reflected signal is then measured which is proportionate to the glucose concentration. In a study, a single spiral microchip-based sensor was developed, and the sensor was fabricated on a high-frequency substrate RO3000. The sensor could operate at two different frequency ranges, one from 0 to 2 GHz and another from 2 to 4 GHz to determine the dielectric coefficient of the blood. The variations in the permittivity of the tissue cause a shift in the resonance frequency of the sensor with a larger shift observed for a higher frequency (Buford et al. 2008). In another study, a novel microchip-based glucometer is developed which consists of a band-pass filter, which acts as the sensor, operates approximately at a frequency of 1.9 GHz, and possesses high sensitivity toward the dielectric coefficient of its target site (finger-superstrate). The variation in the blood glucose level leads to a change in the permittivity of the thumb, thereby affecting the response of the sensor (Baghbani et al. 2015). The calibration of these variations leads to the determination of blood glucose levels. The proposed sensor may allow the continuous self-monitoring of glucose levels. A few of the non-invasive devices which have been developed over the years are summarized in Table 3.

Calibration of Non-invasive Measurements

Multivariate calibration techniques are used for determining the analyte concentration in a complex mixture. Based on the non-invasive data, generally, the NIR spectra, the standard error of prediction (SEP), and correlation coefficients (R^2) are calculated. A higher R^2 value and a lower SEP are associated with a successful prediction. Successful predictions are dependent on numerous factors given below:

(i) Overfitting of the data must be avoided.
(ii) Chances of correlation with other time-dependent parameters must be avoided like instrumental drift, time drift, noise, etc. Such parameters affect the prediction performance of multivariate calibration techniques like partial least squares regression (PLS) and artificial neural networks (ANN). The NIR spectroscopy is an indirect method which increases the possibility of chance correlations, because PLS technique takes into account all the sources of variation, thereby increasing the chances of correlation of a nonspecific signal with the analyte (Liu et al. 2005).

Table 3 Non-invasive glucose measurement devices

S. no	Name of sensor	Sample type	Design	Detection limit	Response time	Wireless telemetry	Ref
1	Cavitas sensor	Saliva	Pt and Ag/AgCl electrodes are integrated with an enzyme membrane on a mouth guard	5–1000 μmol/L			Arakawa et al. (2016)
2	Smartphone-based sensor	Saliva	Glucose oxidase enzyme is immobilized in conjunction with a pH-responsive dye over a filter paper-based strip	50–540 mg/dL	20 s	Based on smartphone	Soni and Jha (2017)
3	Fast Fourier transform in near-infrared-based sensor		Sensor module/probe is printed from poly-lactic acid (PLA) which consists of a pair of one or two NIR LED and a photodiode		60 s	Transmission module is a conglomerate of modules used for monitor display and for transmission through Wi-Fi or Bluetooth	Jenie et al. (2017)
4	TensorTip Combo Glucometer	Tissue photography based (NO SAMPLE)	Users have to initially calibrate the device using blood for a few weeks following which they can painlessly measure their blood glucose levels by putting their finger in the space provided			Smartphone based	Segman (2018)
5	Grove's device	Fingertip or earlobe (NO SAMPLE)	Takes reading from blood on the capillary level instead of the skin level		20 s		Siddiqui et al. (2018)
6	Glucosense	Touch based (NO SAMPLE)	Silica gel that has ions having high sensitivity toward the infrared light the		30 s		NetScientific PLC (2015)

			reflected spectrum changes at the touch of a user. It uses a power efficient laser to acquire the readings				
7	glucoWISE	Area between the thumb and forefinger	Measures glucose level at the capillary level		10 s	Wireless data transmission using Bluetooth to generate alerts	glucoWISE®
8	GlucoTrack	Earlobe	It has two components, one is the ear clip that measures the blood glucose levels, and the other that displays the results by using electromagnetic, ultrasound, and thermal techniques				Lin et al. (2018)
9	iQuickIt saliva analyzer	Saliva	It employs disposable draw wick sticks for the samples which are transmitted to other smart devices			Transmission to smart devices	Siddiqui et al. (2018)
10	Contact lens	Tissue (eye)	It is composed of a wireless transmitter for transmitting the glucose readings and a static electrical charge for drawing power			Transmission to other devices	Keum et al. (2020)
11	Noviosense	Tears	Electrochemical			The device has a wireless module to transmit data and to power the device	Noviosense; Geelhoed-Duijvestijn et al. (2021)

(iii) The training and prediction sets must be taken at different time intervals.
(iv) The number of input data points must be larger than the parameters used in the fitting equations.

The calibration models may be generated by fitting the non-invasive data to the invasively determined values. The standard error of calibration (SEC) and calibration correlation coefficient are calculated based on this fitting (Khalil 2004).

Leave-One-Out Cross-Validation

The validation of the calibration model can be performed by evaluating the standard error of cross-validation prediction (SECV) and the cross-validation correlation coefficient (RCV) values. The process involves the prediction of a single data point by using the rest of the data points as the calibration set also known as the leave-one-out cross-validation (LOOCV). The prediction performance of the calibration model depends on a low SECV and a high RCV value (Khalil 2004).

The calibration of non-invasive devices depends on several invasive blood glucose measurements along with non-invasive measurements. Oral glucose tolerance tests (OGTT) are used to determine the changes in the glucose levels in vivo which are required for the calibration of non-invasive devices. The sequential collection of spectral data is preferred in OGTT, because randomized collection will add to the complexity of the calibration model (Delbeck et al. 2019). Furthermore, in the OGTT, a given concentration of glucose is administered to the subject, and the changes in the blood glucose levels are monitored over a fixed duration of time. However, time drift and the circadian rhythm may influence the calibrations due to variations in the OGTT. Therefore, a self-calibrating device is needed, which does not require frequent invasive measurements; for this purpose the spot test approach may be adopted, which is performed at random time slots over a long period, thereby minimizing the chance of correlations, and changes induced by variations in the circadian rhythm (Khalil 2004).

Conclusion

Various glucose measurement techniques with all their current prospects, technical aspects, calibration, and ISO standards for testing have been briefly reviewed. Furthermore, the different glucose measurement devices which have surfaced over the years have also been traced. In addition, the different non-invasive devices which have been developed over the past four decades are also highlighted. Over the years, a tremendous amount of research has been directed toward the development of glucose measurement devices. Given the rapid upsurge in the number of diabetic patients globally, the economic burden and healthcare costs have increased by several manifolds. This has led to the generation of several economic prospects and research opportunities. Even though the blood glucose monitors exhibit excellent accuracies, they suffer from several limitations like false negative/false positive, due to mishandling or exposure of the sensor to extreme ambient conditions,

incorrect coding (leading to >30% measurement errors), and interference from other biomolecules like uric acid, triglycerides, etc. Furthermore, the stability and shelf life of biomolecules are also questionable. Hence, extensive research is being carried out on the development of abiotic sensors which do not require need a bioreceptor (enzyme) for detection. The principle is based on the direct detection of an analyte using novel transducer materials exhibiting catalytic properties paving the way toward the fourth generation of glucose biosensors. In addition, minimally invasive devices are also being thoroughly explored for the detection of blood glucose levels. They may also cause several problems like skin irritations, allergies, generation of a vast amount of data, painful sensor insertions, etc. Therefore, over the past two decades, non-invasive glucose measurement is being employed as a possible alternative to invasive devices. Several techniques have been adopted for this purpose, but the development of a device that has accuracies comparable to the established glucometers is a farfetched dream. Even though several non-invasive devices have been developed, mass-scale commercialization is yet to happen. However, the economical fruits of the development of a non-invasive device are lucrative, and the commercialization of such a device may become possible soon.

Acknowledgments Deepshikha Yadav would like to thank the Indian Council of Medical Research for providing the Senior Research Fellowship (SRF), grant number ISRM/11(60)/2017, dated 17/4/2018 for carrying out the research activities.

Abstract

Human cognition is the essential building block of human intelligence, and it is what makes us who we are. Cognition is defined as the capacity to recognize and respond appropriately to external stimuli based on one's beliefs, actions, experiences, and senses. It is one of the fundamental reasons for human existence and is one of the most important aspects of the brain. In childhood, adolescence, and maturity, the cognitive processes of humans are always evolving and developing. Although some of these abilities begin to diminish as one grows older and approaches older maturity, others begin to deteriorate when neurons die and the systems that replace them become insufficient. Understanding cognition is essential not just for healthy cognitive growth and survival but also for the treatment of

a variety of neuropsychological conditions, such as Alzheimer's disease. It is necessary to examine the cognitive functions of the human brain before one can comprehend cognition. fNIRS and electroencephalography (EEG) are low-cost methods of assessing and evaluating cognitive function. The principles of electroencephalography (EEG) and functional near-infrared spectroscopy (fNIRS), as well as a number of methods for preprocessing and interpreting EEG and fNIRS data, are therefore covered in this chapter. Lastly, the use of simultaneous EEG-fNIRS is discussed along with its limitations and advantages.

Introduction

One of the fundamental characteristics that distinguish the human species from other animals is intelligent behavior. Humans are not one-trick ponies; they may participate in complex goal-oriented actions over time rather than just reacting impulsively to circumstances or stimuli in front of them (Rosati 2016). And one of the building blocks of human intelligence is human cognition, and intelligence and cognition are like the two sides of the same coin. The Latin verb *cognoscere*, which means "to know" or "to come to know," is where the term cognition originates (Bernhard 2007). It is the mental process through which humans learn and interpret things. At its most basic level, it is the capacity of a human to detect and respond appropriately to external stimuli based on its ideas, actions, experiences, and senses. The sensory information one gets is quite huge, extensive, and complicated, cognition helps distill all of this information down to its fundamentals, and humans interact appropriately with their surroundings. As a result, cognitive functioning is essential for daily functioning as well as in guiding human ideas and behaviors and is one of the building blocks of human intelligence. Cognition is comprised of a variety of cognitive processes, which may be further classified into six core neurophysiological domains, which include attention, learning, language, social cognition, motor function, and executive function (Andrianopoulos et al. 2017). Each of these domains deals with a specific function of human cognition starting from basic response to stimuli to higher-level capabilities that determine human intelligence.

Cognition continuously evolves and adapts to new knowledge and stimuli, controlling human behavior throughout their lives, and is heavily impacted by both environmental factors and heredity. The physical basis of cognition can be traced from the approximately 100 billion neurons found in the human brain. Each of these neurons has a significant number of connections with other neurons (Herculano-Houzel 2009). Therefore, cognition – which is directed by distinct brain circuits supported by a variety of neurotransmitters – is the primary regulator of human ideas and actions. Chemical messengers called neurotransmitters to pass messages from one neuron to another. Common neurotransmitters are dopamine, noradrenaline (norepinephrine), serotonin, acetylcholine, glutamate, and GABA (Jones 1986). Dopamine is a neurotransmitter that is produced by the brain's reward system. Hence, it is crucial to investigate cognition and the

underlying neurobiology that supports behaviors in both healthy and illness situations in order to better understand what drives them. Processes occurring inside various sections of our brain give rise to different cognitive functions, but only some of them make it into our conscious consciousness. Human cognitive processes are constantly improving during childhood, adolescence, and adulthood. However, as one ages and enters older maturity, some of these abilities begin to decrease as neurons die and the mechanisms that replace them become inadequate (Arain et al. 2013). Understanding cognition is vital not just for healthy cognitive development but also for the treatment of a variety of neuropsychological illnesses in which cognitive deficiencies emerge. Many of the world's most pressing health problems are linked to underlying cognitive deficiencies, which can be easily alleviated through early intervention. The real-time monitoring and assessment of cognition have the potential to alter human lives and prevent cognitive capacity from deteriorating at a quicker pace than it should as people naturally age.

Measuring Cognition

With suitably validated screening tests for cognitive impairment, it is simple to acquire an early estimation of a patient's cognitive functions by comparing the patient's score to reference standards (Andrianopoulos et al. 2017). This allows for a more accurate diagnosis and treatment plan. The three main methods for assessing daily cognitive function are self-report, informant report, and performance-based screening tests. Self-report has been demonstrated to have certain limits in cognitively impaired individuals as self-reports frequently deteriorate in these individuals (DeBettignies et al. 1990; Farias et al. 2008). In contrast, performance-based measures the cognitive functioning of patients using well-defined functional tasks, which are then compared with an appropriate comparison group (Gevins et al. 2011). These functional tasks are mostly used in clinical neuropsychological assessments to pinpoint the cognitive strengths and limitations of patients across a wide range of cognitive areas. A key part of performance-based tests is the cognitive test battery which was created to evaluate key cognitive abilities (Rapp et al. 2012). According to several researchers, this is the most valid and trustworthy approach to evaluating functional ability (Avitan et al. 2009; Giovannetti et al. 2006). The bulk of performance-based evaluations take place under controlled circumstances when the subject is encouraged to finish a job and is provided with the necessary tools. Although neuropsychological assessments like performance-based tests are the benchmarks for clinical evaluation of cognitive ability, the efficacy of these tests is highly subjective (Gevins et al. 2011). Multiple factors may affect the cognitive performance of the patient such as fatigue, sleepiness, affect, and mood, all of which may alter the results of the test (Gevins et al. 2011). However, in recent times, researchers have started using neuroimaging tools like positron emission tomography (PET), functional MRI (fMRI), electroencephalography (EEG), or functional near-infrared

spectroscopy (fNIRS) during cognitive testing to extract pertinent information regarding the cognitive performance as well as brain function during these tests (Herold et al. 2017; Smeha et al. 2022). When the various types of data available from direct brain function tests and neuropsychological testing are merged into a single index, it has the potential to deliver significant benefits for both clinicians and researchers (Gevins et al. 2011; Dahal et al. 2011). EEG and fNIRS are simple, portable, and cost-effective technologies that stand out as potential methods for assessing neural function in a variety of operating contexts, particularly in the field.

Electroencephalography (EEG) is a technique for recording the electrical activity of the brain caused by the firing of neurons within a brain. In order to perform it, numerous electrodes are placed on the scalp (Congedo and Sherlin 2011). EEG records the changes in electric waves and serves as an all-encompassing reflection of the electrical activity of nerve cells on the scalp or cerebral cortex surface (Klonowski 2009). It is a common practice to record EEG during certain moments of cognitive processing and then compares the results to those obtained by recording EEG during a resting or baseline time. The use of EEG has the benefit that cognitive events can last for a lengthy period of time, in the range of seconds or even minutes. Additionally, EEG has a high temporal resolution as it records electrophysiological responses at a millisecond scale. When different stimuli are presented to the brain, distinct parameters may be retrieved from the EEG and utilized as a metric in the study of cognition (Bell and Cuevas 2012).

Functional near-infrared spectroscopy (fNIRS) is a noninvasive neuroimaging method that is still in its infancy and is used to track cerebral blood flow (Farias et al. 2008). Compared to EEG, it has a higher spatial resolution, as well as its mobility, movement tolerance, and safety of usage; therefore, this technology is particularly well suited for researching brain activity in newborns and children, among other applications (Pinti et al. 2020). In the field of schizophrenia, fNIRS is being used extensively in research, with a focus on functional abnormalities in the prefrontal cortex (PFC) during verbal fluency tasks (Sun et al. 2020). With the use of fNIRS, it is possible to compute the temporal variations in cerebral blood flow by monitoring changes in the light absorption of hemoglobin. fNIRS is a technique that, in its most basic form, monitors variations in the concentration of oxygenated and deoxygenated hemoglobin in brain tissue by beaming near-infrared (NIR) light (650–950 nm) into the head (Pinti et al. 2020). Because of its low sensitivity to body motions and mobility, fNIRS is particularly well suited for monitoring cerebral hemodynamic responses during motor activities or walking tasks, among other applications. Because EEG signals are very susceptible to movement, functional near-infrared spectroscopy (fNIRS) offers an alternate method for monitoring everyday cognition in a noninvasive way (Liao et al. 2017).

In what follows, we first explain the functioning of the EEG and how it is used to measure cognition, as well as future challenges. Next, we elaborate on neurophysiological data acquisition using fNIRS and how it helps in understanding cognition. Lastly, we broach the topic of simultaneous EEG and fNIRS data collection and its impact on measuring cognition.

Measuring Cognition Using EEG: How EEG Works

How EEG Measures Cognition

Measuring cognition requires explaining cognitive processes and behaviors with regard to the functioning of the human brain and the underlying processes of the nervous system (Purves et al. 2008). Behavioral responses to cognitive activities are measured in order to get an understanding of the underlying processes when the nervous system creates appropriate responses to stimuli. When it comes to investigating cognition, neuroscientific methodologies may be classified into two major categories. In the first category, disruptions in brain function caused by degenerative changes or trauma have been utilized to investigate the role of the brain in certain cognitive functions, while in the second category measuring brain activity while a subject is engaged in a specific cognitive task has been utilized to understand the neural underpinnings of cognition. Brain network exploration and understanding are accomplished through the use of electroencephalography (EEG). Scientists have used EEG to map the brain areas that are active during a psychological process, in what is known as the hunt for the neural correlates of cognition (Purves et al. 2008). For example, researchers discovered that neurons in the prefrontal cortex increase their firing rate when information is retained in memory; this new understanding encouraged further investigation into the involvement of that brain area in a variety of executive functions. EEG was initially designed for the purpose of assessing individuals with epilepsy, and it is now utilized for a broad range of purposes, including exploring functional connectivity and functional brain networks, which allows for the evaluation of cognitive processes (Šneidere et al. 2020). Ongoing EEG signals measured over time are widely used in clinical settings to assess various aspects of brain function (Light et al. 2010). Mostly, EEG signals are segregated into multiple frequency bands and analyzed by looking into their respective band powers (Purves et al. 2008). It is possible to utilize the relative power in these bands, in conjunction with other features of the EEG, to assess the general condition of the brain, such as the degree of alertness and sleep phases, as well as to detect and monitor aberrant activity associated with epilepsy.

How Neurons Communicate

The human brain is made up of millions of neurons, each playing a significant part in managing the behavior of the human body in reaction to internal/external and motor/sensory impulses, among other things (Arai et al. 2019). These neurons will serve as information transfer agents between the human body and the brain (Kumar and Bhuvaneswari 2012). Understanding the cognitive behavior of the brain may be accomplished by the analysis of signals generated by the brain. It has been estimated that the typical human brain has around 86 billion neurons (Herculano-Houzel 2009) and that communication between neurons is the key to brain function. A cell body, dendrites (treelike structure), and a number of axons ending in synapses primarily

constitute a neuron. When neurons receive messages in the form of neurotransmitters (dopamine, epinephrine, acetylcholine), the receptors on their dendrites fire, resulting in electrical changes in the neuron, which is referred to as an action potential (Hodgkin and Huxley 1952). Membrane potential is defined as the differential in electrical charge between the interior and the outside of a cell membrane (Chrysafides et al. 2021). It is measured in microvolts. The formation of ion clusters on the outside and interior of the membranes results in a differential in electrical charge between the two membranes. The different ions that are present in the cell membranes are the positively charged sodium and potassium ions and the negatively charged chloride and organic anions. When the neuron is at rest, the sodium and potassium ions are prevalent outside the cell membrane, while the potassium and organic anions are prevalent inside the cell membrane. The average resting membrane potential for a neuron is approximately −70 millivolts. This is because the inside of the neuron has a greater negative charge than the exterior, which causes it to be more negatively charged. When the dendrites of a neuron receive neurotransmitters, it can lead to depolarization, i.e., causing it to move toward 0 millivolts. When neurotransmitters interacting with dendrite receptors cause repeated depolarization of the neuron, it forces the membrane potential to reach the threshold potential (−55 millivolts). When the membrane potential reaches the threshold, a large number of positively charged sodium ions are released into the inside of the cell leading to massive depolarization of the cell which results in the membrane potential being positively charged. This influx of positive ions creates the electrical signal known as action potential which then travels down the neuron (Chrysafides et al. 2021). Eventually, the action potential reaches its peak, which results in the closing of the sodium channels, and no more sodium ions are released inside the cell. In the same period, positive potassium ions are released outside the cell leading to repolarization. As a result, the neuron starts returning to the resting membrane potential; however, it overshoots it and becomes hyperpolarized. In the hyperpolarization stage (or refractory period, where the neurons try to return to resting membrane potential), it is very hard for the neuron to fire again. If the action potential is strong (excitatory), it is then sent to the axon ending at the synapses, resulting in the release of the neurotransmitters (Chrysafides et al. 2021). The axon consists of a myelin sheath that helps in protecting the signal from degradation during transmission. The neuron where the signal originates is called a presynaptic neuron. The neuron where the signal is received is called a postsynaptic neuron. Neurotransmitters interact with the receptors of the postsynaptic membrane resulting in an excitatory neuron or an inhibitory neuron. Excitatory neurons release neurotransmitters that fire an action potential in the postsynaptic neuron, whereas inhibitory neurons release neurotransmitters that inhibit the firing of an action potential.

The Source of EEG

An EEG signal is generated by a population of cortical neurons whose synaptic activity is synchronized. Because of the excitation of postsynaptic neurons, there is a

bigger negative extracellular voltage at the neural dendrites than there is everywhere else along the neuron; this leads to the formation of a dipole (Avitan et al. 2009). A dipole is an area separating a region of positive charge and a region of negative charge (Jackson and Bolger 2014). The electrodes in an EEG device detect the total number of positive and negative charges in their immediate environment. Electrodes can only detect dipoles if they are closer to either the positive or the negative end of the dipole. Since an electrode will measure neutral if it is equidistant from both the source and the sink of a dipole, this means that dipoles can only be detected by electrodes that are closer to either the positive or the negative end of the dipole (Jackson and Bolger 2014). This means that dipoles that are perpendicular to the surface (tangential dipoles) and parallel to the surface (radial dipoles) can both be measured in EEG (Jackson and Bolger 2014; Whittingstall et al. 2003). Because dipoles have a positive and negative side, they will create positive and negative deflections in various areas of the scalp. The dipole of a single neuron is very small, making it hard to be measured from the scalp. The dipoles from several neurons in a location will total up since electrodes sense the sum of charges in their surroundings. The amplitude of a single dipole is quantifiable as the sum of many individual dipoles in a region (Kandel et al. 2000). However, because electrodes in the brain detect the cumulative sum of both positive and negative ends of dipoles, neurons need to be active in both a parallel a and synchronous manner for there to be a quantifiable (nonzero) signal (Jackson and Bolger 2014). Therefore, if the neurons are all arranged in the same direction, their impulses can accumulate to make a bigger signal, and the parallel arrangement is required to produce a quantifiable dipole. In any other configuration, the positive and negative ends of the separate dipoles will accumulate and cancel each other out.

The transmission of the EEG signal across the brain is attained through volume conduction. The electrical signal generated by a collection of neurons (or neuronal activity) travels from the brain, through the dura layers, through the skull layers, through the scalp, and ultimately to the electrode in order to be measured with an EEG electrode placed outside the head on the scalp (Jackson and Bolger 2014). When the signal that is being carried by volume conduction reaches the boundary of the volume it is moving through, volume conduction can no longer take place because ions are unable to exit the volume. The signal's ability to travel from one volume to the next is due to a sort of capacitance that exists between the volumes. In its most fundamental form, a capacitor consists of two charge reservoirs that are physically separated by an insulating layer (a dielectric). If there were no insulating barrier, then the charges would be able to freely mix, and the end result would be a pool that was neutrally charged. However, the presence of the insulating layer prevents the ions from mixing. On the other hand, if there is an insulating layer between the membrane and the medium that surrounds it, there is a possibility that a charge difference will develop between the membrane and the medium that surrounds it. This will result in positive ions accumulating on one side of the membrane and negative ions pushing up on the other side of the membrane (Baars and Gage 2010; Jackson and Bolger 2014). The amount of charge that it accumulates on the other side is determined by the properties of the insulating materials (Keil et al.

2014). An array of layers starting from the brain to the dura layers forms a series of conductive volumes analogous to a stack of capacitors. The extracellular positivity will propagate via volume conduction to the near side of the closest insulating layer, at which point volume conduction cannot carry the signal further because the insulating layer is a physical barrier to ion flow. The positive ions that have collected on the near side of the insulating layer will resist the positive charges that have accumulated on the other side of the layer. Positive charges that are repelled and amass on the far side of the insulating layer will, in turn, repel and push other positive charges away from the insulating layer. This procedure will be repeated through each capacitor in the stack until it reaches the electrode at the end of the stack. It is thought that the capacitive arrangement described above accounts for the vast bulk of the EEG signal's content. The passage of electrons between the gel and the electrode (Usakli 2010) does result in the generation of half-cell (DC) potentials. EEG system users are instructed to allow the electrodes to "settle" for a few minutes before recording. This is done to allow the interaction between the electrode and the gel to reach a steady state, at which point the steady DC offset can be accounted for somewhere else in the system.

EEG Analysis

Event-Related Potentials (ERPs)

The continuous EEG signal is beneficial for analyzing the general condition of the brain; however, its value in researching individual cognitive functions is restricted due to the fact that it is not tied in time to any specific cognitive processes or events (Purves et al. 2008). It is more effective to use a time-locked average method such as event-related potentials (ERPs) to map scalp electrical activity to cognitive performance than to use a single point in time. Event-related potentials (ERPs) are very small voltages generated in the brain structures in response to specific events or stimuli (Sur and Sinha 2009). They reflect the summed electrical activity of neuronal populations specifically responding to these events. As such, they can provide high temporal resolution of neural processing underlying various cognitive functions (Blackwood and Muir 1990). ERPs are often smaller in size than the raw EEG signals in which they are contained; yet, in order to separate ERP signals from background noise, several trials need to be averaged over a period of time (Sur and Sinha 2009). These time-locked epochs of the EEG signal are averaged throughout the many occurrences of a particular cognitive event in order to extract ERPs. ERPs are then analyzed (Blackwood and Muir 1990). These random fluctuations in the EEG tend to average away, leaving only those voltage changes directly related to the processing of the event of interest. The amplitude of the EEG varies more or less randomly in relation to the timings of these events. The average ERP trace that can be acquired in this manner normally consists of a number of peaks, both negative and positive, that are labeled according to their electrical polarity (N or P for negative or positive) and their latency. These peaks are named according to their electrical polarity (Purves et al. 2008).

Recordings of ERPs are typically made when the participants being studied are engaged in a variety of cognitive tasks and are being exposed to a range of stimuli. The variability of ERP responses as a function of the type of stimulus and the task conditions is then utilized to infer something about the mechanisms behind the cognitive process that is under investigation (Purves et al. 2008). ERPS represents neural activity with a very high temporal precision since the signals arise from the electrical elements of neuronal activity. Because of this, ERPS is particularly effective for investigations in which the timing and sequencing of functional brain activity are very relevant. For instance, ERPs can indicate how early attention can exert an influence on the processing of sensory input, or they can indicate the time point in language processing at which the semantic analysis of a word begins. Both of these are examples of how early attention can have an effect on later processing.

Even though ERPs' primary advantage in the study of cognitive processes is their high temporal resolution, information may also be gleaned from the geographical distribution of the scalp recordings. This information can be used to get some insight into the potential origins of the activity, which can be a useful complement to ERPs' high temporal resolution. For instance, focused activation over the occipital scalp is likely to be originating from the visual cortex and, as a result, include visual processing (Sur and Sinha 2009). ERP recordings, because of their great temporal resolution, are able to provide a dynamic picture of the activity that occurs in the brain throughout time. When many electrodes are utilized, it is possible to estimate the locations of the neural generators producing scalp-recorded ERPs with the use of analysis algorithms (Rugg 2009).

EEG Spectral Bands

The frequency bands of the EEG waveform are commonly divided into five categories (alpha, beta, theta, delta, and gamma bands). In terms of the frequency range, delta oscillations have the smallest frequency range. Delta oscillations are neuronal oscillations arising from the thalamus or cortical region associated with global processing, mainly pertaining to evolutionary processes (Neske 2016). They span large cortical regions and have been hypothesized to be involved in integrating cerebral activities across diverse cortical sites to homeostatic processes (Knyazev 2012). Researchers have also found implications of delta oscillation in higher emotional involvement, behavioral inhibition, as well as synchronization of brain activity with autonomic functions (Neske 2016). When looking at ERP studies, it has been demonstrated that delta EEG power correlates favorably with the amplitude of the P300 component, which is often connected with activities in the dopamine reward system. Therefore, states associated with the necessity of meeting fundamental biological requirements can be related with greater delta activity, according to research. Theta oscillations (between 4 and 7 Hz) are frequently associated with memory and emotional control. According to a number of research, theta oscillations are important in the encoding of information during exploratory movements and spatial navigation. Theta band power variations have also been demonstrated to be connected with discriminating between pictures of positive and negative emotional valence, and people with low vs. high skin conductance responses exhibit different

power changes in theta band than those with high conductance responses. It appears that theta oscillations, like delta oscillations, are associated with the P300 ERP component and have a role in salience detection, demonstrating the strong relationship between motivational and affective processes. Theta predominates in the EEG of nonhuman animals, whereas delta predominates in the EEG of reptiles.

Alpha waves, also known as the alpha rhythm, are neural oscillations that occur in the frequency range of 8–12 Hz and are thought to be caused by the synchronous and coherent (in phase or constructive) electrical activity of thalamic cells in humans. According to prior research, the alpha frequency band is inversely connected to cortical activation, and more activity in the left prefrontal cortex is associated with increased approach desire (Harmon-Jones and Gable 2018). As a result, it has also been viewed as a predictor of emotionally valenced reactions that are positive in nature (Zhao et al. 2018). It can be inferred from the role of alpha oscillations in human EEG that the development of higher brain functions is heavily reliant on inhibitory mechanisms or other functions associated with alpha oscillations, such as working memory and mental representation of objects and events, which are all associated with alpha oscillations (Bazanova and Vernon 2014). It has been found that as youngsters grow older, the percentage and power of slow waves in their brains diminish but the power of alpha waves in their brains grows dramatically as they become older.

Beta oscillations (13–30 Hz) are frequently implicated in the sensory processing of the brain (Barone and Rossiter 2021). They are formed during stable postures and are reduced during active phases, such as movement planning and execution, to maintain a stable posture (Barone and Rossiter 2021). Just prior to and during movement execution, a decrease in the amplitude of beta oscillations throughout sensorimotor regions is observed. In contrast, a rise in beta amplitude above baseline values has been reported at the end of motor movement.

Finally, the building of object representation is related to the use of the gamma band (30–50 Hz or above). There are two main processes involved: the binding of distinct pieces of a single object through bottom-up processes and top-down processes that include the activation, retrieval, or rehearsal of an internal representation. When doing difficult and attention-demanding activities, the power of the gamma band rises, and this increase is generally considered to represent the neural substrate of cognitive processes (Tallon-Baudry and Bertrand 1999). It is well known that distinct aspects of things or events are encoded and processed in different areas of the brain, and it is possible that humans see coherent representations as a result of gamma oscillations. According to research, gamma activity is involved in the binding together of spatially diverse aspects in visual objects as well as the reflection of linkages between words and the meanings they imply. The integration of sensory and motor processes has also been linked to it in the context of human movement.

EEG Preprocessing

Among the most important steps in EEG data analysis is data preparation. This is important because data errors caused by noise in the data might lead to inconsistencies in the results. EEG data often contains a great deal of noise, which can make

it difficult to distinguish weaker EEG signals. Apart from that, people who take part in EEG experiments frequently blink and fidget, which results in the formation of ocular and muscle artifacts that might taint the data. When EEG data is preprocessed, it assists in the removal of undesired artifacts from the EEG signal and makes it appropriate for further processing. One of the most important aspects of EEG data processing is the detection/removal of defective channels because many analysis algorithms will break down if they are presented with egregiously bad signals (Bigdely-Shamlo et al. 2015). The following procedures are followed by the majority of EEG data processing pipelines: noise reduction, bad channel detection, bad channel removal, interpolation of the bad channels, artifact rejection, and referencing.

The following is a summary of EEG preprocessing:

1. Downsampling: It refers to the process of reducing the sampling rate of a signal. Downsampling is useful to compress the data size. It also helps independent component analysis (ICA) (Sun et al. 2005) to produce better decomposition by eliminating unnecessary high-frequency components.
2. Filtering:
   (a) Line noise removal: Usually, a notch filter at 60 Hz is used to eliminate line noise from EEG recordings. In practice, however, notch filters frequently have a notch width of 10 Hz or greater, resulting in severe signal distortion in the frequency range of 50–70 Hz. This distortion should not be a problem for analyses that apply a 40-Hz low-pass filter to the signal; however, it is problematic for studies that require high-frequency signals to be examined. Some investigations have also demonstrated that noncausal low-pass filtering can have a considerable impact on the beginning of ERPs (Rousselet 2012; Van Rullen 2011). As an additional point of reference, studies (Barnett and Seth 2011) have demonstrated that filtering, namely, low-pass filtering, can have a negative influence on Granger causality and other connection calculations.
   (b) High-pass filtering: The application of a high-pass filter has the goal of removing baseline drift, which is a type of noise in the signal. The use of lower cutoff frequencies, such as 0.01 Hz for cooperative participants and 0.1 Hz for youngsters and patients, is often advised (Luck 2005).
   (c) Low-pass filtering: Frequencies below a certain value are kept while others are discarded. This is usually done to focus on the frequencies that are relevant to the study.
3. Re-referencing: When recording EEG data, the voltage of each electrode is recorded in relation to the voltage of other electrodes in the same session. The "reference," which might be a single electrode or a set of electrodes, is the point at which the voltage will be measured in relation to Choi and Hwang (2019). This implies that any brain activity detected at the reference electrode will be mirrored in all of other electrodes, potentially contaminating the signal. Most EEG investigations employ the Common Average Reference for re-referencing (Bertrand et al. 1985). Using a reference electrode decreases

the influence that a single failing electrode will have on the outcome of the experiment. However, employing this reference only makes sense with systems that have enough channels to ensure that the total activity averages to zero on a consistent basis. Other frequent reference techniques include the use of Mastoids (electrodes that are implanted roughly behind a person's ears) and the central electrode Cz (which stands for center electrode). Mastoids are generally used as reference electrodes because the region around the mastoids do not elicit a great deal of neuronal activity since they are located relatively far away from the brain while still being adjacent to other electrodes. On the other hand Cz electrodes are mostly used as reference electrodes when the region of interest is away from the central region (Choi and Hwang 2019).

4. Detecting and interpolating bad channels relative to this reference: An important stage in EEG preprocessing is the detection of defective or outlier channels, which is one of the most difficult to do. To identify bad channels, four primary criteria are typically used. These criteria are as follows: extreme amplitudes, lack of correlation with any other channel, lack of predictability by other channels, and unusually high frequencies (Bigdely-Shamlo et al. 2015). Many of the criteria make use of a robust z score, with the mean being replaced by the median and the standard deviation by the robust standard deviation in some cases. In order to compensate for the problematic channels that have been identified, data for the bad channels are interpolated using data from the nearby channels. The interpolation of poor channels is generally accomplished through the use of spherical splines, in which the channel locations are projected onto a unit sphere and a matrix characterizing the connection between good and bad electrodes is produced and used. Finally, the result of the matrix is utilized to interpolate the data for the electrodes that did not perform well.
5. Artifact removal: Artifacts are signals that do not originate from the brain but are still picked up by the EEG electrodes. The sources of EEG artifacts are generated from multiple sources and can manifest in different ways. Most EEG artifacts can be generally classified into two categories: environmental and biological. Environmental artifacts are generated from the environment or through outside interference from where the day is being collected. This includes power line noise, improper contact of the EEG electrode with the scalp, and movement of individuals near the EEG system. On the other hand, environmental artifacts are easier to discern than their biological counterparts, as biological artifacts are produced by the body. The vast majority of biological artifacts are thought to have arisen from sources within the body. The act of blinking, eye movement, head movement, heartbeat, and muscular sounds are all examples of common biological artifacts. A potential source of artifacts is any brain signal that does not directly relate to the phenomenon that is the subject of the current investigation. The most common technique for artefact correction is ICA. ICA separates independent sources linearly mixed in multiple sensors. It has two basic assumptions: statistical independence of sources and non-Gaussian distribution (Sun et al. 2005).

Current Challenges in EEG Preprocessing

Although EEG has shown to be a valuable tool in a variety of fields, it still has substantial disadvantages that prevent it from being successfully used for analysis or data processing in most cases. To begin, the signal-to-noise ratio (SNR) of EEG is poor because the brain activity being monitored is typically buried beneath many sources of comparable or larger amplitude ambient, physiological, and activity-specific noise, generally referred to as "artifacts," that obscure the signal (Roy et al. 2019). Consequently, a range of filtering and noise reduction techniques must be used to limit the effect of various noise sources while still allowing actual brain activity to be recovered from the recordings. Aside from that, the EEG is a nonstationary signal, which means that its statistics fluctuate as time progresses. Therefore, when applied to data acquired from the same individual at a later time, a classifier trained on a tiny quantity of user data collected over a short period of time may perform poorly. This is a substantial challenge for real-world EEG applications, which typically need the utilization of limited amounts of data in order to be successful (Acharya et al. 2013). Finally, the significant intersubject variability of EEG applications lowers the usefulness of these applications in clinical settings. This phenomenon is caused by physiological differences across individuals, and while the magnitude of these differences varies, they can have a considerable influence on the performance of models that are designed to generalize over a large number of participants. The ability to generalize from one set of individuals into a second, previously unknown group is crucial to many practical applications of electroencephalography, and significant research effort is being directed toward developing systems that can cope with intersubject variability. In order to address some of the issues stated above, processing pipelines using domain-specific approaches are typically used in conjunction with domain-specific techniques. Significant research has been conducted on EEG data in order to construct processing pipelines that are capable of cleaning, extracting valuable properties, and categorizing the data. A few sophisticated techniques, such as Riemannian geometry-based classification and adaptive categorization, are able to successfully resolve these challenges in some circumstances, but they fail horribly in others (Roy et al. 2019). Another advantage of greater levels of automation is that it would be useful for a greater variety of various vocations. Incorporating more advanced automated EEG processing into this approach might result in a far quicker and more flexible procedure. Similar to this, real-time detection or prediction of the onset of an epileptic seizure would be tremendously beneficial to epileptic patients, but it would involve the use of automated EEG processing to accomplish this. Currently available EEG-based technologies are less flexible and generalizable than they were in the past, and the most popular implementations of each of these applications require the usage of domain-specific processing pipelines, which are not available in the past (Biasiucci et al. 2019).

EG Feature Extraction

After the EEG data has been preprocessed, the next stage is EEG processing utilizing feature extraction. Multiple features can be extracted from EEG data. The most commonly extracted features are statistical, time domain based, frequency domain based, time-frequency domain based, and spatiotemporal features, with time domain

based features being the most basic. Statistical features include mean, median, variance, standard deviation, skewness, kurtosis, and energy of the EEG signal (Jiang et al. 2019). Skewness shows the symmetry of the probability density function (pdf) of the amplitude of a time series, kurtosis indicates the peakedness of the probability density function (pdf) of a time series, and energy (E) is the sum of the squares of the amplitude of a time series, respectively. Statistical features may be approximated across participants and across various electrodes, as well as across different electrode configurations, but it does not look into the interaction between electrodes. Other statistical features include wave duration, peak amplitude, and instantaneous frequency (IF) (Stancin et al. 2021) which are extracted using period-amplitude analysis. Statistical features such as the Hjorth parameters (Vourkas et al. 2000) can also be used to derive additional features. Hjorth parameter is based on the variance of the derivatives of the EEG signal. The most commonly used Hjorth parameters are mobility, activity, and complexity, which are the first three derivatives of the EEG signal.

Frequency is the number of occurrences of a repeating event per unit of time. Since EEG is a nonstationary signal, it contains events that occur at different frequencies. The term frequency domain analysis refers to the process of representing a signal by its frequency component and estimating all of its related properties in terms of frequency. Frequency domain features are extracted widely using power spectral density (PSD) (Dempster 2001). It can be calculated with several parametric and nonparametric methods. Nonparametric approaches, such as the Fourier transform (which is typically performed using the fast Fourier transform algorithm (FFT)) (Rampil 1984), Welch's method (Zhao and He 2013), and Thompson multitaper method (Karnik et al. 2021), are more frequently employed than parametric methods. Autoregressive (AR) models, multivariate auto-regressive models, and autoregressive-moving average (ARMA) models are all examples of parametric approaches for the estimation of the PSD (Stancin et al. 2021). Furthermore, relative and absolute powers of the five frequency bands, delta, theta, alpha, beta, and gamma, are some of the most commonly used features in the frequency domain. Additionally, these features can be further extended by the calculating ration between frequency bands. Measurements of band ratios are often viewed as quantitative measures of periodic, or oscillatory, activity in nature (Donoghue et al. 2020). This is predicated on the assumption that the measure represents the relative strengths of separate periodic components that are properly represented by predetermined frequency ranges. It is feasible to obtain features such as reflection coefficients and partial correlation coefficients from autoregressive models when they are used in conjunction with other models. Another method for extracting features is to use wavelet coefficients that have been obtained after conducting wavelet decomposition. It is a usual practice to employ the PSD approach in order to calculate the second-order statistics of an EEG signal. Since EEG is a nonstationary signal, the study of the EEG signals in both temporal and frequency domains at the same time is a very effective technique. Spectrogram (Ng et al. 2019) is a common time-frequency processing technique that is calculated using short-time Fourier transform (STFT) (Ng et al. 2019). The STFT approach

maps the signal into a two-dimensional function of frequency and time, which is then analyzed.

Entropy (Kumar et al. 2012) is another feature that can be extracted from an EEG signal; however, the distinctiveness of entropy stems from the fact that it can be derived both in the time domain and in the frequency domain, which makes it very useful. When applied to a time series signal such as EEG, the idea of entropy is used to measure, in a statistical sense, the degree of uncertainty or unpredictability in the pattern, which is also roughly comparable to the amount of information contained in the signal. In the time domain, entropy measurements often divide up the signal into segments that are then compared for similarity, either immediately (in the time domain) or after some type of processing of the signal has been applied (such as the power spectral density). Most of the time, this is determined by a few fundamental characteristics, such as the segment length chosen, whether or not the signal has been transformed, and the distance metric, or the method by which the segments are compared. While in frequency domain entropy measures, the EEG signal is first transformed into the frequency domain using various methods such as the Fourier transform or more advanced methods such as wavelets and then examined. The most common forms of entropy-based features in the time domain are sample entropy (Kumar et al. 2012) and approximate entropy (Kumar et al. 2012) while in the frequency domain are spectral entropy and wavelet entropy (Liang et al. 2015). Approximate entropy (ApEn) is a measure that quantifies the complexity or irregularity of a time series. A higher value of ApEn indicates that the signal has greater complexity and irregularity. In order to improve on approximation entropy, the sample entropy (SampEn) concept was proposed. To reduce the inaccuracy of the approximation entropy, it is necessary to eliminate two of its drawbacks: (1) self-matches and (2) a dependence on the length of the time series under consideration. Additionally, sample entropy may be used as an estimate of signal complexity. The spectral entropy (SEN) of an EEG signal is obtained by first translating it into the frequency domain and then calculating the entropy on the normalized PSD of the EEG signal. With the exception of the fact that it is derived using the coefficients of the wavelet decomposition of the provided time series, wavelet entropy (WE) is very similar to spectral entropy in that it is calculated based on the coefficients of the wavelet decomposition of the given time series (Stancin et al. 2021).

It is important to note that all of the features described above are computed using a single EEG channel. In contrast, spatial-temporal characteristics explain the interaction between distinct channels, providing more insight into the understanding of brain functions. Spatial-temporal features can be divided into two categories: directed and nondirected (Stancin et al. 2021). The nondirected spatiotemporal features evaluate the synchronization of two or more channels without any knowledge of the direction, whereas the directed spatiotemporal features evaluate the causation between two or more channels, i.e., they assess functional connectivity between two or more channels (Jiang et al. 2017). Nondirected spatiotemporal features include coherence, partial coherence, phase coherence, phase-locking value, imaginary component of coherency, phase lag index, and mutual information (MI). Coherence (Srinivasan et al. 2007) is a mathematical measure of the degree to

which two EEG signals collected at different sensors are comparable to one another. It is a metric that has been routinely used to infer synchronization across distinct locations at the sensor level. The value of coherence varies from 0 to 1. If the phase (rise and fall) of the two signals becomes synchronized with time, it indicates that there is a functional connection between these two parts, i.e., the areas might be communicating with each other. Partial coherence (Liberati et al. 1997) is an adjusted coherence in which the linear influence of the common signal has been eliminated. It is calculated using a third channel that is not physically adjacent to the two observed channels. Phase coherence (Thatcher 2012) is a phenomenon that occurs when there is a continuous phase difference between any two signals or waves that have the same frequency as one another. It was created in order to solve the challenge of nonlinear relationships between the two channels that had previously existed (Stancin et al. 2021). The phase-locking value (PLV) (Schmidt et al. 2014) is the absolute value of the mean phase difference between two signals represented as a complex unit length vector. It is used to determine if two signals are locked together. Similarly, if the marginal distributions of the two signals are uniform and the signals are not reliant on one another, then the relative phase will have a uniform distribution as well, and the PLV will be zero . However, if there is a significant degree of correlation between the two signals' phases, the PLV will approach unity in this situation. The most significant shortcoming of coherence is that it is significantly influenced by volume conduction conditions. The imaginary part of coherency (ICOH), suggested by Nolte et al. (2004), is aimed at removing any forms of superfluous coherence that arise as a result of instantaneous action. Lastly, the phase lag index (PLI) (Stam et al. 2007) is a measure of the asymmetry of the distribution of phase differences between two signals. Since it does not take into account the influence of amplitude information, it is an improvement compared to the imaginary component of coherency. Lastly, mutual information (Ramanand et al. 2010) measures the quantity of knowledge received about one time series by viewing the other time series is measured in terms of the number of observations of the other time series. It is a commonly used metric in information theory, and it is computed by starting with Shannon's entropy as a starting point and working outward from there.

The most commonly used nondirected spatiotemporal feature is Granger causality (Seth et al. 2015). Granger causality is an estimation of causality in time series that depends on linear methods. The fundamental concept of Granger causality is that causes both precede and aid in the prediction of their effects. A linear vector autoregressive model of the two time series is used to construct the model. VAR models are basic mathematical models in which the value of a variable at a specific time is described as a (linear) weighted sum of the value of the variable in the past (typically across a number of discrete time steps) and the value of a set of additional variables in the past. Each variable is a vector stochastic process encoding a time series, and each process is represented by a different variable. The process of fitting a VAR model consists of determining the appropriate weights to use in order to reduce estimate errors. According to the theory of Granger causality, one variable X "causes" another variable Y if the history of variable X contains information that helps predict the future of variable Y, in addition to the information that is already

present in the history of variable Y itself (and in the history of other "conditioning" variables Z). When this condition is met, one may say that there is an "information flow" from X to Y (Barnett and Seth 2011).

Complex networks are a graph theory-based approach to EEG feature extraction (Stancin et al. 2021). In complex network analysis, pairwise connections between channels are used to create a connectivity matrix which in turn simulates a graph. These feature extraction techniques look into the interaction of two or more channels by looking into the pairwise interaction between channels. Once the graph is obtained, all graph properties such as degree, mean degree, degree correlation, clustering coefficient, small worldnesss, closeness centrality, eigenvector centrality, betweenness centrality, and diameter can be used as EEG features (Ismail and Karwowski 2020). Degree (D) (the number of edges connected to the vertex) and the mean degree of the network can be used as a feature. The degree correlation coefficient (R) is the correlation coefficient between the degrees of two pairs. The clustering coefficient (Masuda et al. 2018) is a measure of the connectedness of vertices in a network, and it can be either local (for a subgraph) or global (for the entire graph). The presence of a local clustering coefficient of one indicates that the relevant local subgraph in a network is completely linked to all of its neighbors in the graph. This is a second-order graph statistic that is calculated by weighing the trade-off between strong local clustering and low path length. For each vertex in the network, there is a centrality degree associated with it, which indicates the number of shortest routes in the graph that the observed vertex is participating in at any one time. Additionally, each vertex in the network has a measure of proximity centrality, which is the average distance between the observed vertex and all other vertices in the graph, as seen in the graph below. The degree to which a vertex is easily accessible to other vertices is measured by its eigenvalue centrality. In this case, it is calculated using the relative vertex scores, with the primary premise being that high-scoring connections should contribute more to vertex influence than vertices with low scores. Within a network, betweenness centrality is a measure of the importance of each vertex's position. It is calculated based on the number of times a vertex appears along the shortest path between two other vertices in a certain time interval. Finally, the diameter (d) of a graph is the longest shortest path across it (Ismail and Karwowski 2020).

Application of EEG

EEG's noninvasive and portable qualities, combined with its ability to measure cognition with temporal resolution on a millisecond scale, have led to a diverse range of uses for the technology. Traditionally, EEG has been utilized in the diagnosis of mental conditions, such as neurological examination of patients with traumatic brain injuries, neurotherapy, and applications involving brain-machine interfaces. However, recent studies have demonstrated its multifaceted qualities in a variety of domains, including gaming; neurofeedback for the management of pain, trauma, and overall well-being; the management of cannabis use; mindfulness; and

training for cognitive enhancement. In the last 20 years, EEG devices have decreased in size and cost because of commercial multichannel analogue front-end integrated circuits, which have lowered the expertise, time, and cost needed to create a new EEG device. Different headsets with new types of electrodes and improvements in analogue and digital electrical design have simplified the EEG setup, making it more accessible for clinical and experimental uses. In this section, different applications of EEG for measuring cognition are discussed.

Measuring Cognitive Load Using EEG

The cognitive load of an individual can be defined as the amount of strain that a task places on that person's working memory. Because the cognitive load is directly related to the amount of time spent on a task, assessing the impact of instructional interventions requires taking both the average cognitive load and the accumulated cognitive load into account. It is generally accepted that an individual's sense of mental exertion can be inferred from the overall load they have experienced over the course of the task. The majority of psychological research studies use subjective rating scales to assess cognitive load (Paas et al. 2010; Paas 1992; Paas and Van Merriënboer 1994). Examples of these rating scales include the NASA Task Load Index (NASA-TLX; Hart and Staveland 1988) and the 9 point symmetrical category mental effort rating scale established by Van Gog and Paas (2008). However, subjective rating scales do not provide any insight into changes in the instantaneous load over time, unless they are applied multiple times within a task, which is something that has been done with activities that have varied durations. However, due to the relatively large amount of time that passes between each presentation of the rating scale, it is not clear whether subjective methods can provide a continuous measurement of variations in cognitive load while an individual is working on a task. This limitation can be alleviated by using objective measures. Objective measures for measuring cognitive load include measuring neurophysiological responses during secondary task methods using EEG, PET, and fMRI. In secondary task methods, the amount of load imposed by the primary (learning) task is measured by the performance or response time on a secondary task. In other words, the amount of load is measured by the length of time it takes to complete the secondary work.

The most common method for assessing cognitive workload using EEG data is the percentage decrease (event-related desynchronization (ERD)) or rise (event-related synchronization (ERS)) in band power during the activation interval relative to (task period) to the baseline interval (rest period). The ERD/ERS index is used to measure cognitive load:

$$\frac{\text{ERD}}{\text{ERS}}\% = \frac{\text{Baseline Int Band Power} - \text{Task Int Band Power}}{\text{Baseline Int Band Power}} \times 100 \qquad (1)$$

Calculating the theta-alpha ratio, which in recent years has come to be seen as a potentially relevant signal in the field of research pertaining to the examination of cognitive capacities, is another approach that has been used to measure cognitive

load. Because it is presumed that the theta-alpha ratio varies with age as well as cognitive capacities, this indicator can be utilized not only to quantify cognitive load but also to identify cognitive deficiencies in those who are elderly. In a manner similar to that of the earlier research, Gevins et al. (1998) and Smith et al. (2002) employed EEG indices to evaluate different stages of working memory. The brain activations that occurred during pattern recognition were examined. When they increased the mental load associated with the memory task, they found that an increase in frontal theta frequency activity occurred alongside a drop in alpha frequency activity. This was made abundantly clear by the findings of the study. It has been discovered that the levels of theta and alpha channels measured by EEG in the frontal and parietal regions of the brain correlate with the amount of mental or cognitive load. The majority of research has shown that frontal theta increases in response to increased cognitive load, whereas alpha decreases in response to increased cognitive burden.

Analyzing Mild Cognitive Impairment Using EEG

The term mild cognitive impairment (MCI) refers to a syndrome in which a mild cognitive loss occurs which may result in functional impairment in the patient (Baker et al. 2008). It is interesting to note that a high percentage of people with MCI go on to develop dementia and Alzheimer's disease (AD) as a result. Previous research has hinted that certain signal characteristics connected with the electroencephalogram (EEG) might be relevant in understanding AD. This is due to the fact that various EEG abnormalities have been recorded in the community of people with Alzheimer's disease (AD). For instance, there have been reports that the EEG patterns of people with Alzheimer's disease often exhibit a shift toward increased power in the lower EEG frequencies and diminished coherence of fast EEG rhythms. Researchers have demonstrated that unusual EEG patterns are present in Alzheimer's disease (AD) patients. These patterns are characterized by a decrease in alpha and beta power, as well as a corresponding increase in delta and theta power when compared to normal age-matched controls (Coben et al. 1983; Gianotti et al. 2007; Mattia et al. 2003). Many researchers also suggest that the earliest alterations in the EEG occur in the beta and theta bands, while changes in the alpha and delta bandwidths show later in the time course of the disease.

Resting-state EEGs have been used in clinical research with AD patients. A considerable body of work based on single-session resting-state EEG has identified differences between AD and controls in EEG parameters such as spectral powers, complexity, and connectedness (Trinh et al. 2021). AD patients had lower signal complexity (higher power of slow oscillations (delta, theta) and lower power of fast oscillations (alpha, beta, gamma) over temporal, parietal, and occipital scalp regions (Huang et al. 2000; Roh et al. 2011; Rossini et al. 2007). Moreover, entropy-based EEG complexity decreases with illness progression (Sun et al. 2020). Few studies indicated a nonsignificant reduction of complexity in MCI compared to controls (Dauwels et al. 2011; Labate et al. 2013; Roh et al. 2011; Xu and Tao 2013). However, finding a differentiating EEG pattern based on resting-state recordings to classify MCI and HC is difficult.

In clinical studies with Alzheimer's disease patients, resting-state EEGs have been utilized. Differences in EEG characteristics such as spectral powers, complexity, and connectivity have been found between people with Alzheimer's disease (AD) and controls, according to a substantial body of research based on single-session resting-state EEG (Trinh et al. 2021). Patients with Alzheimer's disease had lower signal complexity (Abásolo et al. 2005, 2006, 2008; Liu et al. 2016) and higher power of slow oscillations (delta, theta) and lower power of fast oscillations (alpha, beta, gamma) over temporal, parietal, and occipital scalp regions (Huang et al. 2000; Ishii et al. 2017; Roh et al. 2011; Rossini et al. 2007). In addition, the complexity of the EEG as measured by entropy tends to diminish as the illness progresses (Sun et al. 2020). Comparing patients with MCI to controls, only a few studies found a decline in complexity that was not significant (Trinh et al. 2021). Finding a distinguishing EEG pattern that can differentiate MCI and HC based on recordings taken when the subject is in a resting state can be challenging.

Memory loss can also induce important EEG rhythms to distinguish AD/MCI from controls. Working memory impairment is a common symptom of MCI and AD (American Psychiatric Association 2013). Working memory allows one to access and manipulate the information quickly (Baddeley 2015). Spatial orientation, problem-solving, and reading require working memory (Kirova et al. 2015). MCI affects verbal/visual working memory, sentence span, operation span, digit span, letter-number sequencing, and arithmetic operation (Kessels et al. 2011). Working memory activities are an excellent choice for inducing task-relevant changes in MCI and controls in resting-state EEGs.

Measuring Cognition Using Functional Near-Infrared Spectroscopy (fNIRS)

How fNIRS Measures Cognition

Functional near-infrared spectroscopy (fNIRS) is an optical noninvasive imaging technique for the brain that is similar to electroencephalography (EEG) in that it uses near-infrared and visible (red) light to determine the amount of oxygen present in organic tissue and blood (Karim et al. 2012). Based on the hypothesis that neural activation and vascular response are tightly coupled, this technique is an effective optical neuroimaging method that monitors changes in the optical absorption of oxygenated and deoxygenated forms of hemoglobin in tissue (hemodynamic response) in response to brain activation (Chen et al. 2020). A lineal link has been demonstrated between neural activity and hemodynamic responses, which demonstrates that variations in hemodynamic response are an appropriate marker for the evaluation of neuronal activity (Arthurs and Boniface 2003; Logothetis 2001). fNIRS offers functional contrast comparable to the functional MRI blood oxygen level-dependent (BOLD) signal, representing changes in regional blood flow to regions of the brain engaged in processing

functional activities. fNIRS evaluates brain functions by measuring the mobilization of distinct chromophores (oxygenated hemoglobin, deoxygenated hemoglobin, and cytochrome c-oxidase) and the timing of these mobilizations with events. However, because of methodological and theoretical issues connected with cytochrome c-oxidase (Cyt-Ox) functioning, fNIRS is mostly used to measure and analyze oxyHb and deoxyHb mobilizations in order to examine brain processes in humans (León-Carrión and León-Domínguez 2012). A total of two sets of flexible fiber-optic cables are employed during fNIRS recordings: a set of source or transmitter optodes and the second set of reception optodes. The source fiber-optic optodes are used to distribute near-infrared light (0.4 W/cm^2) to a number of different locations on the head using a fiber-optic network. Each location has two (or more) different hues of light, which are utilized to distinguish between the absorption changes of oxygenated and deoxygenated blood in the same place. They are directly tied to the cerebral blood flow (CBF) associated with an event as well as the physiological reactions triggered by the brain's functioning state (fNIRS measures this reaction in the cerebral cortex) (León-Carrión and León-Domínguez 2012). fNIRS head cap source optodes emit near-infrared light, which enters the tissue and diffuses throughout the tissue after entering through the source optodes. This light will be able to penetrate the cortex of the brain down to about the outer 5–8 mm of the cortex based on earlier modeling research. When the light departs the head, it is captured by an array of fiber optics, which then transports the light back to photon detectors on the fNIRS device (Dahlstrom-Hakki et al. 2019). The quantity of light that travels from the source optode to the receiver optode is proportional to the amount of absorption that occurs in the underlying tissue between that pair of measuring devices. Biological tissue has a high scattering coefficient. Before scattering, light in the wavelength range of 650–900 nm passes into brain tissue for roughly one-tenth of a millimeter (Rupawala et al. 2018). Evoked brain activity causes localized changes in blood flow in the active region, which in turn causes differential changes in the concentrations of oxyhemoglobin and deoxyhemoglobin in the brain. Because the two forms of hemoglobin have different optical absorption profiles, this results in differential changes in the absorption of light at different wavelengths (León-Carrión and León-Domínguez 2012). By using a modified Beer-Lambert equation, it is possible to recover changes in hemoglobin from fNIRS observations taken at several wavelengths. The position of the brain signal can be approximated by putting the optical sensors on the head in a spatially organized manner. The evaluation of these task-related mobilizations done in the context of a baseline provided by the researcher himself or herself. The difference between the oxyHb and deoxyHb concentrations at baseline and throughout task performance defines where an increase or reduction in CBF occurs in the cortex (Rupawala et al. 2018). Because an increase in CBF is associated with increased brain activity, the temporal and spatial correlation between CBF and task is a predictor of cerebral function. The ability to analyze cerebral functioning in both spatial and temporal domains is what gives the technology described its name: functional near-infrared spectroscopy (fNIRS).

How fNIRS Works

Oxyhemoglobin and Deoxyhemoglobin

For generating energy and action potentials, neurons require nutrients which in turn are required for the generation of neuronal activity. Glucose and oxygen and other chemicals are delivered to metabolically active neurons by blood perfusion through capillaries, resulting in an increase in regional cerebral blood flow (rCBF) and regional cerebral blood oxygenation (rCBO). As a result, variations in regional cerebral blood flow (rCBF) or regional cerebral blood flow (rCBO) may be utilized to map brain activity with a high spatial resolution ("functional neuroimaging"). The rate of oxygen metabolism in the brain (cerebral metabolic rate of oxygen (CMRO2)) increases significantly during the functional engagement (Chen et al. 2020; Dahlstrom-Hakki et al. 2019; León-Carrión and León-Domínguez 2012). Because of increased oxygen consumption during neuronal activity, tissue oxygenation decreases, which is counteracted by an increase in oxygen supply when cerebral blood flow (CBF) and cerebral blood volume (CVB) increase (León-Carrión and León-Domínguez 2012), which is caused by a mechanism known as neurovascular coupling. Increasing capillary density, which in turn increases total cerebral blood volume, is required to maintain consistent glucose and oxygen consumption if the stimulation is to be sustained over time (Karim et al. 2012; León-Carrión and León-Domínguez 2012; Rahman et al. 2020). When the stimulus is brief, the aforementioned hemodynamic and metabolic changes do not occur in the same way as they do when the stimulus is long-lasting. In addition to producing CBF and oxygen metabolism, the body produces them to offset the effects of tissue deoxygenation as well as to oxygenate the blood. During the process of transferring oxygen, hemoglobin is known as oxyhemoglobin (oxyHb). However, when it releases oxygen as a result of a rise in oxygen metabolism, it is referred to as deoxyhemoglobin (deoxyHb) (deoxyHb). As a result, a brain area might be termed active when its rCBF rises, resulting in a drop in deoxyHb and an increase in oxyHb, which in experiments is often connected with a specific event (Lindauer et al. 2010). Typically, the additional oxygen supplied to the brain region outpaces the local CMRO2 usage, resulting in an overflow of cerebral blood oxygenation in active parts of the brain (Irani et al. 2007; Karim et al. 2012; Kohl et al. 2020; León-Carrión and León-Domínguez 2012). Hyperoxygenation of the tissues occurs as a result of an increase in cardiac output. The results of many optical experiments, including fNIRS and fMRI, have revealed that when brain activity begins, hyperoxygenation (owing to an increase in CBF—increased oxyHb) occurs first, followed by low oxygenation (increase in deoxyHb). This vascular response is difficult to measure and very controversial (Irani et al. 2007; León-Carrión and León-Domínguez 2012; Pinti et al. 2020). Because oxyHb and deoxyHb have distinct optical properties in the near-infrared light range, as well as a broad range of sensitivities to different wavelengths, it is possible to quantify changes in chromophore concentration during neurovascular coupling using optical methods (Caumo et al. 2022; Chen et al. 2020; León-Carrión and León-Domínguez 2012; Taylor et al. 2020). The modified Beer-Lambert law is used to compute the varying amounts of oxyHb, deoxyHb, and

Hb_{TOTAL} concentrations in the bloodstream (León-Carrión and León-Domínguez 2012). The attenuation of light intensity after absorption and scattering by biological tissue is expressed as:

$$I = GI_0e - (\alpha_{HB}C_{HB} + \alpha_{HBO2}C_{HBO2})^L \quad (2)$$

where G is a factor that takes into account the geometry of the measurement and is expected to remain constant regardless of the change in concentration. I_o is the amount of light that is coming in; α_{HB} and α_{HBO2} are the molar extinction coefficients; C_{HB} and C_{HBO2} are the concentrations of oxyHb and deoxyHb chromophores, respectively; and L is the photon path, which is a function of the absorption and scattering coefficients μ_a and μ_b (León-Carrión and León-Domínguez 2012). According to León-Carrión and León-Domínguez (2012), the relative change of oxyhemoglobin and deoxyhemoglobin vs time can be determined through the measurement of changes in optical density (OD) at two different wavelengths. If the intensity measurement was taken at the initial time (baseline) and it was I_b, then the OD change owing to fluctuation in C_{HB} and C_{HBO2} during that period is as follows:

$$\Delta\text{OD} = \log(I_b/I) = \alpha_{HB}\Delta C_{HB} + \alpha_{HBO2}\Delta C_{HBO2} \quad (3)$$

The calculation of ΔC_{HB} and ΔC_{HBO2} is made possible through the performance of measurements at two distinct wavelengths. After this, conclusions about oxygenation and total blood volume (Hb_{TOTAL}) can be drawn (Izzetoglu et al. 2007):

1. Oxygenation $= \Delta C_{HBO2} - \Delta C_{HB}$
2. Blood volume (Hb_{TOTAL}) $= \Delta C_{HBO2} + \Delta C_{HB}$

When taking a baseline, it is vital to consider whether or not the patient is medicated or nervous, since these are variables that might have a quantifiable influence on CBF during the experiment. A comparison of various measurements is dependent on the assumption that the proportion of arterial to venous intracerebral compartments remains constant because NIRS monitors changes in oxyHb and deoxyHb concentrations in both arterial and venous intracerebral compartments of the brain. As a result, variables that affect venous volume should be taken into consideration. It is possible that changes in head position, which are expected to occur during the clinical use of NIRS, will have an impact on venous pressure and the fraction of arterial and venous compartments within the cerebral vasculature. Furthermore, the posture of the body may alter the tone of the resistive arteries, allowing for the maintenance of a steady cerebral blood flow.

fNIRS Measurements

NIR light is beamed onto the scalp in order to perform fNIRS measurements. The NIR light must travel through a number of layers (such as the scalp skin, the skull, and cerebrospinal fluid), each with its unique set of optical characteristics before it

can reach the cerebral cortex. Due to the anisotropic and inhomogeneous nature of human tissue throughout its layers, the interaction of near-infrared light with it is challenging. Among the many components of human tissue that absorb light differently at different wavelengths are water, lipids, hemoglobin, melanin, and cytochrome coxidase, to name a few. Human bodies are made up of around 70% water, and water's absorption in the near-infrared optical window is moderate, allowing NIR light to pass through the tissue without being absorbed. Among the NIR optical window's absorbing chromophores, hemoglobin is the most noticeable and physiologically dependent absorbing chromophore. The oxygenation or deoxygenation of hemoglobin is determined by the saturation condition of the oxyhemoglobin (HbO2) or deoxyhemoglobin (HbR) in the blood. For example, HbO2 and HbR absorb NIR light in different ways: HbO2 oxygen has a greater absorption coefficient at wavelengths more than 800 nm, whereas HbR has a greater absorption coefficient at wavelengths less than 800. This difference in absorption is represented in the color of the blood, which is redder for oxygenated blood (arterial blood, which is 98% saturated) and more purple for deoxygenated blood (venous blood, which is 75% saturated), and can be detected using spectroscopic techniques in both arterial and venous blood. A task that requires the engagement and participation of a brain area raises the metabolic demand for oxygen and glucose in the brain, resulting in a regional cerebral blood flow (CBF) overflow to satisfy the increased metabolic demand.

It is possible to employ fNIRS technology in two different ways, depending on the number of channels available and their architectural design. Source and detector optical fibers (or optodes) for fNIRS sources and detectors are distributed uniquely at various spots on the head and at fixed source-detector separations in their most basic, most common, and most commercially available configurations (Chen et al. 2020). Each source-detector separation serves as a measurement channel, displaying the topographical distribution of HbO2 and HbR concentration fluctuations over the cortical surface of each subject. Using overlapping channels and different source-detector distances applied over the head, an alternate design may be used to generate a topographical image of the distribution of changes in HbO2 and HbR concentrations over the cortical surface (Kohl et al. 2020). It is the latter form of fNIRS, in which much denser arrays of channels sample brain areas that overlap, that is used in the study of diffuse optical tomography (DOT). Wearable and/or fiberless fNIRS sensors have recently been created to improve the usability of the technology. This type of equipment makes use of LEDs that are permanently attached to the head and are powered by batteries. They are employed in the CW technology field. Because there are no fiber-optic bundles, they are lighter and more resistant to movement artifacts than traditional fiber optics. Consequently, participants will be able to move around more freely as a result of the change. In many cases, data is recorded on a wearable recording device and wirelessly sent to a laptop (Almulla et al. 2022).

fNIRS Preprocessing

Once the fNIRS data has been acquired, preprocessing and analyzing of the NIRS signal must take place to identify and isolate hemodynamic changes happening in the

gray matter's vascular network. This is accomplished by the filtering of raw data and the estimation of a hemodynamic response via modeling. Preprocessing is the process of removing unnecessary noise from raw data with the goal of improving accuracy. Noise can be categorized into systematic noise, such as breathing, heart rate, fluctuations in blood pressure, and movement (motion artifact (MA)) noise. Once they are recognized, they must be distinguished and removed. Preprocessing steps such as channel pruning, removal of physiological noise, de-trending, and motion artifact removal/correction are applied to the data prior to hemodynamic response estimation. Frequency filters, wavelets, and smoothing filters are among the preprocessing techniques that are frequently employed. Alternative procedures, including pre-whitening, can also be employed. Once the raw data has been preprocessed, various methods are employed to transform changes in light intensity to changes in hemoglobin concentration. Analysis is used to compare baseline hemodynamic changes with task-related changes. These may be divided into two categories: general linear model (GLM) processing methods and non-GLM processing methods (Uga et al. 2014).

The following is a summary of fNIRS preprocessing:

1. Noise Removal: This is the initial stage in fNIRS preprocessing, and it is performed prior to the estimate of hemodynamic response to the stimulus. Environmental and instrumental noise, heart pulsation, breathing, and cyclic fluctuations in arterial blood pressure, collectively known as Mayer waves, can all inject noise into the fNIRS signal (Kohl et al. 2020). Here, the high-frequency components of the signal are eliminated from the equation. In order to filter away noise from fNIRS signals, researchers employ a variety of filter types and designs. The bandpass filter is one of the most often encountered frequency filters. For the most part, bandpass filters are simple combinations of two types of filters, in that they pass just a certain band of frequencies while attenuating the frequencies that are placed outside of the band (de Cheveigné and Nelken 2019). Unlike a high-pass filter, a low-pass filter allows signals with frequencies lower than a set cutoff frequency to pass through while attenuating sounds with frequencies greater than the given cutoff frequency. Similarly, a high-pass filter allows frequencies higher than the cutoff to pass through while attenuating frequencies lower than the cutoff. In order to properly use these filters, it is necessary to take into account the variances in physiology that exist across various people within the populations. Sporting athletes, for example, have lower resting heart pulsation rates compared to those who do not participate in sports. To account for the lower resting heart rate of the athlete when using a low-pass filter, a researcher would need to change the cutoff frequency of the low-pass filter. This would not be necessary when using a high-pass filter. Furthermore, in order to account for the nonathlete's higher resting heart rate, it is possible that the researcher will choose a higher cutoff frequency for the low-pass filter in the experiment. Additionally, the type of work that is completed may have an influence on the filter options. For example, when exercising as opposed to engaging in non-exercise motor activity, the heart rate and respiratory rate both increase. In order to prevent this difficulty,

it is not advisable to choose a cutoff frequency that is "one size fits all" in all situations (Dans et al. 2021).

2. Smoothing filters (Klein and Kranczioch 2019) are yet another sort of filter that is frequently employed. High-frequency noise in fNIRS data is typically reduced by using smoothing filters, which are commonly employed in this field. Smoothing signals may be accomplished in two ways: either by smoothing in the time domain or by smoothing in the spatial domain. When using time domain smoothing, high-frequency noise is reduced, whereas spatial smoothing averages signals from bad channels with the signals from neighboring fNIRS channels, minimizing the influence of a noisy channel while still maintaining some of the signals from the noisy channel. The most common smooth filters are the Gaussian filters and Savitzky-Golay smoothing filters (Afonso et al. 2017). Gaussian smoothing (Khan et al. 2020) is accomplished by the use of a Gaussian weighting function, which doubles the value of each point based on where it falls on the distribution. The center of the Gaussian is fixed on a single point, which is then weighted in proportion to the points around it. Afterward, the distribution is transferred to the next spot, and the procedure is repeated. In order to smooth out spike motion artifacts, the Savitzky-Golay smoothing method is most commonly used. As a smoothing filter, it may also be used to smooth physiological noise in data.

   Another technique that is mostly used in conjunction with GLM is pre-whitening (von Lühmann et al. 2020). The premise behind pre-whitening is that fNIRS data contains consistent physiological noise that changes in a predictable manner. Some frequencies are overrepresented in the noise distribution as a result of the predictable nature of the noise, which is in violation of one of the GLM criteria for a normal noise distribution (von Lühmann et al. 2020). It is possible to estimate this noise using pre-whitening, which will result in a reduction in the weights of the overrepresented frequencies in the noise distribution. There is a downside to utilizing this approach in that it estimates noise, and as a result, noise might be overestimated or underestimated, thus contributing to bias.
3. Motion Artifact (MA) Correction: Motion artifacts are usually introduced into the fNIRS signals by head movements that cause the source-transmitter pair to shift relative to the scalp (Brigadoi et al. 2014). MAs might appear as substantial and quick increases in magnitude (spikes) when compared to the baseline data. These spikes can be hundreds of times bigger than tissue-related hemodynamic changes. Additionally, the baseline fNIRS signal might vary as a result of the movement of the source-detector pairs on the scalp during the experiment. An unnaturally exaggerated positive correlation between oxy-Hb and deoxy-Hb might result as a result of this phenomenon. Wavelet filters (Duan et al. 2018) are a regularly used approach for removing motion distortions from fNIRS data, and they have a number of advantages. Using wavelet filtering, one can distinguish between distinct frequencies in the cortical signal and different frequencies in MAs. A mother wavelet is used as the starting point for wavelet filtering, which is then scaled and translated to produce daughter wavelets. In the following step, the fNIRS recording is deconstructed using these daughter wavelets. The equations for the wavelet coefficients demonstrate how well the wavelet transform captures

the fNIRS measurements (Perpetuini et al. 2021). The greater the number of wavelet coefficients, the better the wavelet transform's ability to characterize the full signal. These wavelet coefficients combine to generate a distribution that is connected to the scaling and translating parameters of the wavelet transform. MAs are outliers in this distribution because of their deviations from the cortical signal, and they may be deleted as a result (Brigadoi et al. 2014).

fNIRS Analysis

General Linear Model

The GLM is a statistical modeling approach that can be used with fNIRS data (Dans et al. 2021). It has previously been used to simulate the functional magnetic resonance imaging (fMRI) BOLD response, and it has been embraced because of the similarities between BOLD and HRF responses. The GLM makes use of predictors in order to explain the most significant causes of variability in the data by modeling the measured data as a linear mixture of M functionally different processes (Uga et al. 2014). In its simplest form, the GLM is represented as follows:

$$Y = X.\ G + \epsilon \tag{4}$$

where $Y \in \mathbb{R}^{T\times N}$ is the observation matrix where the column vectors are represented as $y_n \in \mathbb{R}^T$ and row vectors are represented as $y(t) \in \mathbb{R}^N$, T signifies the fNIRS data from all time points, and N is the number of channels. $X \in \mathbb{R}^{T\times M}$ is the design matrix, which takes into account a priori knowledge of the predicted form of the evoked hemodynamic response, the experiment's temporal structure, and regressors for drifts and/or physiological error signals. $G \in \mathbb{R}^{M\times N}$ represents the set of weights for the regressors that models functional brain activity and physiological and nonphysiological confounding components. These weights are to be estimated. ϵ is the residual/noise term represented as $\epsilon \in \mathbb{R}^{T\times N}$. To put it another way, the amplitude of the hemodynamic response in one channel (Y) is equal to the predictor (X) multiplied by the predictor's "weight" (G) plus the error term (ϵ). Weights are allocated to predictors depending on how much they contribute to the signal's variability when forecasting the signal. In other words, if the researcher's estimate/assumption regarding the hemodynamic response's shape is correct, the model will give that estimate a higher weight than the other estimates/assumptions (von Lühmann et al. 2020). The noise in the recording is represented by the error component in the equation, which includes physiological, instrumental, and motion noise, as well as other kinds of noise. The GLM makes assumptions about the data and the system noise (von Lühmann et al. 2020). The following are the assumptions:

1. The responses to the task are non-stochastic, which means they are not random and they remain consistent between several iterations of the same task.
2. The distribution of noise is both independent and identical, having a mean of zero and some degree of variance around that point.

3. The noise is homoscedastic, which means that it only comes from one distribution throughout the whole set of data.
4. There is no correlation between the noise in the past and the noise in the present or the noise in the future.
5. The relationships between the predictors do not follow a linear progression.

Applications of fNIRS

Mental Workload

Complex operational situations require comprehending neuronal resource allocation for task completion. An increase in mental workload can lead to diminishing performance resulting in deadly implications. Mental workload represents the interplay between environmental pressures, human capabilities, and task performance. Thus, a person's mental effort cannot be inferred from task features alone. EEG, fMRI, and PET can evaluate mental workload continually and unobtrusively, however, are not suitable for ecological circumstances. EEG tests are susceptible to head and/or body movement artifacts, whereas PET and fMRI require subjects to lie down and not move. Mental exertion levels necessitate sensitive, ongoing, and thorough assessments. fNIRS is a portable, field-deployable imaging technique that meets these requirements. The mental workload construct assumes that task-related neuronal activity uses a specific amount of mental resources proportionate to task difficulty. fNIRS has been used to measure cognitive workload in fundamental, clinical, aging, and human factors studies. Ayaz et al. (2012) reported consistent variations in oxygenation in the left dorsolateral prefrontal cortex as a function of memory load when utilizing fNIRS to detect activation during a conventional n-back test. Similar to Ayaz et al. (2012), Fishburn et al. (2014) showed linear increases in right and left prefrontal cortical activation as working memory load increased. Blood flow variations detected with fNIRS are also linked to executive processes like mental flexibility and reaction inhibition. fNIRS has shown changes in oxygenation due to considerable increases in job difficulty (e.g., piloting unmanned air vehicles). However, modest differences in task difficulty could not be consistently discriminated.

Epilepsy

Studies conducted on animals over the course of the last several decades have led researchers to the conclusion that fNIRS is capable of identifying increased cerebral blood flow and oxygenation in correlation with epileptic spikes and high-frequency oscillation (Hoshi et al. 2001; Zhang et al. 2014). These alterations, which were observed by fNIRS, can occur approximately 5 s before the emergence of spikes caused by bicuculline methiodide. There has been a significant amount of research conducted on the oxygenation response to seizures using fNIRS. An early clinical case study using fNIRS, for instance, found that individuals who suffered from temporal and extratemporal lobe epilepsies had a constant ictal increase of oxygenation on the epileptic hemisphere in comparison to the non-epileptic hemisphere during seizures (Monrad et al. 2015). During a seizure, it has been demonstrated that regional frontal

oxygenation drops in patients suffering from generalized epilepsy as well as secondary generalized seizures (Buchheim et al. 2004; Sokol et al. 2000). Moreover, the recent development of fNIRS devices with many channels is one of the most recent steps forward in the field of epilepsy research. The primary challenge that oligo-channel fNIRS faced was a lack of sufficient spatial resolution, which inspired the development of multichannel fNIRS. SMA seizures (Sato et al. 2013), mesial temporal epilepsy (Rizki et al. 2015), and other focal seizures have all been shown to have a differential increase in regional oxygenation or blood flow (Yücel et al. 2014). Epileptologists would be able to better comprehend the hemodynamic changes that occur during the distinct stages of seizures (preictal, ictal, postictal, and interictal phases) and enhance seizure detection and localization if they used multichannel fNIRS in conjunction with prolonged EEG.

Mild Cognitive Impairment

Investigations of MCI using fNIRS have indicated a reduced increase in oxyhemoglobin. Additionally, during memory retrieval, dorsolateral prefrontal cortices showed hypoactivation (Uemura et al. 2016). However, with an accuracy ranging from 60% to 70% on average, it has not been possible to identify MCI patients in a reliable manner (Yang et al. 2019). In addition, the results of fNIRS have been conflicting, although they seem to indicate that patients who have MCI have a higher oxyhemoglobin response in the regions of interest when compared to the healthy control group (Yoo and Hong 2019). Because of this, it is doubtful that the hemodynamic response that may be identified by fNIRS will be sensitive and specific enough for use in clinical practice. In more recent times, functional connectivity has become the primary focus of noninvasive neuroimaging biomarkers for mild cognitive impairment and Alzheimer's disease. Patients with MCI and AD show reduced frontal and long-range connection in the resting-state fMRI, according to a recent systemic review that included 36 papers from the past two decades (Yeung and Chan 2020). A more recent study came to the same conclusion as well (Yoo and Hong 2019). The number and strength of prefrontal functional connections were found to increase during a working memory task (Yu et al. 2020), whereas left and interhemispheric connectivity during a verbal fluency test was found to be lower (Nguyen et al. 2019) in the patients with MCI compared to healthy controls.

Future Work: Measuring Cognition Using Simultaneous EEG and fNIRS

Multimodal integration, which integrates distinct neurophysiological signals, is gaining popularity in addition to its potential to compensate for one modality's shortcomings and produce consistent findings by extracting complementary aspects. Integration of electroencephalography (EEG) with functional near-infrared spectroscopy (fNIRS) is particularly cost-effective and portable, making it an intriguing technique. The association between EEG and fNIRS signals is yet unknown, and combining the advantages of electrical and optical measures remains a challenge

(Zich et al. 2017). More future research is needed to examine possible applications, integrations, and algorithms in EEG/fNIRS analysis in order to encourage EEG/fNIRS application innovation with the goal of maximizing the benefits of combination (Shin et al. 2018). Most of the selected research uses EEG/fNIRS to classify data by merging obtained electrical and optical handcrafted elements. To detect brain-evoked potentials, the advantages of EEG's temporal resolution can be used by monitoring oscillatory correlates (ERP or ERD/ERS) from the complete head. Optodes can be placed on the local region, such as the occipital or prefrontal regions, to evaluate significant attentional or visual processes, thanks to fNIRS' high spatial resolution (Mele et al. 2019).

HbO and HbR are distinctive aspects of fNIRS recordings that have been widely exploited to date. Because HbO and HbR are both temporal characteristics, determining the temporal period and using filtering methods based on the temporal domain are critical in signal processing. EEG, on the other hand, can employ both spectral and temporal properties; therefore, individuals are frequently exposed to fast and brief stimuli. Due to the intrinsic response delays and low temporal resolution in fNIRS recordings, such stimuli are not appropriate. Although various commercial instruments exist that allow simultaneous EEG-fNIRS monitoring, recording neural activity from the same site is problematic. Because hemodynamic responses in fNIRS are recorded from the center of emitters and detectors, EEG electrodes should be placed in the center of these emitters and detectors to create the same channel arrangement. EEG electrodes can be quite small, but fNIRS emitters and detectors must be somewhat large to properly emit and detect infrared light. Without a well-tuned hardware combination, one approach to equip an EEG-fNIRS device in the lab is to manually combine them. There are several applications of hybrid EEG-fNIRS in which the use of electrodes/optodes has been distributed in the different parts of the brain (Shin et al. 2018). Comparing hybrid EEG-fNIRS performance with various setups is thus one route for future research (Zich et al. 2017). It's also interesting to see how the optodes and electrodes are arranged differently depending on whether the focus is on optimizing system processing or detecting individual brain activations. Optodes and electrodes are generally found in the same areas when it comes to building system processing. Electrodes are primarily utilized to measure event-related desynchronization (ERD) from brain oscillations as well as optodes that are set on the implicated cortical regions to intensify the signal on these regions in order to emphasize the weights of experimentally connected cortex regions in measurement.

The simultaneous evaluation of electric and hemodynamic brain activity is made possible by multimodal EEG-fNIRS, which is a feature that confers a number of significant benefits. EEG-fNIRS has been increasingly employed in a variety of fields, including clinical neurology, neurorehabilitation, and brain-computer interface. The development of wearable, integrated EEG-fNIRS technology is an essential next step in the advancement of this discipline. To this day, numerous integrated systems that make use of discrete components that are commercially available have been developed. These technologies, despite their success, are susceptible to the following limitations: (1) large size, heavy weight, and limited wearability and subject comfort, (2) cross talk between optical and electrical signals, (3) inaccurate timing precision/synchronization

for simultaneous fNIRS and EEG recording, and (4) low signal quality and/or limited capability of long-term recording of EEG electrodes (Uchitel et al. 2021). Despite their achievements, these technologies still have some room for improvement. Utilizing designs that are integrated both mechanically and electrically by means of microchips is becoming increasingly popular as a means of overcoming some of these restrictions. Microchip technologies have a number of important advantages, including a small footprint, low-power consumption, improved timing synchronization between fNIRS and EEG measurements, and potentially improved signal quality with reduced noise and cross talk (Lin et al. 2014; Von Luhmann and Muller 2017). Microchip technologies also have a number of other advantages. In the past 10 years, numerous attempts have been undertaken to create a microchip-based, wearable, integrated EEG-fNIRS system. These attempts have been unsuccessful. In addition to the designs of integrated circuits, other emerging trends include designs that are modular, lightweight, and flexible, designs that can communicate wirelessly, designs that make use of shared ADCs to achieve timing precision between optical and electrical data, and designs that take into account both wet and dry EEG electrodes. When considering the development of EEG-fNIRS systems in the future, research into ergonomic designs (i.e., wearable, miniaturized, lightweight, and flexible) will continue to be of primary importance for long-term monitoring, wearability, and subject comfort. To attain the huge dynamic range required for high-channel count fNIRS systems, improvements in resolution, high-speed ADCs, sensitive amplifiers, and accurate logic control will be required. As a consequence of this, more sophisticated data interfaces and control systems would be necessary in order to guarantee a large channel count, a large dynamic range, and high-speed data gathering and transmission. In addition, dry electroencephalogram (EEG) electrodes that have a high gain and a high input impedance are probably going to be the best option for long-term and consistent monitoring. Dry electrodes are increasingly included into the design of EEG-fNIRS systems due to their ability to make stable contact with the scalp, even through hair, as they are lightweight, tiny, and flexible and have the capacity to create steady contact with the scalp.

The application of combined EEG and fNIRS is still in its early stages; however, it may be beneficial in the near future in terms of improving the algorithms and physical system design of hybrid EEG-fNIRS. This could include emphasizing the spatial and temporal advantages of fNIRS and EEG appropriately by designing advanced feature extraction methodologies and splitting nodes in different targeted cortical functions. In addition, it is necessary to keep developing more applications that combine EEG and fNIRS, particularly in fields that involve complex information processing.

computational capabilities. However, the metrological issues and standardization issues are still untouched and need to be addressed critically. This chapter attempts to compile the recommendations, standards, and requirements of such type of systems, as well as a case study of SEMG operated lower limb prosthesis design. The SENIAM recommendations are thoroughly discussed and implemented in the application design. A high-level and low-level control module is used to implement a biologically inspired control structure. The high-level control module is responsible for estimating activity intention, whereas the low-level control module is responsible for estimating the desired angular position of the joints. Both the control modules utilize SEMG signal differently. The high-level control module problem is formulated as classification problem, whereas the low-level control module problem is implemented as classification problem for knee angle prediction and continuous value estimation problem for ankle angle estimation. SVM, LDA, and NN classifiers with time domain feature vector were found suitable for high-level control module. For knee angle prediction, SVMQ was found to be superior, whereas for ankle angle estimation, the autoregressive exogenous neural network (NARX) model with SEMG and knee angle information depicts satisfactory performance over the different locomotion modes.

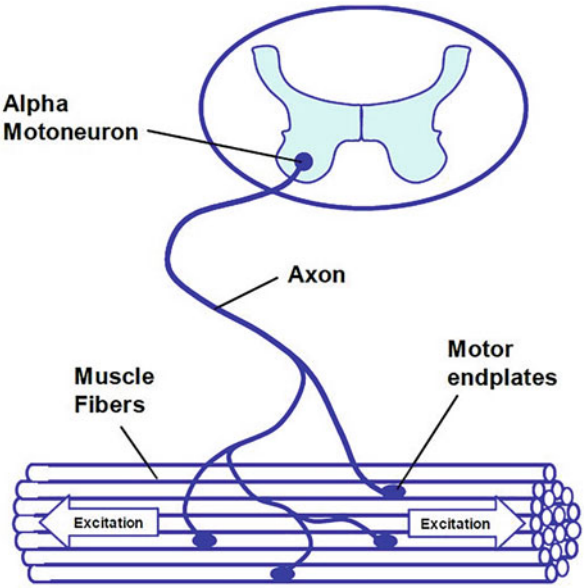
Introduction

All human activities and movements are governed by neural signals that originate in the human brain. The neural signal generated in the cortical region of the brain is transmitted to the appropriate body part via the nervous system. This neural information about limb movement can be recorded as a biopotential, specifically an electromyogram (EMG) signal. It appears as a result of neural commands sent through the peripheral nervous system to activate human limb muscles. It is generated as an electrical impulse and causes muscle fibers in the human body to contract. Skeletal muscles use this electric impulse most often to control limb movements. Skeletal muscle is made up of fiber cells that range in length from a few millimeters to 30 cm and in diameter from 10 mm to 100 mm. Myofibrils, which have a dense array of protein filaments, are found in every muscle fiber. Motor neurons convey neural messages from the brain to protein filaments, resulting in muscle contraction. During muscle contraction, the length of the muscle is typically reduced to half of its resting length. There are three types of muscle contraction: isometric, concentric, and eccentric. Muscle length does not change during isometric contraction. Isometric contractions are commonly used to control posture. Muscle length decreases and increases during concentric and eccentric contractions, respectively (Konard 2012).

Fig. 1 Motor unit illustration



The motor neuron, axon, and muscle fibers that are shown in Fig. 1 combine to form a motor unit. Only when the brain decides on limb movement, such as moving the leg, does the nerve impulse stimulate the contraction, which is carried in the nerve through motor neurons from the brain to the muscle. As a motor neuron approaches the muscle, it divides into many branches (axon terminals). Each muscle fiber in a motor unit is connected through the corresponding axon branch to the accompanying motor neuron at a junction known as the neuromuscular junction. The innervation region is mostly found in the middle of the muscle length.

Motor unit action potential (MUAP) is defined as a resultant action potential of individual muscle fibers within the motor unit. The shape and duration of the MUAP imitate the architecture of the motor unit. Its amplitude is directly proportional to the radius of the muscle, and it carries an inverse relation with the distance between the active fiber and the pickup site. It is considered a complex signal, modulated by the human nervous system which carries significant variation contributed by the anatomical and physiological properties of human muscles. The amplitude of the EMG signal is quite random and can be represented as a Gaussian curve. It ranges between a few μV to 100 μV depending on the muscle under observation. It carries frequency components of 1 Hz to 10 kHz frequency range along with dominant signal power between 20 and 300 Hz. EMG is highly prone to noise generated by various tissues while traveling to the respective muscles. Further, the electrodes used for SEMG acquisition from the skin of the human body capture the effective signal generated by multiple motor units. Surface EMG (SEMG) signals are primarily studied for two applications, namely clinical and kinesiological (Konard 2012). Physicians, neurologists, and physiatrists do clinical studies by observing the

characteristics of the MUAP to diagnose neuromuscular diseases and injuries. Kinesiological EMG is used for limb movement studies. It is utilized by physical therapists and ergonomists to determine the behavior of the muscles during the limb movements of the subject. The acquisition of good quality SEMG signals and their real-time processing is a challenge. In particular, application SEMG is preferred due to its noninvasive nature.

In biomedical engineering, the acquisition of good quality SEMG signals and their real-time processing is a challenge. Various research groups have developed low-cost research platforms for laboratory use. However, their calibration repeatability and reliability are still debatable. Furthermore, the metrological aspects of SEMG systems are unexplored.

Material and Methods

Amputation and Prosthesis

Amputation is an acquired condition that results in the loss of a limb partially or completely. It can occur due to accidents, animal attacks, battles, etc. It is also performed as a surgical procedure. In the USA, it is estimated that 185,000 persons undergo amputation of the upper and lower limb each year. The most frequent type of amputation is the below-knee amputation (transtibial) followed by the above-knee amputation (transfemoral) (Dillingham et al. 2002; Renzi et al. 2006). The word transtibial amputee refers to a person who got a lower leg amputation between the knee and ankle or on the tibia bone, whereas the transfemoral amputee refers to one who got a leg amputation between the hip and knee. Lower limb loss is a potentially disabling condition affecting the health and well-being of the persons worldwide.

The persons living with transtibial limb loss face distinct challenges; they need more metabolic energy and cognitive effort to perform any locomotion-related task. Moreover, their locomotion is very slow and unstable. Innovations in the design and development of new prosthetic devices should address these clinical issues (Versluys et al. 2008).

The lower limb prosthesis is considered the substitute for the lost limb of an amputee. The rapidly increasing figures for amputation around the world always motivate researchers to provide the effective solution as efficient prosthesis. The development of lower limb prosthesis has a vast history (Duraiswami et al. 1971). The initially developed prostheses were completely passive and provided only support to the lower limb. Most of the time, the passive prosthesis is augmented with passive elastic elements, which store and release energy in different phases of the gait cycle. These passive elements underperform as compared to the biological limb in producing effective push-off during locomotion. However, active prostheses can provide the required push-off. But such powered prostheses require adaptability and an indispensable controller. In these prostheses, the control commands for cyclic/rhythmic activities are synthesized via central pattern generators (CPG) with the locomotion model of humans. Control command generation using EMG signals offers a viable technique for prosthetic actuation and control. A blend of CPG and

EMG signals provides an effective solution in controlling a device like an ankle-foot prosthesis (Simão et al. 2019).

A prosthesis is considered as an artificial replacement of a missing or malfunctioning body part. The objective of the ankle-foot prosthesis is to provide ankle-foot functionality for a transtibial amputee. The history of leg amputation and lower leg prosthesis is very ancient. The first text of lower limb prosthesis had been found in Rig Veda, an Indian sacred book, written around 3100 B.C. There it is mentioned that an iron leg was fitted to Queen Vishpla after being amputated in a battle (Duraiswami et al. 1971). The lower limb prosthesis can be divided into three subgroups: passive, semi-active, and active prosthesis. Passive prosthesis utilizes gear, clutch, springs, or dampers to achieve a human-like gait pattern, whereas the semi-active prosthesis incorporates electronics to control the mechanical components as per the need of the gait phase. In an active prosthesis, the main actuation mechanism of the joint is externally powered (electric, hydraulic, or pneumatic) and controlled by the amputee using sensory information. Table 1 shows a few of the most popular ankle-foot prosthesis with their features.

Human Lower Limb Anatomy and Gait Cycle

This section covers the basics of human lower limb anatomy and gait cycle in brief. The lower limb anatomy includes ankle as well as knee movements and their responsible muscles. The human gait cycle covers its definition, description during walking, and biomechanical characteristics.

Ankle-Foot Anatomy

The human ankle-foot is designed to provide a stable platform so that the dynamic activities of daily life can be performed. It provides contact between the human body and the environment during various activities like sitting, standing, walking, and running. It must be able to provide the required range of motion (RoM), control, and stability to the body during various activities. The ankle-foot work act as a shock absorber and weight bearer. Figure 2 shows the major bones, joints, and ligaments of the human ankle-foot. The ankle-foot is a complex skeletal structure having 33 joints, 28 bones, and 112 ligaments.

The complex structure of the ankle-foot is controlled by 20 intrinsic and 11 extrinsic muscles. The complete entity of ankle-foot is rigid enough to bear bodyweight, and at the same time, it is also flexible in dealing with uneven terrains (Brockett and Chapman 2016). The ankle joint is made up of mainly three bones, namely, tibia, talus, and fibula. The complete foot can be divided into three subparts as rear-foot (tarsus), mid-foot (metatarsals), and forefoot (phalanges). Calcaneus is considered the biggest bone in the foot and resides in the rear-foot part. It transmits the load from the body to the ground and serves as a moment arm for the calf muscles to generate sufficient moment for propulsion to move the body forward. The talus bone is attached to the calcaneus bone of the foot (heel bone) through the Achilles tendon and provides articulation at the subtalar joint (Brockett and Chapman 2016). The RoM of ankle-foot is defined around the particular joint in any DoF. The ankle-foot

Table 1 Various ankle-foot prostheses and their features

S. No	Ref/type	Prototype	Features
1	Passive (Staros 1957)		Non-articulated ankle joint Internal keel to assist smooth rolling action Cushioning material absorbed the impact during heel-strike (HS) Heel wedge provides pseudo-plantarflexion The rigid wooden keel provides midstance stability
2	Passive (Goh et al. 1984)		Articulated ankle joint Two adjustable bumpers limit and control ankle DF and PF movement PF bumper permits the foot to contact the floor more rapidly during loading response Heavyweight Offers little lateral movement Requires more frequent maintenance
3	Passive (Sethi et al. 1978)		Jaipur foot Vulcanized rubber material provides slight inversion/eversion movement Improved performance as compare to solid ankle cushion heel (SACH) foot An amputee can sit in a squat position, in a cross-legged position, and walk barefoot Heavyweight
4	Passive (Lee et al. 2006)		Has a flexible elliptical-shank monolimb Made up of one piece of thermoplastic material Much lighter in weight as compared to the conventional prosthesis Provides more comfort to amputee and also the gait is improved Long-term effect of shank flexibility is not there
5	Passive (Burgess et al. 1985)		ESR foot Spring-like structure to store and release the energy in different phases of the gait cycle Improved push-off
6	Passive (Pitkin 1995)		Articulated ankle joint The dynamic performance was found better than SACH and flex-foot

(continued)

Table 1 (continued)

S. No	Ref/type	Prototype	Features
7	Semi-active (Collins and Kuo 2010)		Controlled energy storing and returning (CESR) foot Captures collision energy during HS and returns it for push-off The complete foot has two components: rear and forefoot components One microcontroller and two small motors were used to release the stored energy in spring
8	Semi-active (Paper et al. 2013)		Ankle mimicking prosthetic (AMP) foot The mechanical structure had a planetary gearbox, a spring, and two servo pawls A microcontroller was used to control overlocking and unlocking of the pawls It regenerates energy during the dorsiflexion phase and releases it over the entire push-off phase
9	Semi-active (Shepherd and Rouse 2017a, b)		Variable-stiffness prosthetic ankle-foot (VSPA foot) A cam-based transmission and a fiberglass leaf spring had been used as in mechanical structure A small motor was used to modulate the support condition of leaf spring and its stiffness Controlled by tracing the torque-angle curve of ankle-foot
10	Semi-active (*Raize Ankle Foot System* n.d.)		Microprocessor controlled (MPC) hydraulic ankle-foot Adjustable heel height Adjustable plantarflexion and dorsiflexion range and stiffness Adapt to uneven terrain Simulates natural ankle movement and reduces vertical shock Automatically adjusts to allow maximum dorsiflexion when walking on an incline Range of motion (RoM) for the ankle is 10° dorsal flexion and 18° plantarflexion

(continued)

Table 1 (continued)

S. No	Ref/type	Prototype	Features
11	Semi-active (Elan n.d.)		Microprocessor-controlled self-aligning plantarflexion and dorsiflexion Standing support mode increases resistance when stationary to help improve balance and stability Adaptable to different walking speed and terrains Provides extended dorsiflexion during swing phase to increase toe clearance and reduce risk of trips and falls Provides higher resistance during slop walking for better stability and safety
12	Active (Au et al. 2008, 2009)		Utilized series elastic actuator (SEA) using physical spring in series with drive Manual EMG triggering based transition control Two-level finite state machine controller Only level-ground and stair-descent locomotion are considered One degree of freedom (DoF)
13	Active (Bellman et al. 2008; Hitt et al. 2010)		SPARKy (spring ankle with regenerative kinetics) Brushless motor and linear transmission Smaller and more powerful brushless motor without the need for a gearbox Walking speeds over 4 miles per hour Toe design is considered DoF is 2
14	Active (Cherelle et al. 2014a, b, 2016)		Ankle mimicking prosthetic (AMP) foot Adaptive speed using variable stiffness components A hybrid controller is used Lightweight actuators are used Two locking mechanisms and a compliant crank-slider mechanism One degree of freedom
15	Active (Versluys et al. 2009)		Pneumatic actuators are used Finite-state controller EMG-based control Only for level walking with speed adaptation One DoF

(continued)

Table 1 (continued)

S. No	Ref/type	Prototype	Features
16	Active (Zhu et al. 2014)		Powered below-knee prosthesis with ankle and toe (PANTOE) Finite-state control strategy Electric actuator with spring EMG signal-based control A linearized trajectory control method One degree of freedom
17	Active (Sun and Voglewede 2014)		Four-bar mechanism linkage design Electric actuator with spring High-level finite-state controller and low-level proportional-integral-derivative (PID) controller One degree of freedom

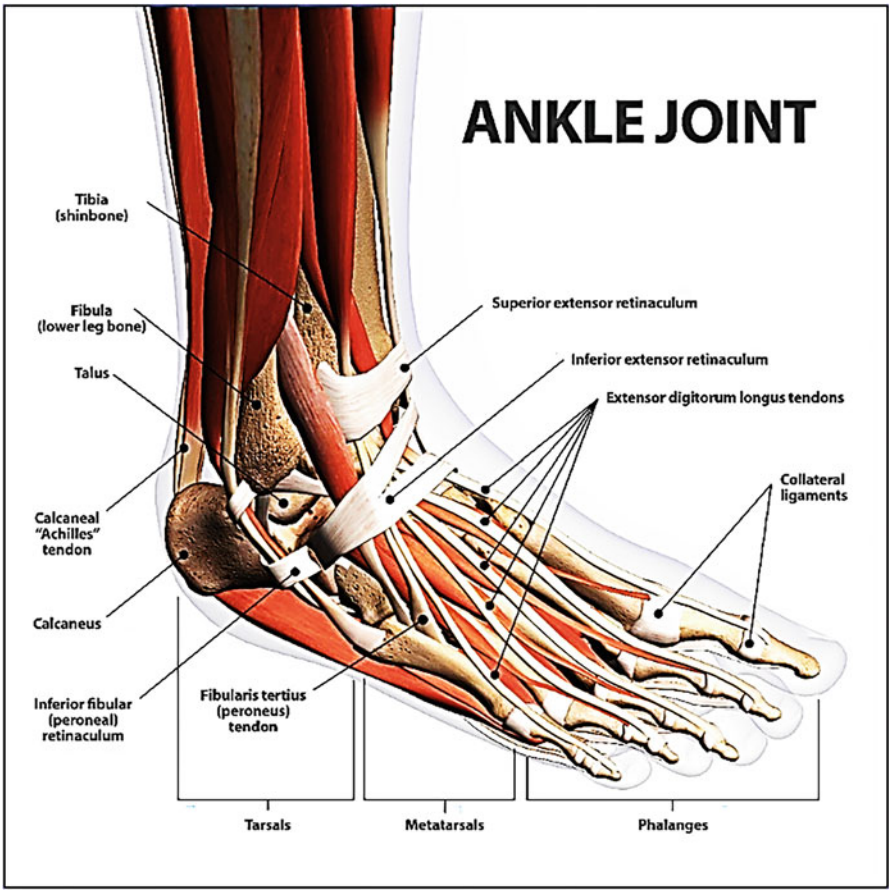


Fig. 2 Ankle-foot bones, joints, and ligaments

has three DoF, one in the sagittal plane, one in the transverse plane, and one in the frontal plane. Hence, there are three possible motions of human ankle joints; dorsiflexion (DF)/plantarflexion (PF), inversion/eversion, and abduction/adduction. Table 2 shows the RoM of ankle joint motions along with their respective reference planes (Riegger 1988).

Figure 3 shows the different movements of ankle-foot. The movement of the ankle joint, pointing the foot towards the leg, or movement of toes lifting the foot away from the sole, is termed DF. The movement at the ankle joint, pointing the foot downwards away from the leg or movement of the toes that curl them down towards the sole, is termed PF, shown in Fig. 3a. Inversion is the movement of turning the sole inwards at the ankle joint, while eversion is the movement of turning the sole outwards, as shown in Fig. 3b. Abduction and adduction movements are in the

Table 2 RoM of a natural human ankle

Motion	RoM (degrees)	Reference plane
Dorsiflexion/plantarflexion	20/50	Sagittal
Inversion/eversion	35/25	Transverse
Abduction/adduction	20/25	Frontal

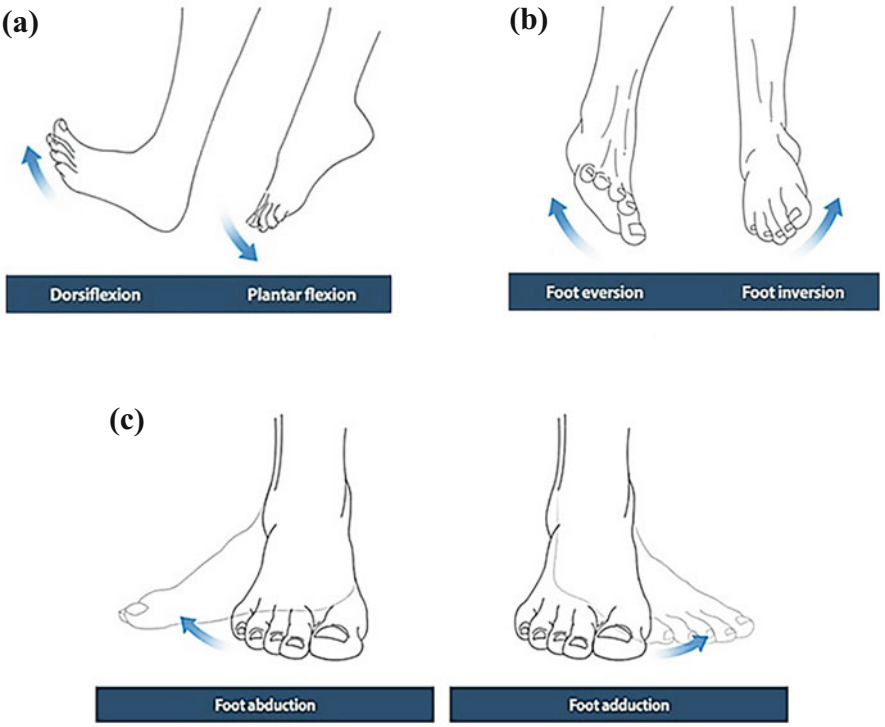

Fig. 3 Human ankle-foot movements

frontal plane and involve moving a body part away from or towards an imaginary center line. As shown in Fig. 3c, abduction moves the body part away from the central line, whereas adduction moves it towards the central line.

Various lower limb muscles control the movements of the ankle-foot structure. The musculature of the ankle and foot is classified into two parts: intrinsic and extrinsic muscles. Twenty intrinsic layered muscles in the human foot support locomotion by extending, flexing, abducting, and adducting the toes and the arch of the foot, whereas 12 extrinsic muscles or longer muscles spanning the tibia and foot act as the main drivers for ankle major joint motions. These muscles are: gastrocnemius (Gast), soleus (Sole), tibialis anterior (TiAn), tibialis posterior (TiPo), plantaris (Plan), peroneus brevis (PeBr), peroneus longus (PeLo), peroneus tertius (PeTe), flexor digitorum longus (FlDL), extensor digitorum longus (ExDL), extensor hallucis longus (ExHL), and flexor hallucis longus (FeHL). Figure 4 shows the anatomical illustration of major below-knee muscles (Riegger 1988).

The ankle joint is extremely complex and provides motion along two axes. Primary muscle actuators are muscles that contract in response to ankle joint motion about a specific axis. However, it is extremely rare for a muscle contraction to result in only one axis of rotation; usually, the second joint of motion occurs as a byproduct. As a result, each rotational axis has both primary and secondary muscle actuators, as summarized in Table 3 (Riegger 1988).

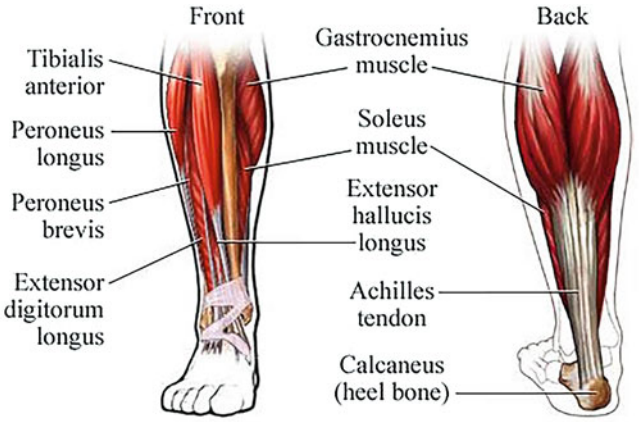

Fig. 4 Major below-knee muscles of the human

Table 3 Primary and secondary movers for each axis of motion of ankle joint

Joint movement	Primary muscle actuators	Secondary muscle actuators
Dorsiflexion	TiAn	ExDL, ExHL, PeTe, and Plan
Plantarflexion	Gast, Sole	TiPo, Plan, FlDL, FlHL, PeBr, and PeLo
Inversion	TiPo	FlDL, FlHL, TiAn, and ExHL
Eversion	PeBr, PeLo	PeTe, ExDL, and ExHL

Human Knee Anatomy

Bones, muscles, cartilage, tendons, and ligaments comprise the knee joint. Their bones provide basic support and rigid structure to the knee joint, while their ligaments provide stability and muscles aid in joint movement. The four bones that make up the human knee joint are the femur, tibia, fibula, and patella. The thigh bone, shin bone, the smaller bone that runs alongside the tibia, and the kneecap are all names for these bones. The knee joint is depicted in Fig. 5 from both the lateral and anterior sides. Tibiofemoral (tibia-femur) and patellofemoral (patella-femur) knee joints work together to form a modified joint that allows the knee to extend and rotate slightly (side to side).

Flexion and extension about the virtual transverse axis in the sagittal plane are the primary movements of the knee joint. The knee can rotate slightly medially and laterally when it is flexed. Knee flexion is the movement of the shank towards the thigh, which decreases the angle of the knee joint (KA). The contraction of the knee flexor muscles allows for this movement of the knee. Knee extension is a straightening of the knee that is achieved by contracting the knee extensor muscles and relaxing the knee flexor muscles. The knee movements are depicted in Fig. 6.

Muscles responsible for knee joint movements are divided into two categories – knee flexors and knee extensors. Knee flexors consist of muscles which are responsible for knee flexion. The knee flexors shown in Fig. 7a are a group of seven muscles which cross the posterior of the knee joint (except the sartorius muscle). Knee flexors comprise the hamstrings (biceps femoris (BiFe), semimembranosus (Semb), and semitendinosus (Semd)), the gastrocnemius muscle, the gracilis muscle, the sartorius muscle, and the popliteus (Flandry and Hommel 2011). The knee extensors are a group

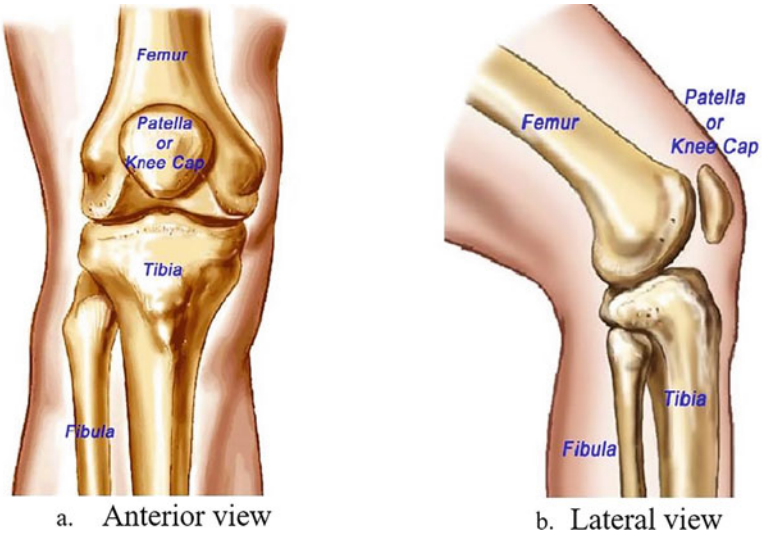

Fig. 5 Human knee joint

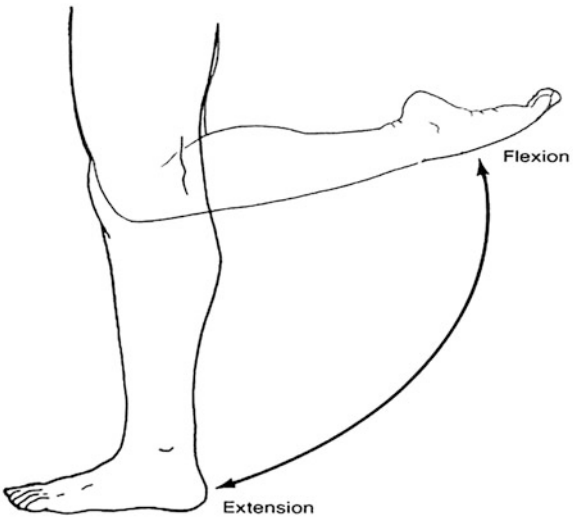

Fig. 6 Human knee joint movements

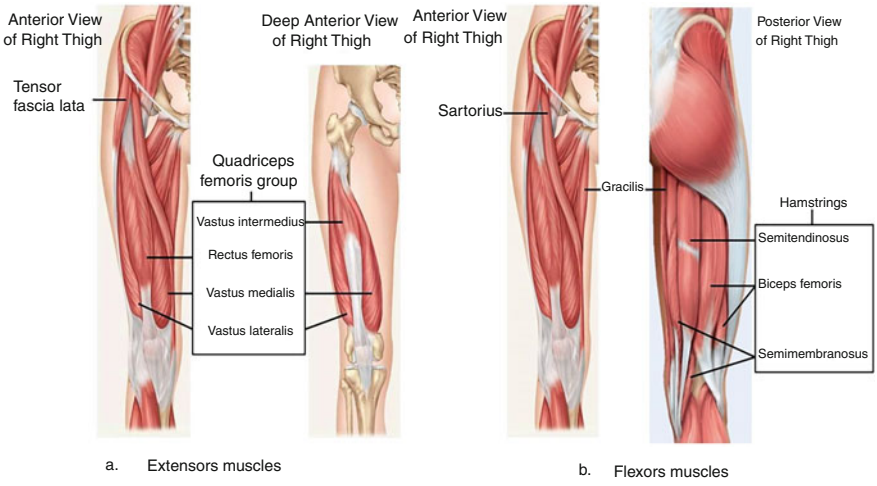

Fig. 7 Major muscles of the human knee

of five muscles located towards the anterior thigh. Their contraction induces the extension of the knee joint by pulling the calf and foot back to their anatomical position. During this motion, knee flexors are relaxed returning to their normal position. Knee extensors showed in Fig. 7b comprise the tensor fasciae latae and the quadriceps (rectus femoris (ReFe), vastus lateralis (VaLa), vastus intermedius (VaIn), and vastus medialis (VaMe)) (Abulhasan and Grey 2017).

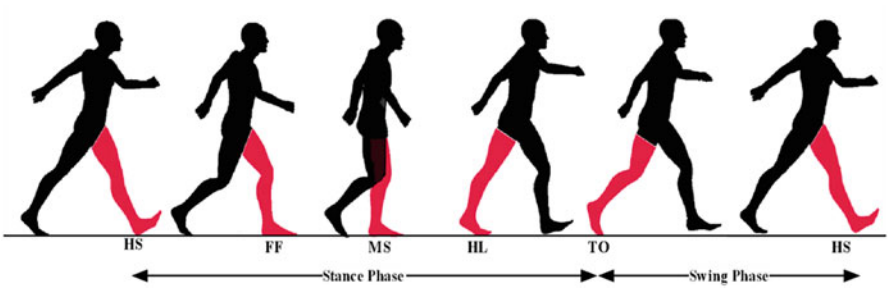

Fig. 8 Human gait cycle for a level walk

Human Gait Cycle

Walking is an essential part of human activity. It is depicted as a gait cycle, with a cyclic sequence of foot movements to move the body forward. Figure 8 depicts a human gait cycle for level walking with various phases and subphases.

A typical human gait cycle consists of two phases: the stance phase (when the foot is on the ground) and the swing phase (when the foot is in the air). Normally, the stance phase accounts for 55–60% of the total gait cycle, while the swing phase accounts for 40–45% of the total gait cycle. The stance phase is initiated with the heel-strike (HS) of the leading foot on the ground, while the trailing foot is still in contact with the ground. At this time, the body weight starts transferring to the leading foot. After that, flat-foot (FF) subphase starts in which the leading foot comes in full contact with the ground, and complete weight is shifted to the leading foot. This subphase ends when the entire human body is supported by the leading foot, and the trailing foot is about to leave contact with the ground. The midstance (MS) subphase starts, which ends when the opposite foot aligns with the stance foot. It is also considered the mid-subphase of the stance phase and occurs during the 25–30% of the complete gait cycle. After that, heel-off (HO) subphase starts which terminates with the toe-off (TO) of the same foot or at the start of the swing phase. During the swing phase, the foot is in the air, and the new gait cycle of the same foot starts when the HS event for the same foot occurs again (Winter 1991). During the different phases of the gait cycle, the ankle joint modulates its stiffness and angular position to provide sufficient propulsion force. This ankle joint angular position modulation ability helps humans to walk on different terrains (level, stair, and ramp). During level walking, the human ankle joint angle follows a specific profile, also known as the displacement profile. Figure 9 shows the normalized displacement profile during a complete gait cycle with the phases and events of the gait (Mai and Commuri 2016).

A General Control Structure for Prosthesis

The control structure, in essence, acts as a link between the prosthesis and the amputee's sensory-motor control loop, as well as the residual musculoskeletal system, which should be governed by the central nervous system.

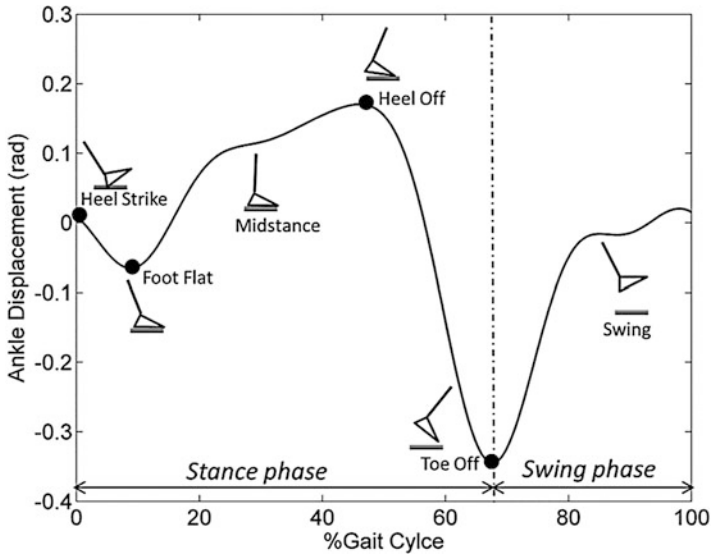

Fig. 9 Gait cycle with ankle joint angle during the level walk

For effective, efficient, and natural control of prostheses, it is vital to understand how able-bodied people regulate their movement in the regular course of events. Most of the time, human locomotion is dependent on fundamental patterns that are created at the spinal level (Zehr 2005; Pons et al. 2013) (Fig. 10). The CPG is a network of spinal interneurons that generates the primary motor pattern. The origin of locomotor pattern modulation can be traced back to the supraspinal or cortical levels, which also carry the accumulative effect of feedback from muscle spindles, mechanoreceptors lining joint capsules, and feedback from the skin, which detects pressure, pain, heat, and stretch, among other things. In addition, nerve fibers (sensory neurons) transmit information from the musculoskeletal system to the central nervous system (CNS), closing the feedback loop of the body's natural locomotor control (Crommert et al. 1998; Duysens 1998; Dietz 2002).

Figure 11 depicts a generalized control structure that can be applied to a variety of prosthetic or assistive devices. When a powered prosthesis is used in real time, the framework accurately represents the physical interactions and signal-level feedback loops that occur. Among the major control structure subsystems are the hierarchical control unit, the amputee, the prosthetic device, and the environment in which the amputee ambulates (Geethanjali 2016). Considerations for amputee safety are also taken into account within each subsystem.

The environment in which the prosthesis will be used (surface condition, terrain type, etc.) limits the motions that can be performed with the assistance of a prosthetic device. The high-level control system must be able to differentiate between the amputee's current activity and the desired activity. This has two effects: The current motor task (standing, level walking, and stair descending) is recognized by activity mode recognition, whereas intended activity recognition allows for direct volitional control, allowing the amputee to voluntarily change the state of his or her prosthesis.

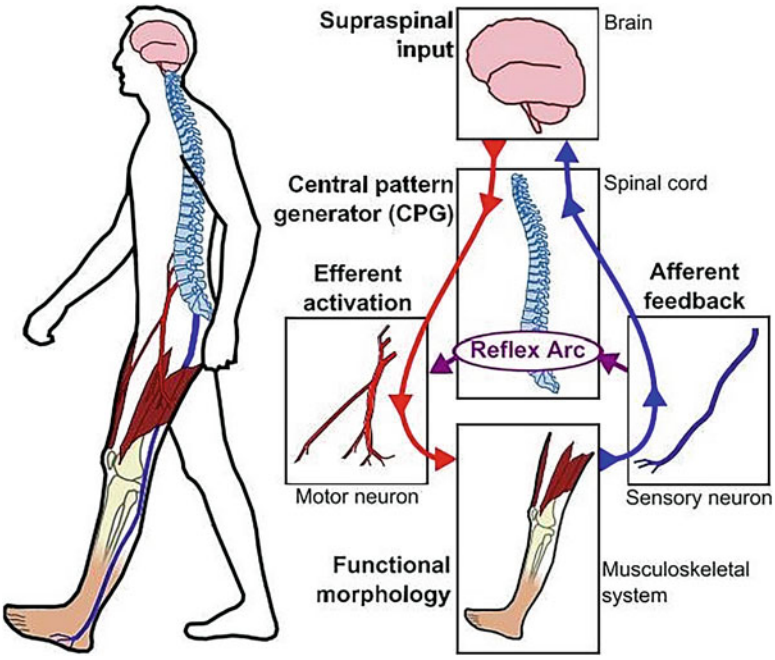

Fig. 10 Locomotion control structure of abled body person

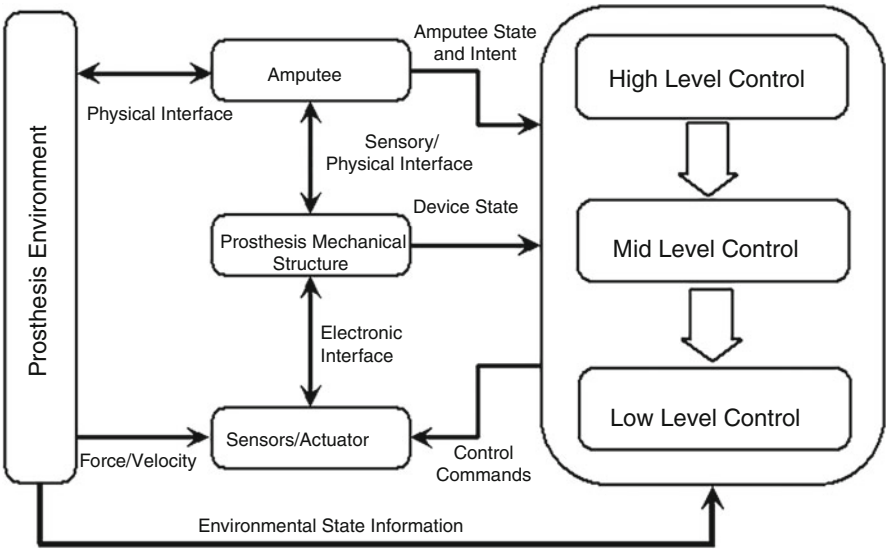

Fig. 11 General control structure for prosthesis control

Integration of both is possible and advantageous, in which volitional control affects prosthetic behavior while participating in a specific activity. The high-level controller may convert amputee activity intents into desirable device states via the mid-level

controller, which can then be tracked by the low-level controller. At this level, the amputee's status within the gait cycle is determined, and a specific control law (position/velocity, torque, impedance, or admittance controller) is applied (Eilenberg et al. 2010). So, once the required condition of the prosthesis has been determined, it is passed on to the next level of the controller, which is the low-level controller. When the error with the current state is computed, a command signal is sent to the actuator(s) to minimize the error with the current state. The structure of the low-level controller can be either feedforward or feedback in nature, depending on how the kinematic and kinetic parameters of the prosthesis are taken into account (Huang et al. 2011). More advanced prosthetic devices can also provide artificial sensory feedback to the amputee, allowing them to be fully integrated with the physiological control system. It is used at the highest level of the controller. The efficient locomotion identification method is expected to be successful in increasing the efficiency of the control system.

Methodology and Experiment Design

Figure 12 shows the block diagram representation of the methodology opted for SEMG operated prosthesis design.

SEMG signal, lower limb joint angle, and gait phase information of the subject have been used to operate the prosthesis. Here, the SEMG signal has been utilized in

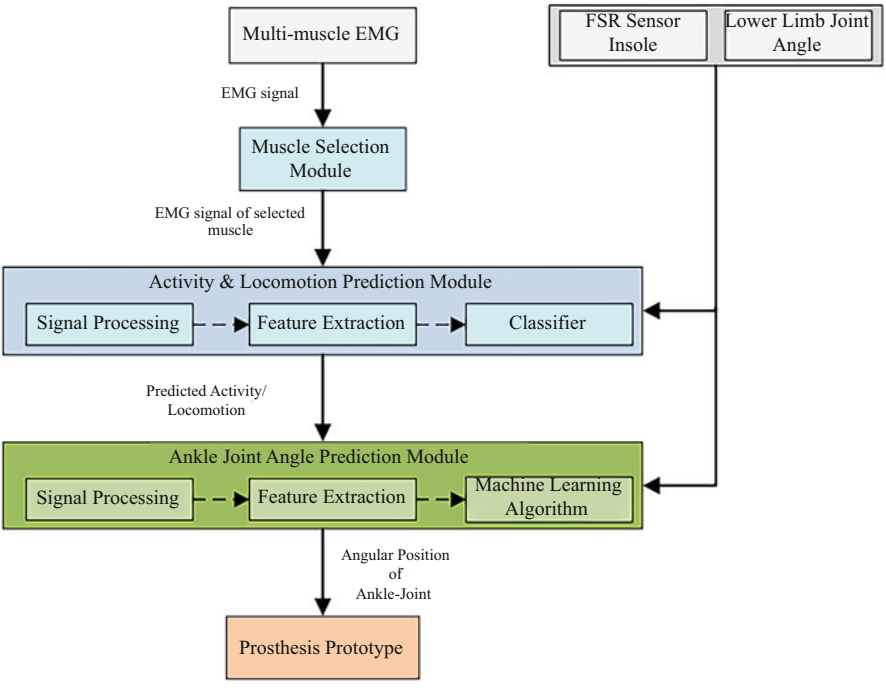

Fig. 12 Methodology adopted for the development of ankle-foot prosthesis

two ways: to extract the locomotion intension of the subject and to estimate the angular position of the joint. A multichannel EMG signal acquisition module has been used to acquire SEMG signals from various lower limb muscles (below-knee and above-knee). The lower limb joint angle information has been recorded using IMU units, and the gait events heal-strike (HS) and toe-off (TO) have been detected with force sensor resistor (FSR) sensors. The human musculoskeletal structure is highly redundant. Therefore, the recorded SEMG signal of various lower limb muscles has been analyzed to select the appropriate set of muscles for ankle joint movements. The muscles have been selected based on their reliability and consistency of SEMG signal for repetitive dorsiflexion (DF) and plantarflexion (PF) ankle movements, i.e., gastrocnemius and tibialis anterior (Gupta and Agarwal 2021).

The opted control structure is inspired by the biological control structure of an abled human and consists of two control modules, namely, high-level and low-level control modules. The high-level control module is at the top of the hierarchy and is sometimes also termed as high-level controller. It perceives the user's activity and locomotion intention like standing, level walking, stair ascent/descent, or ramp ascent/descent. The output of the high-level control module is further transmitted to the low-level control module. The low-level control module is also referred to as a low-level controller. The output of the low-level control module depends on the input of the high-level control module. This control module estimates the desired position/torque/velocity of the prosthesis for a given set of inputs. An activity and locomotion identification module has been designed to predict the activity and locomotion intention of the subject. This module serves as the high-level controller of the prosthesis and provides movement anticipation ability to the prosthesis. It utilizes the EMG signal as a source of neural information and KA signal to predict the activity and locomotion intention of the subject. As shown in Fig. 12, it has three subsystems, namely, signal processing, feature extraction, and classifier. In the signal processing subsystem, the filtering of input signals has been done to remove the noise. After that, the filtered signal is passed through the feature extraction subsystem. In this subsystem, the appropriate information/features from the filtered signal have been extracted to construct the feature vector. The feature vector has been used as the input to train and test the classifier.

Further, an ankle joint angle estimation module has been designed to estimate the angular position of the ankle joint. It has three subunits, namely, signal processing, feature extraction, and machine learning algorithm. An individual angle estimation module has been trained and tested for each locomotion mode. It requires SEMG signal, KA, and locomotion information as the input to estimate the ankle joint angle. This module is considered a low-level controller of the prosthesis, which provides the desired angular position of the prosthesis. Finally, an electrical actuator-operated prosthesis prototype has been realized and controlled using the predicted angular position information in the laboratory environment.

Data Acquisition Protocol

The literature strongly emphasized using biopotential signals along with the mechanical sensors signals to achieve efficient control over prosthetic devices. Hence, for current research work, EMG, lower limb kinematics, and gait events have been acquired. Lower limb joint angle (knee and ankle) signal has been calculated using three, 6-DoF, IMU sensor (MPU-6050) signals attached to the mid-position of the thigh, shank, and foot of the subject. The knee and ankle joint angles have been calculated using IMU sensor signals (Saito et al. 2009; Kumar et al. 2018). These joint angles have been utilized for further analysis in this research work. FSR sensors' foot insole has been used to capture HS and TO events of the gait cycle. SEMG signal has been recorded using a multichannel SEMG acquisition system developed around ADS 1298 (Gupta and Agarwal 2017). The sampling frequency for SEMG, IMU, and FSR sensors has been kept at 1000 Hz (Huang et al. 2011; Zhang et al. 2011). SENIAM standard have been followed for SEMG signal recording, which includes electrode selection, electrode placement, skin preparation, and muscle identification (SENIAM 2016).

SENIAM Recommendations

A good electrode-skin contact, a low electrode-skin impedance, and stable behavior in time are all requirements for the material used to establish the contact with the skin during the electrode-skin contact process (i.e., for impedance and chemical reactions at the skin interface). According to previous research, many types of materials are utilized, including Ag/AgCl, AgCl, Ag, Au, and others, with Ag/AgCl electrodes being the most commonly used electrodes. These provide a consistent transition with little noise and are by far the most widely accessible in the commercial marketplace. Electrodes are frequently used in conjunction with electrode gel. Electrode gel and paste are used to minimize the impedance between the electrode and the skin. Performance of both pre-gelled electrodes and non-gelled is at par. However, a significant amount of time and effort is required for the application of non-gelled electrodes (which must be gelled before attaching to a muscle). If the procedure is not followed properly, there is a considerable likelihood of poor SEMG recordings. It was decided to employ pre-gelled Ag/AgCl electrodes in differential mode, as shown in Fig. 13.

Inter-Electrode Distance (in Millimeters)

It is defined as the distance between the conducting areas of two bipolar electrodes measured from one to the other. The effect of inter-electrode distance on signal pick-up area and crosstalk is an important topic in the literature. When applying the bipolar SEMG electrodes around the specified sensor site, SENIAM recommends spacing the electrodes 20 mm apart. When bipolar electrodes are placed on relatively small muscles, the space between the electrodes should be no more than one-fourth the length of the muscle fibers being studied. In this manner, it is possible to avoid unstable recordings caused by tendon and motor endplate effects.

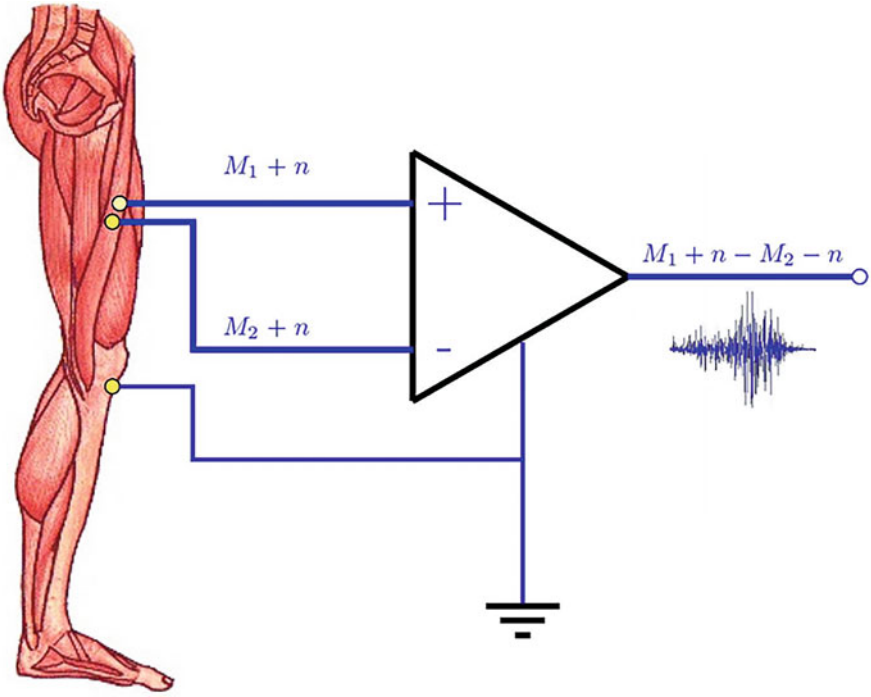

Fig. 13 Differential mode configuration for SEMG recording

Skin Preparation

Following the selection of the sensor, the patient's skin must be prepared to ensure a good electrode-skin connection. To obtain better SEMG recordings (in terms of amplitude characteristics), fewer and smaller artifacts (electrical interference), less risk of electrode imbalance (smaller common mode disturbance signal), less noise (better S/N ratio), good electrode-skin contact are required. It is critical to properly prepare the skin to improve the electrode-skin interaction. Various (combinations of) skin preparation techniques, such as shaving, washing with alcohol, rubbing with gel, and sandpaper, are described in the literature. According to the SENIAM instructions for skin preparation, if the skin area on which the electrodes are to be put is covered with hair, the patient should have his or her hair removed. Afterward, alcohol is applied to the skin, which should be allowed to evaporate for several minutes to ensure that the skin is completely dry before the electrodes are applied.

Examining the Connection

Once the SEMG electrodes have been placed and secured, they can be linked together (along with the reference electrode) and a clinical test can be carried out to determine whether the electrodes have been placed and connected correctly to the muscle to record a reliable SEMG signal. The clinical test ensures that the examined muscle will be active (under normal circumstances) during the procedure. SENIAM

suggests that each muscle be subjected to the clinical examination. The clinical tests that are discussed are universally acknowledged muscle tests that ensure the activation of the examined muscle (under normal circumstances) and are, therefore, recommended. The clinical test must begin with the beginning posture stated in the SENIAM recommendations for sensor sites, and it must be completed by those recommendations. The clinical tests described here are not "selective" contractions, which are contractions in which just the desired muscle is activated and all other muscles remain dormant.

Noise-Related Issues in SEMG Signal Acquisition

The SEMG signal is stochastic in character, with an amplitude that ranges from a few millivolts to several hundred millivolts. Noise has a significant impact on it. SEMG signals are primarily affected by two forms of noise: noise in the environment and noise generated by the device itself.

Noise in the Environment

Radio and television transmission, fluorescent lamps, and electrical power sources (with a frequency of 50/60 Hz) are examples of electromagnetic equipment that emit noise. When this noise is present, its magnitude can be of the order of two to three times that of the SEMG signal. The use of high common mode rejection ratio (CMRR) differential amplifiers, the use of shielded leads, and the usage of right leg drive (RLD) circuits can all help to significantly reduce this noise. When the electrodes are moved, motion artifacts are produced. This is caused by the movement of the wires connecting them to the amplifier, as well as the interface between the skin and the electrode surface. The amplitude of the motion artifacts noise is almost equal to the amplitude of the EMG signal. Recessed electrodes have the potential to considerably reduce movement artifacts. It is also possible to decrease this noise by properly preparing the skin before signal capture. In addition, the frequency range of motion artifacts noise is 0–10 Hz, which is a wide range. Incorporating a high-pass filter, either in hardware or software, can help to reduce this noise to an acceptable level. Wavelet de-noising can also be used to minimize motion artifact noise in electromyographic signals.

Noise Generated by the Device Itself

Electrical noise is generated by every electronic equipment. Noise with frequency components ranging from zero Hz to several thousand Hz is present in this sample. The use of high-quality components is the only way to minimize this noise.

SEMG signal is prone to inherent volatility due to the following reasons: When motor units fire, the rate at which they do so is quasi-random in nature, and this noise has a frequency range of 0–20 Hz. This noise can be reduced by incorporating a high-pass filter with a frequency of 20 Hz in either hardware or software.

Figure 14 shows the picture of the fully instrumented subject. The data acquisition has been conducted during the two experiments, and for each experiment, ten subjects have been recruited. All the subjects who participated in the research work were volunteers and had no history of neural disorders. The signal recording

Fig. 14 Fully instrumented subject

protocol was explained to all the subjects individually. Further, written consent was signed by each subject before the experiment. They were permitted to withdraw at any time during the data collection. The method adopted for signal acquisition in the present research work was purely noninvasive. The experiment procedure adopted was in accordance with the Helsinki declaration, 2013, and duly approved by the institutional research board.

Experiment Design

The experiment should be designed in such a way that it should cover maximum applications for a wide range of the population. The experiment was designed to

acquire the signals for different dynamic lower limb activities. Figure 15 illustrates the daily life activity % of a healthy subject over a period of 12 hr after waking up (Pitta et al. 2005). It has been observed that a major part of daily life is occupied by sitting (SIT), standing (STD), and walking (WLK) activities. The walking activity includes different locomotion like level walking (LW), stair ascent (SA), stair descent (SD), ramp ascent (RA), ramp descent (RD), etc. During sitting and standing activities, there is merely any participation of ankle movement. However, for the walking activity, the subject has to pass through the standing position/activity. Hence, for the present experiment, STD and WLK activities have been considered. WLK activity included five locomotion – LW, SA, SD, RA, and RD.

Figure 16 depicts the activity sequence opted for the signal acquisition. For each subject, SEMG signal from six lower limb muscles, tibialis anterior (TA), medial gastrocnemius (GAST), vastus lateralis (VL), rectus femoris (RF), semitendinosus (SEM), biceps femoris longus (BFL), knee and ankle joint angle along with FSR foot insole signal were recorded. The recorded signal has been utilized for locomotion identification module design and ankle joint angle estimation. Ten trials were recorded for each subject. Appropriate resting time was provided in between the sessions as demanded by the subjects.

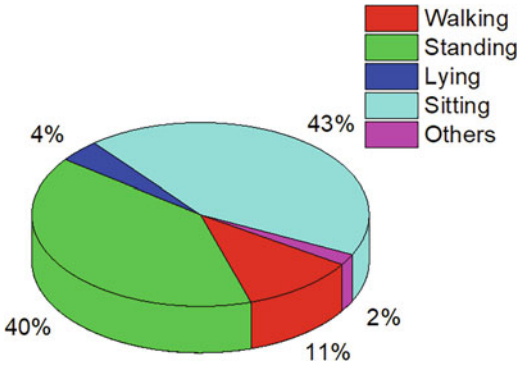

Fig. 15 Activity % of the healthy subject during 12 hr after waking up

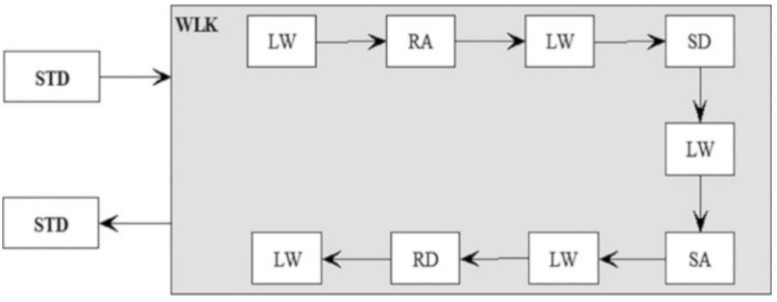

Fig. 16 Activity sequences followed for signal acquisition

Signal Processing and Module Design

The locomotion identification module and the joint angle prediction module are the two primary modules that must be designed. Both modules are distinct; the locomotion identification module is a discrete-class classification problem, whereas the joint angle prediction module employs two approaches. The first method estimates the discrete class of KA, whereas the second method estimates the ankle angle continuously. As a result, different signal processing methodologies were used for both modules.

Locomotion Identification Module

Online processing of the collected SEMG signal was carried out; Fig. 17 depicts the modules that were involved in the processing. There are four basic kinds of modules to consider: signal preprocessing (filtering, windowing), information extraction (feature extraction, feature normalization, feature vector preparation), classification, and validation (Gupta and Agarwal 2019b).

The signal was preprocessed, including filtering and segmentation, to extract features (windowing). Filtering was used to remove undesirable parts of the signal. A 4th order Butterworth bandpass filter of frequency range with 20-500Hz was used to filter the acquired signal. The signal was then segmented, which changed it from nonstationary to stationary. Because the overlapping windowing technique (Fig. 18) has shown promising results in the literature, it was used in this study with a window length of 256 ms and an offset of 32 ms to achieve the desired results (Huang et al. 2009; Huang et al. 2011; Gupta and Agarwal 2017, 2018a, b, 2019a, b, 2021; Dhindsa et al. 2019).

Each segment of the signal was treated as a training set, and the features for each segment were calculated separately. Thirty-eight characteristic features were identified in both time and frequency domains. The features are tabulated in Table 4 (Gupta and Agarwal 2019a). Further, min-max normalization method (Eq. 1) (Gupta

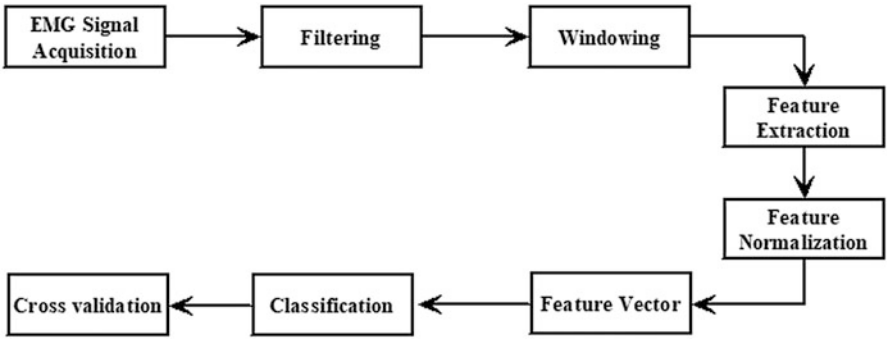

Fig. 17 Segmentation process of EMG signal

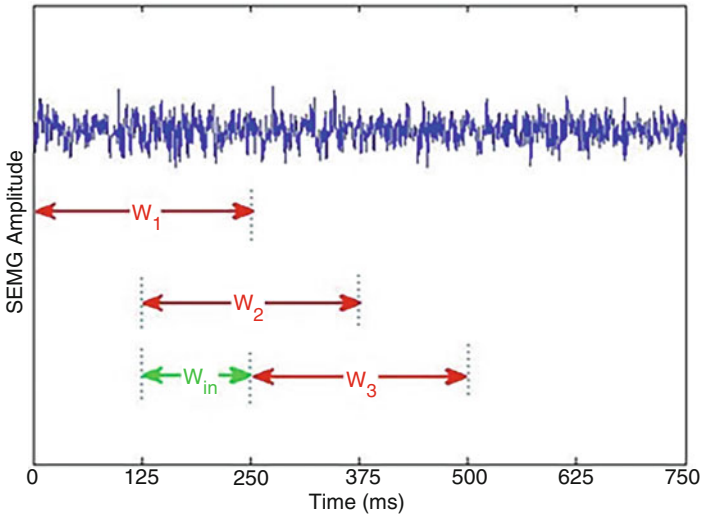

Fig. 18 Segmentation process of EMG signal

et al. 2021) was employed to normalize the features, which resulted in a significant improvement in classifier performance.

$$F_{\text{norm}} = \frac{F - \min(F)}{\max(F) - \min(F)} \tag{1}$$

where F, min(F), and max(F) are individual feature values, the minimum value of feature, and maximum value of feature, respectively.

The feature vectors were created by concatenating the normalized features for each segmented window, which resulted in the final feature vectors (Fig. 19). The performance of each feature was analyzed and compared for both muscles. The performance of five feature vectors with varying numbers of features was compared. These were time-domain features (TD), frequency domain features (FD), predictive information features (ARC), time and frequency domain features (TFD), and frequency and predictive information features (FAR) with 23, 11, 4, 34, and 15 features, respectively.

Six widely used classifiers, which included the support vector machine (SVM), the linear discriminant analysis (LDA), the artificial neural network (ANN), the decision tree (DT), the k-nearest neighbor (KNN), and the naive bias (NB) classifier, were used to evaluate and compare the overall performance of different feature vectors (Yuan et al. 2015; Joshi et al. 2016; Afzal et al. 2017; Gupta and Agarwal 2018b). Classification accuracy is a performance parameter that is widely used in the evaluation of the performance of prediction model performance. It is defined as the ratio of the total number of correctly categorized events to the total number of tested occurrences (Eq. 2). The performance of the classifier was evaluated in this study using a k-fold cross-validation approach. As part of the k-fold cross-validation

Table 4 Name and definition of extracted features

Sr. No.	Abv.	Name of feature	Definition
1	IEMG	Integrated EMG	$IEMG = \sum_{i=1}^{N} \lvert X_i \rvert$

Knee Angle Class Estimation

In literature, joint angle prediction of the lower limb has been proposed as a regression problem (Dhindsa et al. 2016a, 2022; Delis et al. 2009). In the present study, knee angle estimation is proposed as a classification problem and ankle angle is estimated continuously using NARX neural network. The SEMG signals from four muscles, including the VL, BFL, RF, and SEM from the lower limb, were recorded at 2048 Hz. Bipolar Ag/AgCl electrodes with 20 mm inter-electrode distances were used. The sensor positions were the same as described in our previous study (Dhindsa et al. 2016b). SENIAM recommendations for the placement of

electrodes were followed. The study was conducted on a custom-built gait course incorporating three locomotion modes: SD, PW, and SA. The trials were conducted at the institute's corridor. Before the beginning of the trials, the subjects were asked to remain standstill and SEMG data was recorded for 1 min. Subjects then performed SD, turned 90° towards left, performed PW, took 180° turn and performed PW, turned right 90° and performed SA, and came to rest. Ten trials were recorded for each subject daily. The HS and TO events detected using a force sensor resistor placed in the shoe sole as shown in Fig. 20 (Aggarwal et al. 2018), were used to sample the data into gate cycles.

Figure 21 depicts the SEMG signal and KA acquired during the study. For SD and SA, the RoM of KA varies from 0° to 90°; for PW, the RoM for KA is from 0° to 70°. Accordingly, KA was quantized into six different levels: L1 ($KA < 9°$), L2 ($9° < KA \leq 27°$), L3 ($27° < KA \leq 45°$), L4 ($45° < KA \leq 63°$), L5 ($63° < KA \leq 81°$), and L6 ($KA > 81°$). Fifteen features were extracted from the segmented/windowed SEMG signals for each muscle. These included six time domain features, five frequency domain features, and four autoregressive (AR) coefficients (ARn) (Dhindsa et al. 2019).

Figure 21 depicts the SEMG signal and KA acquired during the study. For SD and SA, the range of motion of KA varies from 0° to 90°; for PW, the range of motion for KA is from 0° to 70°. Accordingly, KA was quantized into six different levels: L1 ($KA < 9°$), L2 ($9° < KA \leq 27°$), L3 ($27° < KA \leq 45°$), L4 ($45° < KA \leq 63°$), L5 ($63° < KA \leq 81°$), and L6 ($KA > 81°$). Fifteen features were extracted from the segmented/windowed SEMG signals for each muscle. These included six TDF, five frequency domain features, and four autoregressive (AR) coefficients (ARn) (Dhindsa et al. 2019).

Continuous Estimation of Ankle Angle Module

Figure 22 depicts a block diagram containing the procedures that are used to calculate the ankle joint angle estimation. The EMG signal is, by its very nature, a low-power stochastic signal. During the signal acquisition process, it is easily contaminated by a variety of disturbances. Before using the EMG signal for further investigation, it is required to preprocess it first. To begin with, the raw EMG signal has been filtered by applying zero-lag, fourth order, bandpass Butterworth filter with a frequency band of 20–500 Hz, followed by application of 50-Hz notch filter (Dhindsa et al. 2016b). To eliminate speed variations between trials, the filtered

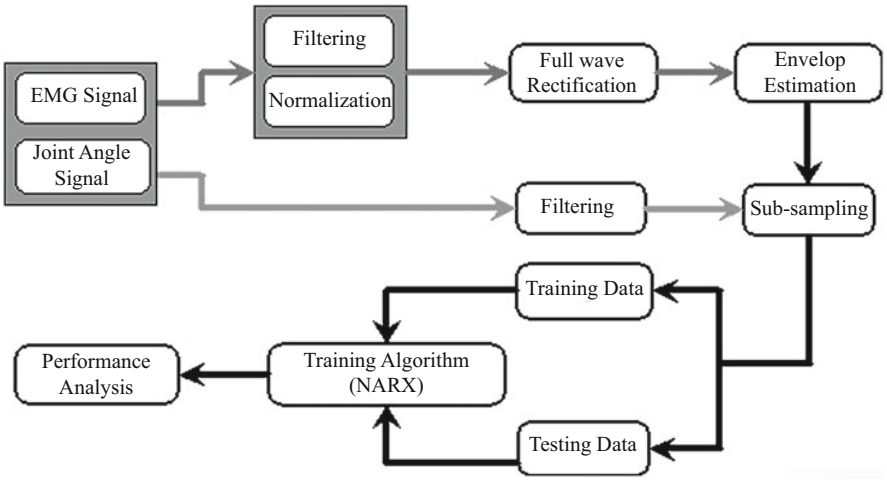

Fig. 22 Signal processing steps for ankle joint angle estimation

EMG signal of each individual muscle has been normalized using maximum normalization (max normalization) (Yokoyama et al. 2016). By nature, the EMG signal is fundamentally random, and it oscillates around the zero-mean value. As a result, full-wave rectification of the signal has been conducted using Eq. 3 to gather information from both side signals.

$$EMG_{\text{rect}}(t) = \begin{cases} EMG(t) if EMG(t) > 0 \\ -1 * EMG(t) if EMG(t) \leq 0 \end{cases} \tag{3}$$

where $EMG(t)$ is normalized EMG signal, and $EMG_{rect}(t)$ is a full-wave rectified EMG signal.

The amplitude of the EMG signal is directly proportional to the intensity of muscle contraction, and it serves as an indicator of change in joint angle with low-frequency characteristics. To retain only low-frequency information in the EMG signal, the rectified EMG signal was processed through a zero-lag, second-order, low-pass Butterworth filter with a cutoff frequency of 10 Hz. A very low-amplitude (mV) EMG signal is captured noninvasively from the human body and is used to diagnose various medical conditions. As a result, it has a higher likelihood of becoming corrupted as a result of environmental noise and electrode movement while being recorded. As opposed to this, joint angles are measured using IMU sensor signals, which have a much higher amplitude (V) than the EMG signal and hence produce more accurate results. As a result, as compared to EMG signals, joint angle signals from the lower limb are more robust, powerful, and less susceptible to noise. To reduce high-frequency noise caused by sensor movements and involuntary limb movement, it has been routed through a zero-lag, second-order, low-pass Butterworth filter with a cut-off frequency of 10 Hz and zero delay. Subsampling at 100 Hz has been performed on the encapsulated EMG signal and lower limb joint angle signals to facilitate further analysis. Finally, the whole data of

each subject has been divided into two sections, which are referred to as training and testing data, respectively. Various training and testing data sets have been used to train and test the learning algorithm, respectively.

Neural networks (NNs) have already demonstrated their effectiveness for a wide range of issues including pattern categorization, optimization, prediction, and grouping, among others. Essentially, it is a black-box modelling technique with the capability of translating a nonlinear mapping between multidimensional input and output space, even when the relationships between those input and output spaces are unknown. NNs are constructed as a mathematical model that is dependent on past information of the system to be described in order to function properly. Given this, the current research subject (predicting the ankle joint angle) can be thought of as a time-series prediction problem with cyclic characteristics.

Nonnegative time series problems have traditionally been predicted by NARX neural networks, which are effective. Many other nonlinear dynamic systems, including time series modelling, had been modelled with it in the past. It is regarded as a dynamic recurrent neural network (DRNN) since it has feedback links that connect many layers of the network together. As an added feature, it allows for the incorporation of previous values of anticipated or/and actual time series or/and predictors. This characteristic of the NARX neural network makes it particularly well suited for the current study challenge, in which the time history information of the inputs (EMG and KA) and output (ankle joint angle) contains a substantial quantity of information about the ankle joint. In the case of a NARX neural network model, the overall mathematical relationship between inputs and outputs is given by Eq. 4 (Leontaritis and Billings 1985). It is used to continuously map EMG signal and KA into ankle joint angle.

$$y(t) = f(x(t-1), x(t-2), \ldots \ldots \ldots x(t-t_d),\ y(t-1), y(t-2) \ldots \ldots \ldots y(t-t_d)) \quad (4)$$

where y(t) is estimated output at time t, x(t) is N-dimensional input vector of two-channel EMG signal and KA, td is delay order in input and feedback output, and f is functional relation relating inputs and output. The NARX model is depicted in Fig. 23 as a basic block diagram, consisting of an input layer, one hidden layer

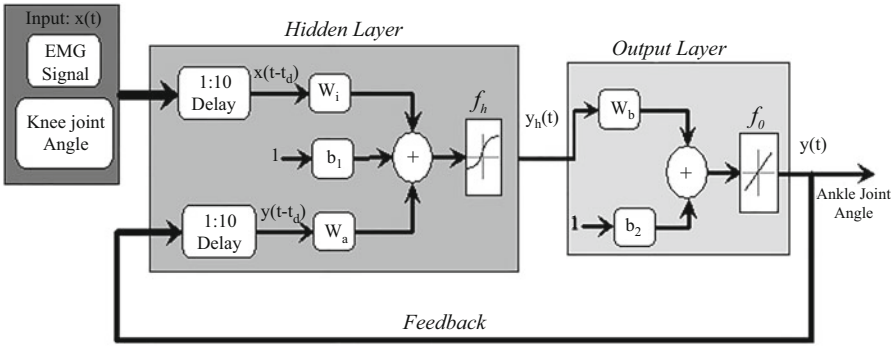

Fig. 23 Basic block diagram of the NARX model applied for ankle joint angle prediction

with nonlinear units, and an output layer with linear units. The input (x(t)), which contains EMG activity from two muscles as well as a KA signal, has been sent over tapped delay lines, together with an ankle joint angle that has been previously determined, to a hidden layer with nonlinear units ($y_h(t)$). Hidden layer output ($y_h(t)$) has been further processed through liner units to estimate the ankle joint angle ($y_h(t)$) over time. The input layer of the model has an encapsulated EMG signal collected from two below-knee muscles, KA, and an estimated ankle joint angle as feedback, whereas the output layer has a single output corresponding to the estimated ankle joint angle. All of the model's inputs have been supplied to the model with an additional delay, and the estimated output has been used as feedback (Gupta et al. 2020).

Using a supervised learning (back-propagation) approach, the proposed NARX model has been trained to reduce the mean square error (MSE) between the predicted and real ankle joint angles. According to Fig. 23 and Eq. 4, the performance of the model is dependent on the number of neurons in the input layer, the order of the delay, as well as the number of neurons in the hidden layer, among other factors. Number of neurons in the input layer is derived by multiplying the number of input channels (N), the number of output feedback (l), and the order of delay (o) together (m). For the time being, the number of input channels and output feedback is fixed at three (two-channel EMG signal and ankle joint angle) and one output feedback (ankle joint angle), respectively. The sequence of delay and the number of neurons in the hidden layer are chosen as 2 and 10, respectively (Gupta et al. 2020).

Performance Measures

The proposed method's performance has been examined for each type of locomotion and for each subject. To evaluate the performance of the training model, the LOOCV technique has been used. The performance of the angle estimation model has been evaluated using two performance measures: the root mean square error (RMSE) and the coef coefficient (CCoef). The RMSE has been quantified using Eq. 5. It is the difference between the estimated and actual joint angle, and a smaller value indicates greater accuracy in angle estimation. CCoef has been calculated using Eq. 6, and it represents the degree to which the actual and estimated joint angles are in agreement. Its value ranges from 0 to 1, with higher values indicating greater consistency (Gupta et al. 2020).

$$\mathrm{RMSE} = \sqrt{\frac{\sum_{i=1}^{n} \left(\theta_{act}(i) - \theta_{est}(i)\right)^2}{n}} \tag{5}$$

$$\mathrm{CCoef} = \frac{\sum_{i=1}^{n} \left(\theta_{act}(i) - \overline{\theta_{act}}\right)\left(\theta_{est}(i) - \overline{\theta_{est}}\right)}{\sqrt{\sum_{i=1}^{n} \left(\theta_{act}(i) - \overline{\theta_{act}}\right)^2 \sum_{i=1}^{n} \left(\theta_{est}(i) - \overline{\theta_{est}}\right)^2}} \tag{6}$$

where θ_{act} and θ_{est} are actual and predicted ankle joint angle, respectively, n is the number of sample points in each trial, and $\overline{\theta_{act}}$ and $\overline{\theta_{est}}$ are average actual and predicted ankle joint angles, respectively, over each trial.

Results

Locomotion Identification Module

For locomotion identification module design, two lower limb muscles were examined. The considered muscles were TA (below knee/Muscle 1) (FL) and BFL (above knee/Muscle 2). The heatmap shown as Fig. 24 represents the classification accuracy achieved by individual features for both the muscles and all compared classifiers. In the heatmap, classifiers and muscles combinations are represented on the x-axis and features on y-axis. SVM classifier shows average classification accuracy (Avg. ± std.) as 41.81 ± 4.75% and 43.38 ± 5.33% for muscle 1 and muscle 2 (p-value >0.05), respectively. For LDA classifier, the classification accuracy of 36.44 ± 3.50% and 41.87 ± 4.52% (p-value <0.05) was shown by muscle 1 and muscle 2 respectively,

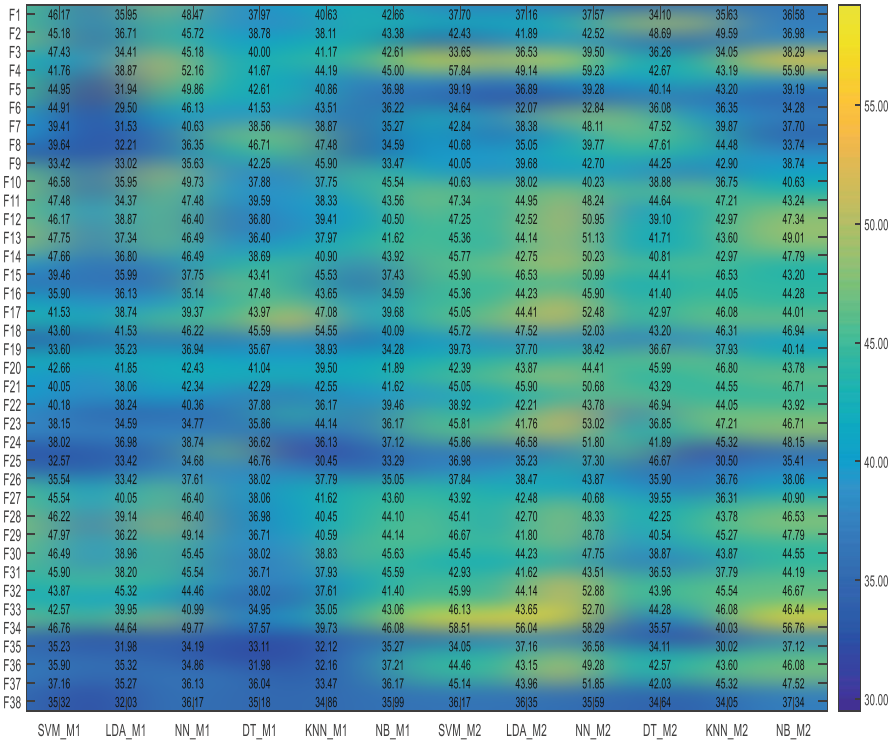

Fig. 24 Performance of individual features for various classifiers

whereas for NN classifier, it came out as 42.42 ± 5.30% and 46.12 ± 6.43% (p-value <0.05) for muscle 1 and muscle 2, respectively. KNN, DT, and NB classifiers show prediction performance of 39.90 ± 4.58%, 39.13 ± 3.49%, and 39.44 ± 4.03% (p-value <0.05), respectively, for muscle 1 and 41.13 ± 4.04%, 41.86 ± 4.86%, and 43.28 ± 5.36% (p-value <0.05), respectively, for muscle 2. Muscle 2 shows the better performance as compare to muscle 1 for all compared classifiers (p-value <0.05, except for SVM). Moreover, the best classification accuracy achieved was 59.23% for muscle 2 with NN classifier (Gupta and Agarwal 2018a).

Figure 25a, b show the average % classification accuracy of intuitive feature vectors (presented in Table 1) for all compared classifiers. LDA classifier displayed the best classification accuracy as 91.17 ± 0.96% for muscle 1 and 92.20 ± 0.60% for muscle 2 using time frequency domain feature vector with a statistically significant difference between them (p-value <0.05). For SVM classifier, time domain feature vector promises the best classification accuracy of 90.85 ± 1.26% and 93.15 ± 0.33% (p-value <0.05) for muscle 1 and muscle 2, respectively. Neural network (NN) classifier shows the best classification accuracy as 83.42 ± 2.34% and 93.96 ± 1.16% (p-value <0.05) for muscle 1 and muscle 2 using time domain feature vector. For decision tree classifier, the best accuracy shown by muscle 1 was 78.69 ± 1.08% using TD feature vector, whereas for muscle 2, it was 85.58 ± 1.18% (p-value <0.05) using the same feature vector. K-nearest neighbor (KNN) classifier achieved best classification accuracy as 81.26 ± 2.45% and 90.49 ± 0.61% (p-value <0.05) for muscle 1 and muscle 2, respectively, using TD feature vector. Bayesian classifier came out as least performance classifier for all feature vectors and muscles. The best classification accuracy shown by NN classifier was 50.04 ± 1.29% and 50.72 ± 2.65% (p-value >0.05) for muscle 1 and muscle 2, respectively, with FAR feature vector.

Tables 5 and 6 show the performance of every possible combination of feature vectors and classifiers for muscle 1 and muscle 2. To select the best classifier and feature vector, the median of classification accuracy (median_classi) over feature

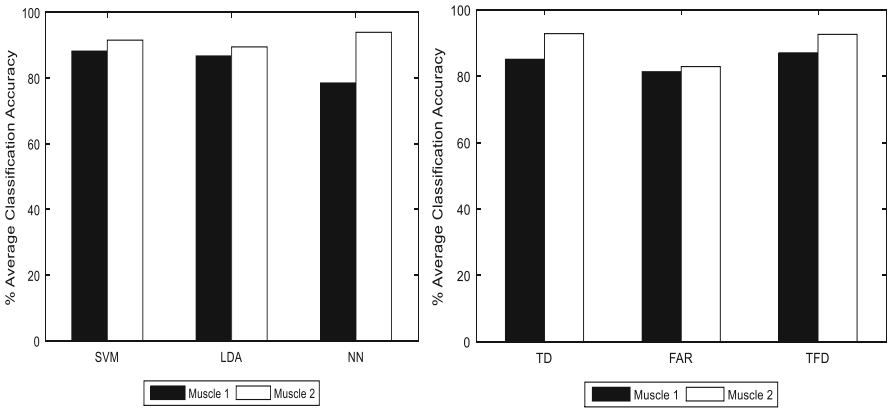
vectors and median of classification accuracy over classifiers (median_feat) were calculated. Following that, a pair of feature vectors and classifiers with higher classification accuracy than median_classi and median_feat were chosen. The mean of selected classification accuracies was taken over classifiers (Fig. 25a) and feature vectors (Fig. 25b) to compare top-performing feature vectors and classifiers, respectively.

Figure 26a shows that the LDA and SVM classifiers performed equally well (p-value >0.05); additionally, for both classifiers, muscle 1 and muscle 2 performed reasonably well with no statistically significant difference (p-value >0.05). Muscle 2 outperforms Muscle 1 in the NN classifier (p-value >0.05). TFD and TD feature vectors imitated the same prediction performance (p-value >0.05) among feature vectors (Fig. 26b). Hence, based on the above-presented results, it was recommended to utilize LDA, NN, or SVM classifiers with TD feature vector of SEMG signal for locomotion identification.



(a) Classifiers performance (b) Feature vectors performance

Fig. 26 Average performance of top three classifiers and intuitive feature vectors

Knee Angle Class Estimation

In the present study, knee angle prediction from SEMG signals was carried out for three different locomotion activities on a custom-built gait course. In a previous study, the performance of LDA and NB classifier was inferior to k-NN and SVMQ classifier (Dhindsa et al. 2019). So, in this study, the performance of only k-NN and SVMQ classifiers was evaluated. Table 7 presents the classification accuracy obtained with both the classifiers for different locomotion modes. The results of the ANOVA test on the classification accuracy achieved while performing the three activities indicate that the performance of SVMQ is significantly superior to that of k-NN for all the three activities (p-value < 0.05). The average classification accuracy obtained with SVMQ classifier is $89.25 \pm 2.32\%$ for stair ascend, $87.58 \pm 2.30\%$ for level plain walking, and $89.91 \pm 2.37\%$ for stair descend.

Ankle Angle Estimation Module

Figure 27 shows the average RMSE and CCoef for each locomotion. The average RMSE and CCoef of subjects, for LW locomotion, has been found $2.30 \pm 0.59^\circ$ and 0.980 ± 0.008, whereas for SA, SD, RA, and RD locomotion, it is $3.00 \pm 0.56^\circ$ and 0.97 ± 0.013, $2.88 \pm 0.70^\circ$ and 0.975 ± 0.008, $3.61 \pm 0.75^\circ$ and 0.970 ± 0.012, and $3.87 \pm 0.61^\circ$ and 0.968 ± 0.011, respectively. However, the average RMSE of all locomotion is found in the range of 2.30° to 3.87° and CCoef as 0.968 to 0.980. Figure 28 shows the actual and estimated ankle joint angle of subject 1 for all five

Table 7 Classification accuracy obtained for k-NN and SVMQ classifier

S9	83.27 ± 2.25	88.54 ± 1.14	81.34 ± 1.99	86.79 ± 1.80	84.25 ± 2.35	89.59 ± 1.26
S10	85.76 ± 1.59	90.16 ± 1.26	84.19 ± 1.91	88.38 ± 1.18	86.13 ± 2.09	90.79 ± 1.10
Avg	84.97 ± 2.73	89.25 ± 2.32	83.41 ± 3.00	87.58 ± 2.30	85.53 ± 2.93	89.91 ± 2.37

activities. It helps in identifying the major events of errors in ankle joint angle estimation. The results show that apart from the lower and upper RoM limit, the model seamlessly estimates the ankle joint angle. Major events of the error have been near the upper and lower limit (peaks) of the joint angle (Gupta et al. 2020).

Figure 29 depicts the average performance of the proposed model with and without knee angle information. Incorporating knee angle information as an input improves model performance significantly (one-way ANOVA, p-value >0.05). In terms of ankle joint angle estimation error (i.e., RMSE), an improvement of 67.85%, 45.74%, 68.17%, 41.35%, and 45.56% has been observed for LW, SA, SD, RA, and RD activity, respectively. The consistency of ankle joint angle estimation (CCoef) has shown enhancement of 36.19%, 57.82%, 68.24%, 22.34%, and 49.05% for LW, SA, SD, RA, and RD activity, respectively. The inclusion of the KA signal for ankle joint angle estimation improves model accuracy and reliability. Furthermore, by including KA as an input, within-subject performance variation has been reduced significantly for all activities. The model's continuous predictive capability may provide a more biomimetic ankle motion. The proposed method's performance in continuously mapping ankle joint angles across five locomotion modes has been evaluated (LW, RA, RD, SA, and SD). The results have been found to be consistent across all locomotion, making it suitable for controlling the active ankle-foot prosthesis.

Conclusion

The recommendations for SEMG signal recording and related signal processing issues for a complete system design are compiled. When dealing with SEMG signals, it is strongly advised to follow the SENIAM recommendations. The experiment must be designed in accordance with the 2013 Helsinki Declaration. A complete system design process for a SEMG signal operated lower limb prosthesis design is also presented. The result is a thorough comparison of six classifiers for multi-muscle SEMG signals and 38 domain-specific features. The results indicate that SVM, NN, and LDA classifiers with time-domain feature vectors are better suited for locomotion mode prediction. Furthermore, for knee angle prediction,

SVMQ outperforms the k-NN classifier. The NARX model performed well for continuous ankle angle estimation with SEMG signals and knee angle as input. The framework and techniques presented here can be used directly to design and control SEMG-based active lower limb prostheses, exoskeletons, and orthoses.

Abstract

Computers are now able to play a role in the diagnostic process for diabetes patients because of developments in the disciplines of medical imaging and information technology. It is difficult to reduce death rates to more reasonable levels by employing early and precise detection approaches. When seeking to identify risk factors for complications, acute and long-term difficulties, mortality, and medical care expenses, data on the prevalence and incidence of diabetes and prediabetes is important. The International Diabetes Federation estimates the occurrence of diabetes based on the present status and prevalence of diabetes worldwide. In addition, variables, such as physiological markers, that may have a role in the development of diabetes are investigated. Complementary and alternative methods, especially iris-based diagnostics, have made significant advances in the identification of diabetes and associated disorders. Diabetes is a leading cause of renal failure globally. It raises the likelihood of heart and blood vessel problems. Diabetic kidney disease is a chronic condition. The blood test is used to identify diabetic kidney disease, which is a difficult and agitating treatment for patients. This chapter combines iridology with current computer-based approaches to diagnose diabetic kidney disease. A total of 130 participants were assessed and categorized based on their health status, such as not having diabetes, having diabetes but not having diabetic kidney disease, and having diabetic kidney disease. Pre-image processing methods are used to extract the region of interest from the iris based on the iridology chart's specified regions. The region of interest was analyzed for first-order statistical and second-order textual characteristics. Finally, several categorization models were examined using different sets of characteristics to discover the optimum model. The maximum accuracy of 94.4% was achieved with the help of a fine Gaussian kernel of the SVM classifier. It is empirically demonstrated that features of specific areas of the iris are highly correlated with the diabetic kidney disease condition of an individual.

Introduction

Diabetes mellitus (DM) is one of the most common metabolic diseases and is characterized by the glucose tolerance capability of the body. A continuous increased blood glucose level can lead to microvascular and macrovascular complications and increases the risk of heart, eyesight, kidney, and nerve system damage (Chen et al. 2011). It is notable that, in the past few decades, as the lifestyle of the population changed, the prevalence of diabetes has increased at a faster rate. Figure 1

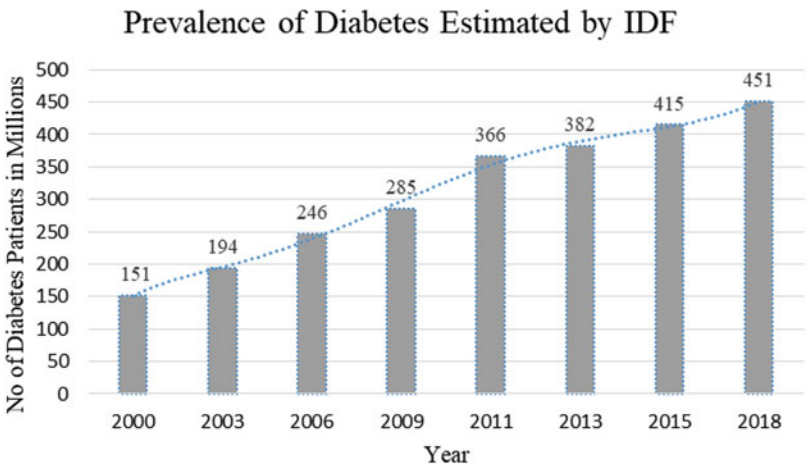

Fig. 1 Prevalence of diabetes estimated by IDF

presents the results of an analysis conducted by the International Diabetes Federation (IDF) on the prevalence of diabetes across the globe (Ogurtsova et al. 2017).

The body converts the carbohydrates of the food into glucose, which provides energy to different parts of the body. When the body does not consume enough glucose, insulin helps to absorb the excess glucose to reduce blood glucose levels. Insulin is an important hormone which is secreted by the beta (β) cells of the pancreas organ (Baier and Hanson 2004). Insulin consumes glucose with the help of three different processes named glycolysis, glycogenesis, and lipogenesis. Glycolysis is the process of converting glucose into adenosine triphosphate (ATP). ATP is an electrochemical form that stores energy (Levin et al. 2011). Glycolysis is a reversible process which converts glucose into glycogen, that is, short-term energy storage in the liver or muscles. Lipogenesis is the process of converting glucose into lipids and fatty acids (FA), to store energy for a long term. It's an irreversible process and remains as adipose tissues or fatty layers in the body. Also, when the glucose level in the body is too low, the pancreas organ secretes another hormone called glucagon. Glucagon helps the liver to release stored glucose. Glycogen undergoes a reversible process of glycogenolysis, which releases the glucose from the glycogen. Glucose is made by another reversible process called gluconeogenesis, in which amino acids are converted into glucose. Together, insulin and glucagon maintain the blood glucose in the body, and this state is called homeostasis. The excess glucose level in the body is called hyperglycemia and the shortage is termed hypoglycemia. If the blood glucose concentration is lower than 70 mg/dl, the person is said to have hypoglycemia. This may result in several disorders including awkwardness, a dilemma in talking, bewilderment, unconsciousness, seizures, or death. Continuous hunger, sweating, unsteadiness, and weakness can also be seen in patients suffering from hypoglycemia. Any person is called hyperglycemic if the blood glucose concentration is over 120 mg/dl after overnight fasting. If the hyperglycemia remains

for a longer period, it results in eye, nerve, and kidney disease; in a more generalized form, this condition is called diabetes. Diabetes is broadly classified mainly according to the function of insulin, type 1 diabetes, type 2 diabetes, gestational diabetes, prediabetes, and other specific types of diabetes.

Type 1 Diabetes

Type 1 diabetes develops when beta cells in the pancreas fail to generate enough insulin for the body to use the glucose that is produced. Insulin is a medication that must be used regularly by people who have type 1 diabetes to prevent the consequences that might arise from having high blood glucose levels for an extended length of time. Type 1 diabetes is a kind of diabetes that affects children and young adults and accounts for around 10% of all occurrences of diabetes. Type 1 diabetes is caused by an autoimmune response, in which beta cells of the pancreatic organ are eliminated by the body's immune system. This leads to the development of type 1 diabetes. Hereditary factors are the primary contributor to type 1 diabetes. Although an unhealthy lifestyle is not the direct cause of type 1 diabetes, it is essential to maintain a healthy lifestyle to keep the condition under control. Type 1 diabetes cannot be avoided at this time, but it may be managed well with a healthy lifestyle, the right medicine, and regular testing at the appropriate intervals. Type 1 diabetes is characterized by many main symptoms, some of which include an increase in thirst and urination, an increase in appetite, exhaustion, a rapid loss of weight, and impaired vision (Than et al. 2005). Type 1 diabetes may, over time, cause a variety of health complications, including cardiovascular disease, renal disease, nerve damage, foot problems, vision problems, depression, etc.

Type 2 Diabetes

In this form, the body develops resistance to the effects of insulin, which causes the amount of glucose in the blood to stay elevated for an extended length of time. Type 2 diabetes is the most prevalent form of the disease, with around 85–90% of diabetic people suffering from this form of the disease. Type 2 diabetes is a chronic condition that worsens with time and is strongly linked to changes in lifestyle as well as genetic and environmental variables that are tied to families. In most instances, persons over the age of 45 years are diagnosed with type 2 diabetes. However, in today's society, many cases of type 2 diabetes have also been detected in children, young adults, and adolescents. If a person lives a lifestyle that is controllable yet includes being overweight, having high blood pressure, and having poor nutrition, then his risk of developing type 2 diabetes is significantly increased (Fonseca 2009). The symptoms of type 2 diabetes include increased thirst and urination, weariness, hunger, skin infections, and impaired eyesight, among other symptoms.

Gestational Diabetes

Gestational diabetes mellitus (GDM) is a form of diabetes that occurs during pregnancy and normally disappears after giving birth. Gestational diabetes can happen at any stage of time but mostly it is found in the second half which is after the fifth month. GDM generally does not show any specific symptoms, although some women feel fatigue, increased thirst, and dry mouth. But these symptoms are common during the pregnancy period. Therefore, the only way to diagnose GDM is a regular blood sugar test. Most women having GDM give birth to a healthy baby, but in some cases, the baby can grow larger than normal which can increase the difficulties during delivery or may be a cause of premature delivery. GDM increases the risk of women to have type 2 diabetes (Linnenkamp et al. 2013).

Prediabetes

Prediabetes is a dangerous health condition in which blood sugar levels are higher than usual but not yet high enough to be classified as type 2 diabetes. Prediabetes increases a person's chance of acquiring type 2 diabetes, heart disease, and stroke. When a person has prediabetes, the cells in his body do not react correctly to insulin. To induce cells to react, the pancreas produces more insulin. Eventually, the pancreas can't keep up, and blood sugar levels rise, setting the foundation for prediabetes and type 2 diabetes later on. People might have prediabetes for years with no obvious symptoms; thus, it typically stays unnoticed until major health concerns such as type 2 diabetes manifests. If a person has any of the risk factors for prediabetes, such as being overweight; having a parent, brother, or sister with type 2 diabetes; being less physically active; having gestational diabetes; or having polycystic ovarian syndrome, it is critical to test the blood sugar.

Other Specific Types of Diabetes

The pancreas becomes inflamed when it fails to secrete critical hormones and enzymes necessary for glucose regulation and digestion. Inflammation is the root cause of many patients' suffering. Long-term pancreatic inflammation, on the other hand, is a known risk factor for type 3c diabetes and pancreatic cancer. The pancreas produces inadequate insulin to control blood glucose levels in type 3c diabetes. Nearly half of the patients require insulin injections to help the pancreas control blood sugar. Diabetes of this type is also known to impair pancreatic digesting. Exocrine pancreatic insufficiency is common when the pancreas is impaired in this way (EPI). EPI is a common complication in both chronic pancreatitis and diabetic individuals. In addition to digestive issues, EPI can cause chronic diarrhea and bloating. Fortunately, pancreatic enzyme replacement therapy is a great treatment option.

A variety of drugs have adverse effects, one of which is an increase in blood glucose levels. The term "drug-induced diabetes" refers to diabetes that develops as a result of the use of a certain medication. This type of diabetes is curable in certain circumstances if the medicine is removed, but in others, drug-induced diabetes may be permanent. Secondary diabetes can be developed as a result of other health conditions. Several drugs have been found to increase the risk of diabetes development: Medications include corticosteroids, thiazide diuretics, beta-blockers, antipsychotics, and statins.

Diagnosis of Diabetes

Diabetes mellitus (DM) is a group of metabolic illnesses caused by chronically elevated blood glucose levels. Diabetic patients experience one or more problems as a result of persistent hyperglycemia's damage to the primary functioning organs. It is expected that difficulties in diabetic individuals' functioning organs begin 5–10 years before the diagnosis. As a result, early diabetes detection is critical for preventing damage and reducing diabetic complications. Diabetes can be diagnosed using clinical tests that employ blood, urine, saliva, or sweat as a test sample. Aside from these modalities, interstitial fluid, ocular fluid, and breath may all be utilized to help in diabetes diagnosis. The concentration of glucose in each of these physiological fluids varies. It has been observed that urine and perspiration have reduced glucose content. As a result, even though it is a noninvasive technology, studies on it have been skipped, and it is currently not used clinically for diabetes diagnosis.

Blood Glucose Tests

The blood glucose level concentration is estimated by blood glucose testing to screen for diabetes. Several diabetic screening tests may be performed and discussed.

Glycated Hemoglobin (A1C) Test

The glycated hemoglobin (A1C) test is a normal blood glucose test that does not need fasting or special preparation. It displays the blood sugar level over the last 2–3 months. The proportion of blood glucose that is directly bound to hemoglobin is the proportion of oxygen that transports the protein to the red blood cells. Blood glucose level is directly proportional to the amount of hemoglobin connected to it. If the A1C result on two separate tests is 6.5 or higher, the patient is diabetic. If the A1C reading is less than 5.7, the patient is considered normal. Furthermore, if the test results fall between 5.7 and 6.4, the person is prediabetic or has a higher risk of developing diabetes. Although the A1C test is a simple and convenient approach for diagnosing diabetes, the findings are not considered reliable. Moreover, in some medical conditions, the results are skewed, making the A1C approach erroneous. This method is not popular among medical practitioners.

Random Blood Glucose Test

The blood sample for a random blood glucose test is collected at a random time. The patient is diagnosed with diabetes if the blood glucose level is 200 mg/dl or above, regardless of the food consumed.

Fasting Blood Glucose Test

Following an overnight fast from food and drink, a blood sample is collected in the morning for the fasting blood glucose test. You must not have eaten or drunk anything for at least 8 h before getting your blood drawn. If the blood sugar level after fasting is less than 100 mg/dl, the individual is deemed normal; if it is between 100 and 125 mg/dl, the person is prediabetic; and if it is greater than 125 mg/dl, the person is diabetic.

Oral Glucose Tolerance Test

The oral blood glucose test is the gold standard for diabetes diagnosis; it is extensively used and respected in the medical profession. The initial measurement of blood glucose concentration is conducted after an overnight fast in this test. After that, a sweet drink is administered, and blood glucose levels are measured every 2 h. Normal glucose levels are defined as blood glucose levels less than 140 mg/dl in the person. The condition is normal if the glucose level is less than 140 mg/dL but greater than 200 mg/dl. Diabetes is diagnosed when the blood glucose level exceeds 200 mg/dl. A person is called prediabetic if his glucose level falls between these two readings.

Diabetes and Its Prevalence

The International Diabetes Federation (IDF) and the World Health Organization (WHO) both keep a careful eye on diabetes prevalence and have created a transparent way of assessing the progression of diabetes throughout the world and in various countries. Guariguata et al. (2013a) reported thorough research prevalence of diabetes in individuals aged 20–79 in 2013 and projected for 2035. The research was carried out using 744 data sources from 130 nations. Diabetes is expected to rise dramatically, particularly in poor nations. Another intriguing and easily understood analysis has been released by the Noncommunicable Diseases (NCD) Risk Factor Consortium (Risk and Collaboration 2008), which projects the global trajectory of diabetes since 1980. The study included 4.4 million people from 751 population-based studies. Both studies indicated that diabetes cases grew more rapidly in emerging and underdeveloped nations than in developed or high-income ones. Diabetes diagnoses in adults surged to 422 million in 2014, up from 108 million in 1980, according to studies. The rate of increase in diabetes prevalence was lowest in northwest Europe and northern Africa, encompassing the Middle East and Middle Asia.

Diabetes prevention has also seen an increase in costs. Fernandes et al. (2014) assessed diabetes expenditure and discovered that at least USD 162 billion was spent on diabetes globally. The study indicates that diabetes is a significant economic burden on the global healthcare system and that a robust and effective public health management system is required to alleviate the cost burden caused by diabetes.

Various models have been published so far to estimate the diabetes population in the future. Ogurtsova et al. (2017) conducted an extensive analysis to forecast the diabetes population for 2040 based on trends up to 2015. All diabetes-related research was considered, and the most acceptable studies from all nations were chosen utilizing the analytic hierarchy approach. Following that, extrapolation was applied to the selected data to create the prediction model, and ultimately, a logistic regression model was used to obtain the diabetes population estimate. According to the projection, around 643 million people will be diagnosed with diabetes by 2040. Whiting et al. (2011) conducted a similar analysis to anticipate the diabetes population in 2030 using 2011 data. Diabetes is expected to impact around 522 million people by 2030, according to the authors. Every year, IDF contributes to a diabetes atlas of reviews and publishes high-impact journal articles that forecast the prevalence of diabetes in the future. Since 2009, IDF published many studies related to the prevalence of the diabetes globally and regionally. Table 1 covers some of the abovementioned IDF research.

Status of Diabetes in India

Diabetes is most common in both developing and developed countries; thus, it should come as no surprise that these two categories are the most likely to be affected. One of them is India, albeit the prevalence of diabetes varies greatly across the country. At the moment, around 73 million Indians have been diagnosed with diabetes, yet there is a substantial disparity between the urban and rural populations (Kumar et al. 2013). As a result, diabetes is without a doubt one of the most serious problems confronting India's healthcare system. According to an Indian Council of Medical Research (ICMR) report, the central, eastern, and southern areas of India have a much higher prevalence of diabetes than the northern region (Anjana et al. 2011). Kumar et al. (2011) have previously demonstrated that diabetes would worsen in India soon and that urban living is a key component of this. Diabetes will impose a significant emotional, economic, and societal cost on developing countries such as India. Kaveeshwar and Cornwall (2014) discovered that body mass index (BMI) has a significant impact on diabetes. Persons with lower BMI are at a higher risk of developing diabetes.

Furthermore, there is a growing recognition of the need for high-quality, patient-centered primary care institutions that focus on both primary and secondary diabetes prevention (White et al. 2015). Medical practitioners are the first point of contact with the health system and provide integrated medical care services with the opportunity for fast referral to specialists, thereby meeting the health needs of the majority of the population (Shi et al. 2002; Ferrer 2007). According to the WHO,

Table 1 Summary of the studies by the IDF on the status of diabetes

Sr. no.	Description	Year
Studies on global population		
1	The International Diabetes Federation (IDF) and the World Health Organization (WHO) performed a survey on diabetes in the population of the world, and estimates were created for the years 2010 and 2030. It was estimated that the prevalence of diabetes would be 6.4% in the year 2010, and it is anticipated that this number will rise to 7.7% by the year 2030 (Shaw et al. 2010)	2009
2	Data about diabetes were compiled by the International Diabetes Federation from a variety of scholarly works that were subjected to peer review. It was suggested that estimation of the number of people who have diabetes might be done using logistic regression (Guariguata et al. 2011)	2011
3	For the year 2011, information on diabetes was gathered from a total of 565 data sources located in 110 different countries, and an estimate of the diabetes population for 2030 was created. According to the findings of the study, undeveloped and poor countries would see the greatest increase in diabetes (Whiting et al. 2011)	2011
4	Burdon of metabolic risk on the world population due to diabetes had been estimated (Unwin et al. 2012)	2012
5	An update on the world diabetic population has been published (Guariguata 2012)	2012
6	A calculation of the diabetes population in 2013 was made using the literature that was accessible, and a prediction of the diabetic population in 2035 was made using logistic regression. For this investigation, a total of 744 data sources from 130 nations were included (Guariguata et al. 2013b)	2013
7	After doing a worldwide calculation of the prevalence of type 1 diabetes in children, researchers discovered that there are around 500,000 children less than 15 years old who have been diagnosed with the condition. There was also research conducted on a regional scale, and it was shown that more children in Europe suffer from type 1 diabetes (Patterson et al. 2014)	2013
8	IDF analyzed the undiagnosed case of diabetes and discovered that around 45% of diabetes cases remained undetected globally. This estimate was based on literature that was readily accessible (Beagley et al. 2014)	2013
9	Guariguata et al. (2013) estimated the worldwide cases of hyperglycemia in pregnancy due to diabetes	2013
10	Linnenkamp et al. (2013) proposed a methodology to estimate hyperglycemia in pregnancy	2013
11	The first documented study to estimate the worldwide mortality owing to diabetes in 2010 and 2011 was released by the International Diabetes Federation (IDF). According to the findings of a study, the Western Pacific regions had the greatest increase in diabetes cases (IDF Diabetes Atlas Group 2013)	2013
12	An updated estimation by IDF estimates the global deaths attributable due to diabetes in 2015 and compensation with the previous studies (Diabetes I D F Group 2015)	2015
13	IDF reviewed total 540 data sources from 111 countries and estimated the diabetes population for 2015 and 2040 (Ogurtsova et al. 2017)	2016
14	IDF estimated the total expenditure on diabetes for the year 2014 globally (Fernandes et al. 2014)	2017

(continued)

Table 1 (continued)

Sr. no.	Description	Year
15	IDF published the diabetes data for the year 2017 and estimated for year 2024 (Cho et al. 2018)	2018
16	In this article, IDF provided a summary of research published between 2015 and 2018 that used retinal photography to assess the prevalence of diabetes-related retinopathy throughout the world	2019
Studies on regional population		
1	IDF estimated the diabetes cases in Africa for the year 2013 (Peer et al. 2013)	2009
2	IDF estimated the diabetes cases in Europe for the year 2013 (Tamayo et al. 2014)	2009
3	IDF estimated the diabetes cases in the Middle East and North Africa for the year 2013 (Majeed et al. 2013)	2009
4	IDF estimated the diabetes cases in North America and Caribbean Region for the year 2013 (Yisahak et al. 2013)	2009
5	IDF estimated the diabetes cases in South and Central America for year 2013 (Aschner et al. 2014)	2009
6	IDF estimated the diabetes cases in South-East Asia and Caribbean Region for the year 2013 (Ramachandran et al. 2013)	2009
7	IDF estimated the diabetes cases in Western Pacific Region for the year 2013 (Chan et al. 2013)	2009

population-centered primary care should be inclusive and continuing, focusing on individual health needs and preferences and facilitating treatment from a trusted practitioner.

Diabetes and Physiological Parameters

Physiological parameters in conjunction with new computer technologies have also demonstrated significant potential for diabetes risk assessment. Using physiological indicators, modern machine learning approaches have achieved extremely high accuracy in detecting diabetes. Hassan et al. (Temurtas et al. 2009) conducted a comparison study on the Pima Indian database for diabetes diagnosis. Age, body mass index (BMI), blood pressure, glucose concentration level, and other physiological characteristics were utilized to train a multilayer neural network for diabetes detection. So far, Pima Indian is the only database that has information regarding the abovementioned physiological indicators associated with an individual's diabetic status. Several researchers (Kayaer and Yildirim 2003; Polat and Güneş 2007; Polat et al. 2008; Dwivedi 2017) have proposed algorithms to predict diabetes using the Pima Indian database. Dwivedi (2017) performed a comparative examination of several classifiers for diabetes prediction using the Pima Indian database. Polat and Güneş (2007) categorized diabetes and nondiabetic groups in the UCI diabetes dataset. Principal component analysis (PCA) was used for feature selection, while adaptive neuro-fuzzy inference

system (ANFIS) was used for classification. Authors raised their accuracy to 89.47%. Polat et al. (2008) proposed a cascade approach for diabetes detection utilizing the Pima Indian dataset. A two-stage method consisting of generalized discriminant analysis (GDA) and the least square support vector machine (LS-SVM) has been presented. GDA was utilized to analyze the discriminant between characteristics, while LS-SVM was employed to identify diabetic and nondiabetic individuals. Heydari et al. (2015) gathered physiological diabetes data from a large population (2536) in Iran and provided an in-depth comparison of categorization algorithms.

Complementary and Alternative Diagnosis

The use of complementary and alternative diagnostic procedures is becoming more popular, not just among the general population but also among alternative medicine practitioners. Complementary and alternative medicine (CAM) practices held substantial power in the medical communities of the United States and Europe even before the turn of the twentieth century. Between 1990 and 1997, there was considerable growth in the use of complementary and alternative medicine (CAM) throughout American countries (Eisenberg et al. 1998).

A range of economic and sociological variables impact the usage of any type of medication. Even for serious diseases, people in underdeveloped countries with inadequate medical infrastructure may seek care from traditional medicine practitioners (Eisenberg et al. 1998). Because scientific therapies are more widely available in industrialized countries, complementary and alternative medicine (CAM) plays an essential role in illness prevention and health promotion (Eisenberg et al. 1998). There is also evidence that people with serious conditions such as cancer frequently use CAM as an adjuvant to biological therapy (Molassiotis et al. 2005; Smith et al. 2018) and self-manage chronic health concerns such as low back pain (Savigny et al. 2009). However, the social factors that promote CAM use in wealthy nations are not well understood. Studies have repeatedly demonstrated that those who use CAM are more likely to be female, to have a higher level of education, to be in their middle age range, and to report having a better health state than those who do not use CAM (Astin 1998; Corp et al. 2018).

The scientific evidence-based CAM diagnosis technique is becoming increasingly popular and reliable for diagnosis and treatment. Ayurveda has a strong intellectual and experiential base as a historic and complete medicinal system (Patwardhan et al. 2005). Eight criteria must be completed to evaluate the patient-based outcome measures of any clinical research. A few of the traits to evaluate include relevance, dependability, validity, scalability, responsiveness, and correctness (Fitzpatrick et al. 1998).

Ayurveda for Diagnoses

In Ayurveda, outcome metrics include physical examination findings or questionnaire scores on body constitution (*prakriti*), lifestyle, diet, and quality of life. To be included in a study procedure, outcome measurements or diagnostic variables such as bodily humors/energies (*dosha*), tissues (*dhatu*), metabolic waste (*mala*), metabolic fire (*agni*), subtle life force (*prana*), material life force (*ojas*), toxicity (*ama*), body parts (*avayava*), essential body part (*marma*), and the five components (*mahabhoota*) must be valid and trustworthy (Streiner et al. 2015). The degree to which two or more raters agree on a diagnosis of the same patient in the clinical environment is referred to as interrater reliability. Reliability studies are important because they provide information on the quality of measurements and play an important role in the process of developing successful diagnostic procedures (Fewell 2005).

Dosha is thought to alter a person's physical, psychological, and physiological characteristics. The ancient Ayurvedic writings *Charak Samhita* and *Sushruta Samhita* discuss in detail how to determine *dosha* traits through the development of *prakriti* and diseases. In recent years, just a few studies have shown a genetic foundation for *prakriti* (Patwardhan and Bodeker 2008). Human leukocyte antigen (HLA) gene variation has been connected to *prakriti* structure (Bhushan et al. 2005). According to a second study, metabolic profiles and hematological features differed among *prakriti* kinds (Prasher et al. 2008).

There is a statistically significant link between the CYP2C19 genotype and the main classes of *prakriti* types, according to Ghodke et al. (2007). Another study found that the aggregatory response of platelets and the inhibition of that response by aspirin varied depending on the *prakriti* subtype (Ghodke et al. 2007). There is a considerable likelihood that the *prakriti* results will have a significant impact on individualized therapy. On the other hand, quantitative research on themes such as the reliability of *prakriti* appraisal is lacking. Seven types of *prakriti* are defined based on the combination of one or more bioentities: *vataja*, *pittaja*, *kaphaja*, *vatapittaja*, *vatakaphaja*, *pittakaphaja*, and *vatapittakaphaja*. Analyzing one's *prakriti* might help him prioritize any nurturing, preventive, or therapeutic program that is unique to him. As a result, *prakriti*-based prescribing may help to increase the therapeutic impact of a regimen while minimizing the likelihood of adverse drug responses. Analyzing the *prakriti* assessment itself is critical to obtain more reliable diagnostic results (Rastogi and Chiappelli 2012; Kurande et al. 2013). *Prakriti* is defined as a natural blend of one or more *doshas*. Another way of determining the current state or degree of *dosha* is pulse examination, also known as *nadi pariksha* (Kumar et al. 2019). Another beneficial process is *jivha pariksha*, often known as tongue diagnostics. The color, shape, and coating of the tongue are all visual features of the tongue that are analyzed throughout the inspection procedure. According to Ayurveda, the basis of all diseases is a malfunction of the digestive or biological fire (known as *agnimandya*). When the biological fire, also known as *mandagni*, is not functioning properly, digestive issues may emerge, leading to the formation of an autotoxin known as *ama* (Tamborrino et al. 2021). This autotoxin binds to the

bioentities, also known as *doshas*, and affects the body's tissues. As a result, the properties of these tissues are weakened or altered, potentially leading to a variety of medical disorders. An inspection of the tongue coating is critical in the early stages for recognizing an impairment of digestive fire. If help is provided at this moment, it may be feasible to prevent the subsequent production of the autotoxin. When combined with other symptoms of *ama*, changes in the coating of the tongue may offer considerable information that may be used to make Ayurvedic diagnosis.

Traditional Chinese Medicine

Over thousands of years, traditional Chinese medicine (TCM) has established its medical system for diagnosing and treating a wide range of diseases (Tang et al. 2008). Based on the Yin-Yang philosophy and its five components, the human body may be viewed as the union of Qi and spirit (Lozano 2014). Using the four essential TCM diagnostic processes of examination, auscultation and olfaction, inquiry, and palpation, experienced TCM practitioners may analyze the source of the ailment, the kind of disease, and the location of the sickness (Liang and Huang 2022). As a result, medical experts may create the right herbal prescriptions for a therapy based on variances in human *Zang Fu*, Qi, blood, and other physiological fluids. Herbs will be used in these prescriptions. Furthermore, TCM utilizes practices such as acupuncture, cupping, Qigong, massage, and diet therapy to preserve the Yin-Yang balance, manage patients' health, and further restore their health. The WHO has recognized TCM as an example of complementary and alternative medicine that is both effective and ubiquitous across the world (Traditional Chinese Medicine Could Make "Health for One" True 2005).

TCM practitioners use their hands to feel for irregularities in the patient's arterial pulse as well as touch the patient's skin, chest, abdomen, and other parts of the body to detect aberrant symptoms. Thus, medical practitioners can use their expertise and abilities to combine information gathered from four independent TCM diagnostic techniques to identify unique illnesses or syndromes (Jiang et al. 2012). TCM syndromes are a pattern that may be thought of as combining pathogenic elements and the human body's reaction to illnesses, as well as recognizing the overall dynamic body response status to diseases. Diagnostic procedures based on TCM may be used to establish the presence of a broad variety of symptoms, syndromes, and diseases.

Even though it is widely used in TCM hospitals all over the world, TCM diagnosis has been demonstrated to be less accurate when compared to modern medicine (Wang et al. 2021). As a result, traditional TCM diagnosis is subjective; the experiences and manual examination of diverse TCM practitioners frequently give varying diagnostic results. TCM practitioners, on the other hand, must dedicate a large amount of time to the study of TCM diagnosis before they can perfect it discreetly. Although several research studies have shown a relationship between the appearance representation of patients in TCM diagnosis and a range of illnesses (Liao et al. 2014; Shu and Zhang 2016), it is suitable and vital for improvement.

TCM diagnosis uses a standardized, scientific, and computerized technique. In recent decades, academics have suggested and developed several computational TCM diagnostic approaches to address the difficulties raised by TCM experts (Liao et al. 2014; Shu and Zhang 2016). These ways have been developed to help TCM professionals overcome the difficulties they confront. These computerized devices are frequently designed to simulate the eyes, hands, and olfactory experience of a TCM practitioner. Other sensations can also be reproduced.

Patients can acquire digital data in the most efficient way possible by using the different devices indicated below. Because of the presence of many algorithms (Jiang et al. 2012; Zhang et al. 2014; Shu et al. 2017; Zhou et al. 2020), it is feasible to analyze these data and, finally, assess the condition of an individual's health. Despite this, for the time being, the bulk of computational diagnosis tools available can only duplicate one of the four diagnostic techniques used by TCM to help in the identification of ailments. This is owing to technology developments as well as early research inquiries.

TCM postulates that there are both interactions and causalities between various factors (Maciocia 2015). For example, the human body can be considered a fully living creature in and of itself. Local lesions have the potential to produce systemically damaging reactions throughout the patient's body. In other circumstances, however, systemically unhealthy changes may manifest as local lesions. As a result, TCM clinicians may evaluate, synthesize, and research a wide range of local lesions or sickness occurrences in the human body using TCM as a guide. This allows TCM practitioners to gain a grasp of the nature of the condition and come to diagnostic conclusions.

The diagnostic process in TCM is based on three fundamental concepts (Zhang et al. 2005). The first advantage is that we may extrapolate the changes that have occurred on the inside by analyzing the alterations that have occurred on the outside of the patients. TCM practitioners, for example, might check a patient's exterior appearance, such as the face, before recognizing any changes in the patient's internal organs, such as the liver. The second advantage is that we can assess the overall state based on relatively few changes. Minor changes in the local component frequently reflect the overall physiological and pathological information, which may be utilized to diagnose many diseases. For instance, TCM practitioners may often examine the state of the tongue or the sublingual veins to conclude the applicants' overall health (Zhang and Zhang 2015; Zhang et al. 2017). Clinical research (Hsu et al. 2019) provides more evidence supporting this concept. The third argument is that abnormal modifications can be discovered based on knowledge of the standard state. TCM practitioners with years of experience, for example, are aware of the common fluctuations that may occur in the arterial pulse. As a consequence, they may easily spot any aberrant changes in the patients' pulses and locate the condition that corresponds to such changes. Practitioners of traditional Chinese medicine are also able to identify a wide range of diseases utilizing these key TCM diagnostic ideas due to their considerable training and years of experience. However, as compared to manual sickness detection, the diagnostic data they produce is still susceptible to

interpretation and takes a long time. As a result, these issues are open to further repair and improvement through the application of computational approaches.

The associated diagnostic performances demonstrate that these computational systems are capable of assisting medical professionals in making straightforward diagnostic judgments that have the potential to be used in TCM. Despite this, several aspects of this business must be enhanced and, in particular, examined shortly. Several studies have focused on the use of pictures of the face, tongue, and sublingual area to forecast future patients' health in the context of computational TCM diagnosis with the inspection. The number of research evaluating tongue images is significantly more than the number of works evaluating the face and sublingual images. This conclusion may be made for a variety of reasons. Images of the tongue, according to TCM philosophy, frequently convey far more vital information than the sublingual vein, which is effective in ailment detection. Because its sections are substantially more compressed, obtaining samples from the sublingual vein is challenging.

Furthermore, the computational acquisition devices for images of the tongue and face are simple to create in a functionally sound manner. Similarly, some human body parts or organs are notoriously difficult to get. There are, for example, very few articles that analyze possible candidates' spirits, motions, or limbs for computational TCM diagnosis. At the moment, computational gadgets or systems capable of capturing the human spirit appear unattainable. The fact that these components have not been explored, on the other hand, serves as a reminder that there is still a lot of space for advancement in computational inspection diagnostics.

People of various nationalities have noticeably different skin tones on their faces. The recommended computational TCM diagnosis procedures may be prone to errors and produce poor classification results when comparing persons of various races based on the color of their facial skin. Oluwagbemi and colleagues, for example, developed a TCM-based computational tool that can collect and evaluate face pictures of individuals living in Sub-Saharan Africa to identify illnesses. Their findings give additional evidence that the proposed computational TCM face diagnostic tool is capable of correctly recognizing a wide range of viral infections as well as noncommunicable diseases (Oluwagbemi and Jatto 2019). However, there have been relatively few studies on the utilization of computational TCM facial diagnosis across several ethnic groups so far. The bulk of current research has mostly investigated facial diagnosis in Asian persons. For more accurate results, researchers should gather a large number of face images from a varied variety of ethnic origins and then standardize the range of facial skin tones using various types of computer processing. As a result, this dilemma raises an exciting research subject that should be addressed further shortly. There isn't much TCM-based research in computational auscultation diagnosis. This is because patient speech signals are frequently insufficient to accurately reflect the specific diseases or symptoms. In general, voice signals include an excessive quantity of noise information, which may affect the diagnostic outcome. For example, the acoustic patterns of coughing, yawning, and snoring, frequently hidden in the general speech signal, might be useful in diagnosing. As a result, greater study on the issue of collecting additional voice signals with

a diversity of patterns and using enhanced feature extraction algorithms might be valuable in the future.

Researchers have recently created a range of odor capture systems for analyzing breath odor for use in olfactory diagnostics. They generally use a gas bag or cylinder to hold subjects' breath before continuing their inquiry with various scent sensors. Diabetes is the most common and sensitive disease that computational odor diagnostics can detect, while other diseases are relatively seldom investigated. As a result, more smell samples from a variety of illnesses are needed to further assess the efficiency of computational TCM odor diagnostics. One further area that we may pursue is the collection of diverse fragrances created by humans, such as sweat. It's possible that employing various scent categories will result in more accurate sickness detection.

In contrast to patient vocal input, which must be transcribed, the bulk of medical records are based on electronic text, which is straightforward to analyze. However, online communication with patients who respond appropriately is required and beneficial in the process of automated TCM diagnosis. Natural language processing (Calvo et al. 2017; Ghosh 2022) may be required to complete this task. Because of the rapid growth and advancement of deep learning methods (Deng and Liu 2018; Kulikowski 2019), we are certain that the active interactive inquiry of TCM diagnosis will soon make significant progress and become a practical application.

The computational palpation diagnosis is more developed in TCM than other diagnostic processes. There have been a lot of studies that have looked into wrist pulse signals for detecting various diseases. Their diagnostic accuracy illustrates the potential use of the wrist pulse diagnostics approaches described. On the other hand, the instruments used to get wrist pulses are too large and unwieldy to be carried around and used instantaneously. There is potential and opportunity to create and utilize mobile and portable wrist pulse collecting devices (Zhang et al. 2020).

Iridology

In biomedical imaging, iris-based diagnosis is a highly intriguing and reliable method. It enables the diagnosis of chronic disorders that are difficult to diagnose using histological approaches. Iridology is a unique and alternative kind of holistic healing. It is a disputed technique founded on a variety of nonscientific assumptions that derive its therapeutic power from a certain worldview and theological framework. It is claimed that iridologists can evaluate an organism's general health by reading diseases or a proclivity to them from the iris of the eye (Rita 1999). Many people appear to be able to do this because they desire health at any cost and in a very easy manner, converting, working on themselves, the church, or religion (Simon et al. 2015). This might explain their success. However, neither the detection nor the rehabilitation of diseases is often possible with iridology.

Iridology is a nontraditional way of diagnosis and therapy that aims to identify the overall health of the organism by reading illnesses or a proclivity to them from the iris of the eye. Iridology is founded on the notion that all of the organs of the body are

represented on the surface of the iris via nerve connections, and that most organ malfunction is indicated on the iris, generally as a pigmented lesion. Iridology also thinks that the right iris represents the right half of the body and the left iris represents the left half of the body (Rita 1999). Iridologists believe that the appearance of the iris might reveal the health of numerous organs in the body. Iridology originated in the East, particularly Ancient Egypt and China; in the past, various illnesses could be identified by analyzing the appearance of a patient's iris (Jensen 2011; Pesek 2016; Simon et al. 2015). Ignác Péczely, a Hungarian physician, was the one who built the framework for modern iridology. Péczely's iridology was founded on his discovery that in an owl, after a paw fracture, a prominent black line developed on the iris of the eye, which faded after the cure; and subsequently, he saw a similar line in a patient. Péczely's iridology is credited with having contributed to the development of the field of ophthalmology.

Iridologists frequently refer to iris maps. An iridological examination entails a thorough study of the iris (either directly, with appropriate eye illumination, such as with a slit lamp, or by taking high-quality color photographs of both irises, sometimes supported by the analysis of specialized computer software). This review can be completed in one of two ways. Iridological maps depict a schematic segmentation of the iris' surface into fields that are the projection fields of certain internal systems and organs. This is done so that each portion of the body has a matching location on the surface of the iris of the eye (Soediono 1989; Salles and Mjp 2006; Jensen 2011). The iris picture is then matched to the iridological maps. This is done so that specific locations on the iris are assigned to particular internal organs. On an iris map, each iris is split into 60 sectors (like the face of a clock), and each sector corresponds to a different internal organ or function of the body; for instance, heart disorders may be seen in the left iris between positions 2 and 3 h (Simon et al. 2015). Iridologists draw maps of the iris as if there is an anatomical or physiological mechanism (e.g., by the nervous system, the bloodstream) underlying the connection between the iris and the rest of the body; as if each internal organ and part of the body were represented in specific areas of the iris; and as if the moles and discolorations of the iris reveal the condition of each organ, the inherited weaknesses and strengths, and the inherited and acquired inclinations to engage in certain behaviors. Meanwhile, these iridological maps are one of the indications that iridology has no basis in reality because none of them can precisely represent approximately 10,000 diseases (as indicated by the ICD-10 number); additionally, there are various versions of the iridodiagnostic key, methods of analyzing the iris, and iris maps; this means that there is no single universal diagnostic key for the iris, and the same changes in the iris are interpreted differently by different practitioners (Salles and Mjp 2006; Jensen 2011; Pesek 2016; Simon et al. 2015).

Changes in the color of the iris, as well as its spots, shadows, and other features, according to iridologists, might give insight into the health of a patient's internal organs by displaying how they are performing abnormally. Meanwhile, there are known medical signs that may appear in the eyes. These symptoms may be caused by systemic illnesses, and the iris is one of them. This, however, only applies to a

tiny fraction of all currently recognized disorders and does not offer a conclusive diagnosis.

According to iridologists, changes in the color of the iris, as well as its spots, shadows, and other characteristics, may provide insight into the health of a patient's internal organs by indicating how they are behaving abnormally. Meanwhile, there are documented medical symptoms that may manifest in the eyes. The iris is one of those organs which can indicate several systemic disorders that can cause these symptoms. This, however, only applies to a small percentage of all officially recognized illnesses and does not provide a clear diagnosis for other diseases. For example, granulomatous anterior uveitis, one of the symptoms which iris manifest, may be associated with one or more of the following systemic diseases: chronic sarcoidosis (D86), the Vogt-Koyanagi syndrome, toxoplasmosis (B58), tuberculosis, syphilis, or leprosy (A30) and B-cell malignant lymphoma.

Iris warts (symptoms: regular, thin, fragile, vermilion-like lesions) may be linked to the development of Ota nevus, neuroblastoma (type 1), and Rieger's syndrome. Lisch nodules (small, brown, domed nodules) may be linked to the development of neuroblastoma and Brushfield spots (symptoms: white or yellow dots, ring-shaped, placed between the outer and center regions) (type 1).

Vascular development on the iris, also known as new blood vessels on the iris, may be an indication of one or more of the following associated systemic diseases:

- A condition known as oculocutaneous albinism may sometimes be accompanied by transillumination of the iris.
- When Rieger's syndrome is present, there may be posterior embryotoxon and iris anomalies, as well as hypoplasia of the proper iris' essence (along with pupil displacement and obvious polycroticus) and nipple-like elevations on the iris' surface.
- Your irises may take on coloration of their own, even if you have Waardenburg syndrome.
- Iris lesions that are characterized by increased transillumination of the iris are a potential complication of diabetes.
- Iris hypoplasia and Brushfield spots are also possible complications of Down syndrome.
- Infiltration and thickening of the iris may occur together with leukemia in certain patients.
- A congenital collapse of the iris-pigmented epithelium may occur if the patient has Recklinghausen's illness in addition to neuroblastoma of type 1, which is a kind of neuroblastoma.
- On the surface of the iris, in addition to the stigma, there may be elevations that resemble nips.
- Oculocutaneous albinism, also known as the tyrosine-negative variant, may cause the iris to appear gray to blue and completely transparent.
- Along with oculocutaneous albinism (the tyrosine-positive variety), the iris may range in color from blue to yellow-brown, and it can have variable degrees of translucency.

- Sturge-Weber syndrome can cause angioma of the iris and ciliary body on the same side.
- When combined with malignant cancer, there is a possibility of lumps on the iris, which might amount to a large number.
- There is some evidence that links Kayser-Fleischer ring's to Wilson's disease, also known as hepatocellular degeneration.

Researchers have proposed several research articles to diagnose different chronic diseases using iris with the help of iridology. Liljequist (1916) discovered alterations in the iris and linked them to various illnesses. Soediono (1989) researched how previously practitioners used microscopes, magnifying glasses, and other equipment to view iris tissue change and assess an individual's health state. Iridology is a noninvasive diagnostic approach that uses iris colors, patterns, shape, and other tissue structure features to forecast an individual's health. Jensen (2011) divided the iris into 80–90 zones corresponding to different body organs. Salles and Mjp (2006) found that literature on iridology is quite limited, and it's essential to have more grim and extensive studies.

Um et al. (2005) investigated the relationship between iridological constitutions and ACE polymorphism in hypertension patients. They stated that it is used as an additional source to detect the medical condition. In this day and age of computer-assisted diagnosis (CAD), various researchers have integrated the basic concepts of iridology with computer-based diagnostic processes to arrive at an illness diagnosis. Qiu et al. (2006) proposed a model to determine ethnicity from iris data using the AdaBoost approach. Using their approach, they were able to achieve an accuracy of 85.95%. This model attempts to assess whether a person is of Asian heritage. While V. Thomas et al. (2007) used machine learning approaches to construct models that predict gender based on iris texture data, Bansal et al. (2014) predicted gender using the CHT model and the support vector machine (SVM) algorithm. Based on the iris texture traits, both of these models predict gender.

Ma et al. (2013) investigated the influence that gastrointestinal disorders have on the geometrical structure of the iris patterns. Manual clustering, which was then followed by manual classification, was carried out to investigate the properties of the iris that are based on its geometrical structure. To determine the cause of the colon disease, Passarella and colleagues (2013) investigated the distinct areas of the iris. Using photographs of the patient's iris, Hussein et al. (2013) were able to determine that the patient had a renal disease. The evaluation was conducted on a total of 166 different participants. The authors had already classified the data using neuro-fuzzy methods after extracting wavelet, entropy, and energy components. Ramlee et al. (2011a) investigated the possibility of detecting the presence of cholesterol in blood vessels via the use of iris recognition algorithms. Both Daugman's (2004) and Masek's (2003) approaches to iris identification have been used in recent years for iris localization and segmentation. Computer software can detect the level of cholesterol in our body by analyzing our irises using iris recognition algorithms and an iridology chart. More study, on the other hand, was undertaken to discover the

specific range or quantity of cholesterol contained in blood vessels (Ramlee and Ranjit 2009; Ramlee et al. 2011a, b) (Table 2).

Bansal et al. (2015) presented an SVM-based model to determine diabetes, using the Gabor filter and 2-D DWT-based features. The authors have performed a close group study on 80 subjects and performed analysis of the different kernels of the SVM classifier with the combination of wavelets. The authors have achieved 87.5% of accuracy in classifying the diabetic and nondiabetic subjects using the radial basis kernel of SVM. Lesmana et al. (2011) proposed a computer method-based iris assessment technique to detect insulin deficiency from beta cells secreted from the pancreas. Neighborhood-based modified back-propagation using adaptive learning parameter (ANMBP) technique has been used to classify the abnormalities in the iris due to insulin deficiency using quantitative and textural features. Banzi and Zhaojun (2015) evaluated the broken tissues and color change of the iris for early detection of diabetes Salles and Mjp (2006) reported a longitudinal study to observe the change in the sign of the cross of the pancreas in the specific areas of the iris due to DM over the period of 4 years.

Methodology

The model for assessing the diagnosis of diabetic kidney disease (DKD) utilizing the idea of iridology was developed. At the same time, advanced machine learning technology was employed to establish a procedure as a standard for an iridology-based diagnosis system. This allows one to supplement the traditional diagnosis procedure and track therapy success. Figure 2 summarizes the approach utilized.

Dataset Collection

DKD is a chronic disease and a worldwide public health problem for the diabetic population. DKD is frequently connected with an increased risk of chronic renal failure and cardiovascular disease. In this study, 43 nondiabetic and 83 diabetes individuals were considered. DKD affected 41 of them. Fasting and 2-h postprandial tests were conducted to determine diabetes. Glomerular filtration rate (GFR) was computed to monitor the progression of kidney injury. If the computed GFR is less than 90 mL/min/1.73 m^2, the patient is classed as diabetic. Cross Match Technologies, USA, used an iris scanner I-SCAN-2 to take images of both eyes.

Image Pre-processing Techniques

In pre-image processing, iris segmentation and normalization techniques were utilized. The center and radius of the inner and outer circular sections of the iris were the most important factors. Several segmentation techniques, however, had already been applied (Masek 2003; Daugman 2004; Ma et al. 2013; Bansal et al.

Table 2 A summarized iris-based disease diagnosis system

Author	Application	Image preprocessing techniques	Remarks
Um et al. (2005)	Relationship between iris constitution and ACE gene polymorphism	For the assessment, a system for iris analysis Bexel Irina was developed.	Neurogenic, abdominal connective tissue weakness, and cardiorenal connective tissue weakness features have been explored from the iris Total 166 subjects were investigated
Thomas et al. (2007)	Predicted gender using iris	Canny edge detector and circular Hough transformation (CHT) used for segmentation and texture encoding Daugman's rubber sheet model, FFT, Gabor filter for normalization Geometric and texture features were studied	LG EOU200 system for data acquisition; tenfold cross-validation method was used C4.5 decision tree (initially on SVM and neural network)
Bansal et al. (2014)	Predicted gender using iris	The CHT was used for segmentation Daugman's rubber sheet model for normalization Combines statistical features with 2-D DWT-based features	I-SCAN-2 dual iris scanner for the data acquisition The accuracy of the system was compared with polynomial, Gaussian, and RBF kernel function
Ma et al. (2013)	Gastrointestinal diseases	Manual blind clustering has been applied The manual classification was performed by six different persons having some medical background	Deformation in the geographical features due to gastrointestinal disease Pupil-based features (pupil roundness and pupil largeness) were extracted
Passarella and Fachrurrozi (2013)	Identified colon disorder	CHT is used for localization and simple edge detection for segmentation	Total 60 student volunteers were evaluated for the experiment 92% accuracy was achieved to classify colon disorder and results have been reconfirmed by the clinical test
Hussein et al. (2013)	Diagnosed kidney disease	Histogram equalization to normalize the contrast of the image CHT for localization and segmentation	The neuro-fuzzy classifier was used Wavelet, entropy, and energy of the specific regions of the iris have been extracted
Ramlee et al. (2011b)	Cholesterol in blood vessel	John Daugman's and Libor Masek's iris recognition methods for localization and segmentation	To determine the cholesterol Otsu threshold method has been used

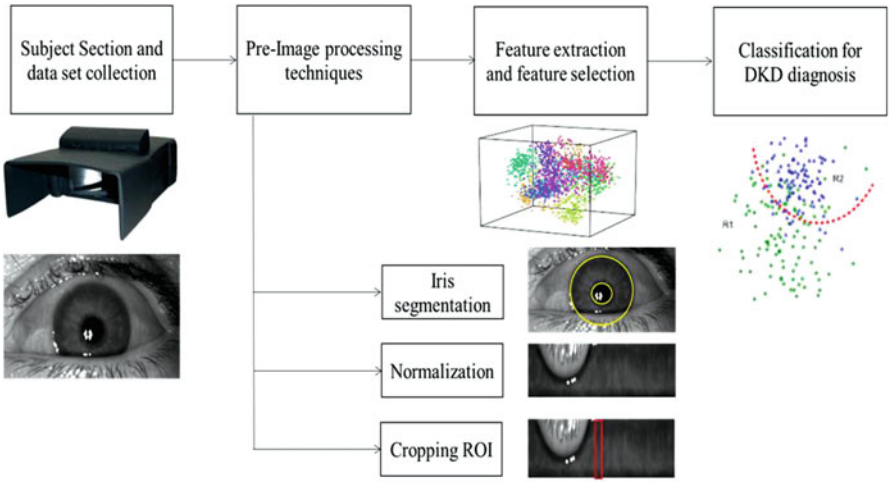

Fig. 2 Block diagram of the adopted methodology

2015). However, the most well-known and widely used iris segmentation technique based on the circular Hough transformation (CHT) (Masek 2003) was used.

The circular iris is converted into a fixed rectangular segment via the rubber-sheet normalizing technique. The rubber-sheet normalization model produced results that were independent of camera orientation, alignment, and location. It eliminates extrinsic variables such as uneven lighting and dimensional imperfections. Daugman's (2004) rubber-sheet model was employed in this study to transform segmented iris into a rectangle with a constant size of 360,720 (pixels). The ROI was then cut from the normalized iris using Jensen's iridology chart. The kidney was shown between 6.30 and 7 o'clock in the left eye and between 5 and 5.30 o'clock in the right eye (Jensen 2011). Therefore, the ROIs were cropped corresponding to these specific areas of the iris as shown in Fig. 3.

Feature Extraction and Model Design

The purpose of feature extraction was to retrieve relevant and indistinguishable data from the ROI. From the clipped ROI for both iris, 5 first-order statistical (FOS), 19 GLCM, and 7 GLRLM-based features were retrieved. The model was created to assess the contribution of feature sets to DKD diagnosis. Only FOS, GLCM, and GLRM (Hussein et al. 2013) characteristics were investigated in separate studies for the diagnosis of DKD. In addition, for the diagnosis, a combined feature set was employed, so that the function of individual characteristics and dominant feature sets could be calculated.

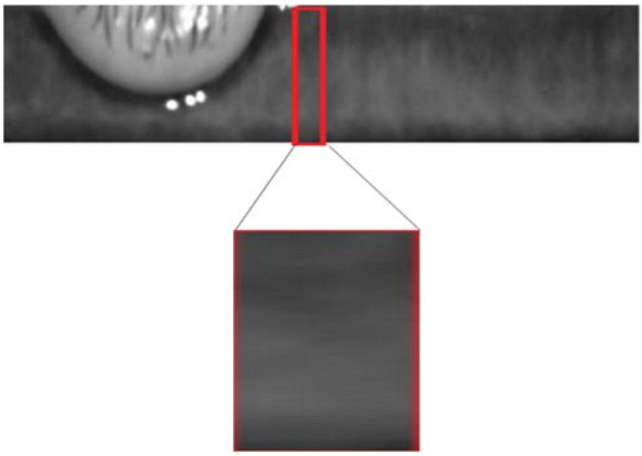

Fig. 3 Extraction of the region of interest

Classification

The categorization was done using different kernels from two distinct classifiers, k-nearest neighbor (KNN) and SVM (Bansal et al. 2015). SVM's fine Gaussian and cubic kernels were assessed, while three KNN kernels were selected for further evaluation: subspace, weighted, and fine. SVM is a prominent biological classifier. It is accurate and simple to grasp, with a high learning capacity, while KNN is the most often used classifier in many benchmark applications. It is superior to other classifiers due to its simplicity and fast performance.

Result and Discussion

Total 62 features were extracted from the group of FOS, GLCM, and GLRLM features. All the results were implemented over the normalized feature set to minimize the influence of the subsequent steps over the features. The trials were performed to design an efficient classification system for the prediction of the DKD.

Classifier Analysis by FOS Features

This study was carried out to investigate the influence and contribution of FOS characteristics on DKD prediction. To assess the performance of the classifiers, the accuracy, sensitivity, and specificity were determined using the tenfold cross-validation approach. Table 3 displays the classification parameters for each of the classifiers that were chosen.

Table 3 Average accuracy, sensitivity, and specificity for FOS features

Classifier	Kernel	Accuracy (%)	Sensitivity (%)				Specificity (%)			
			S_1	S_2	S_3	S_{AV}	SP_1	SP_2	SP_3	SP_{AV}
SVM	Fine Gaussian	94.0	87	99	97	94.3	98.1	91.8	92.5	94.1
	Cubic	72.2	67	77	70	71.3	80.3	69.2	73.5	74.3
KNN	Subspace	85.3	88	85	84	85.6	84.5	85.4	86.2	85.4
	Weighted	76.2	77	81	72	76.6	75.9	59.9	79.7	71.8
	Fine	79.0	88	85	73	82.0	78.6	75.3	83.4	79.1

Where S_1 Sensitivity for nondiabetic class, S_2 Sensitivity for class having diabetic but non-DKD, S_3 Sensitivity for DKD class, S_{AV} Average sensitivity, SP_1 Specificity for nondiabetic class, SP_2 Sensitivity for class having diabetic but non-DKD, SP_3 Specificity for DKD class, SP_{AV} Average specificity

Table 4 Average accuracy, sensitivity, and specificity for GLCM features

Classifier	Kernel	Accuracy (%)	Sensitivity (%)				Specificity (%)			
			S_1	S_2	S_3	S_{AV}	SP_1	SP_2	SP_3	SP_{AV}
SVM	Fine Gaussian	91.7	82	97	99	92.7	98.0	89.2	88.5	91.9
	Cubic	73.0	72	72	74	72.7	73.3	73.4	72.6	73.1
KNN	Subspace	78.6	78	86	73	79.0	78.7	75.0	82.4	78.7
	Weighted	76.6	82	73	78	77.7	75.3	79.0	75.8	76.7
	Fine	77.4	80	75	78	77.7	76.6	79.1	76.7	77.5

The SVM fine Gaussian classifier outperforms all other classifiers, with a 94.0% average accuracy. The average sensitivity and specificity were determined to be 94.3 and 94.1%, respectively. In comparison to other classifications, nondiabetic sensitivity is the lowest. Table 1 displays the greatest accuracy of the SVM classifier's fine Gaussian kernel.

Classifier's Performance Analysis by GLCM Features

GLCMs are second-order statistical characteristics that are produced based on the correlation between pairs of pixels in a certain direction. In this case, the first degree of correlation was used to indicate the correlation between nearby pixels. Table 4 provides the classifier performance analysis of GLCM features.

Classifier's Performance Analysis by GLRLM Features

GLRLM was calculated using the number of runs of a certain pixel in the specified direction. Second-order characteristics were also retrieved from the GLRLM. In this experiment, classifier performance is exclusively tested for the second-order

Table 5 Average accuracy, sensitivity, and specificity for GLRLM features

Classifier	Kernel	Accuracy (%)	Sensitivity (%)				Specificity (%)			
			S_1	S_2	S_3	S_{AV}	SP_1	SP_2	SP_3	SP_{AV}
SVM	Fine Gaussian	94.4	89	98	98	95.0	97.5	92.9	93.0	94.4
	Cubic	71.4	72	73	70	71.7	81.7	70.6	73.3	75.2
KNN	Subspace	84.1	84	86	83	84.3	84.0	83.1	85.3	84.1
	Weighted	77.4	85	78	74	79.0	75.8	76.8	80.1	77.7
	Fine	80.6	91	73	84	82.7	78.0	86.4	78.6	81.0

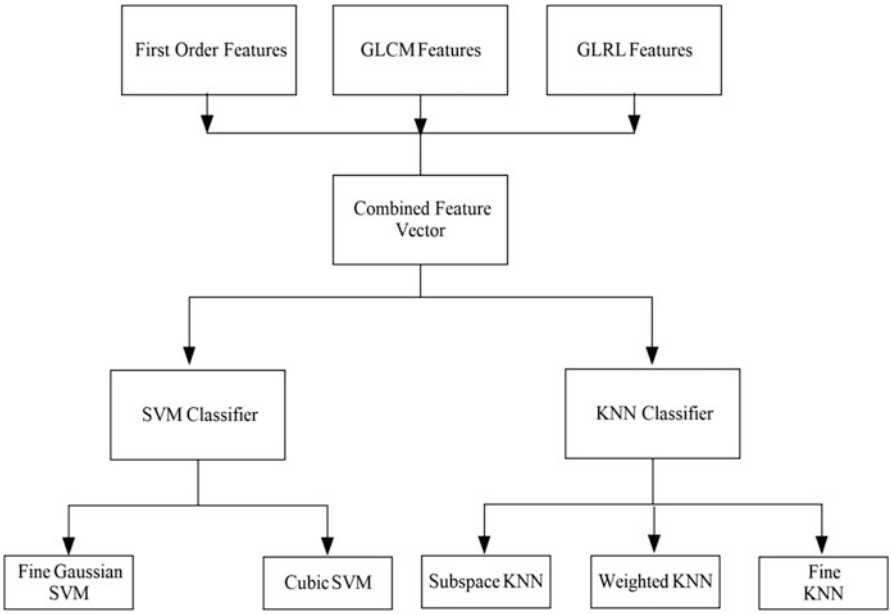

Fig. 4 Block diagram of the experiment designed for combined feature vector

GLRLM-based textural features. Table 5 displays the performance based on the GLRLM characteristics.

Classifier's Performance Analysis Using Combined Feature Vector

Figure 4 illustrated the complete FV that was built to include all of the retrieved characteristics, namely, FOS, GLCM, and GLRLM. In brief, 62 characteristics were retrieved for examination. Table 6 displays the classifier performance in terms of the total FV. Figure 4 depicts a flow diagram. Table 6 displays the greatest accuracy of the SVM classifier's fine Gaussian kernel.

Table 6 Average accuracy, sensitivity, and specificity using combined feature vector

Classifier	Kernel	Accuracy (%)	Sensitivity (%)				Specificity (%)			
			S_1	S_2	S_3	S_{AV}	SP_1	SP_2	SP_3	SP_{AV}
SVM	Fine Gaussian	94.5	86	100	100	95.3	100	91.7	94.2	95.3
	Cubic	81.7	81	83	81	81.7	81.1	81.1	82.3	81.5
KNN	Subspace	84.9	90	86	80	85.3	83.1	84.6	87.9	85.2
	Weighted	73.8	83	73	72	76.0	72.2	74.6	75.3	74.0
	Fine	83.3	87	83	81	83.7	82.3	83.3	84.6	83.4

Further analyses for all three classes for this classifier attain the average sensitivity and specificity as 95.3%. The individual class analysis shows for diabetic and DKD class 100% sensitivity, while for nondiabetic class, it shows 86% sensitivity. Also, the individual class analysis shows 100% specificity for the nondiabetic class.

Conclusion

The issues of diabetes prevalence, variables that contribute to diabetes development, and diabetes diagnosis utilizing the iris are explored. A thorough examination and analysis of the relevant literature concerning diabetes and its present situation throughout the world were carried out. The major focus of the second stage is the care of diabetic patients. The study conducted on a global scale, as well as that conducted on a regional scale, is examined. The procedure involves conducting research on the role of physiological parameters in diabetes and assessing published papers related to this topic. This chapter labels the machine learning backgrounds used to create an outperforming model for the rapid, simple, and early detection of DKD. A comparison of the statistical and textural characteristics' contributions (GLCM and GLRLM) was provided. The SVM and KNN classifiers were used for classification, and the results were compared. The suggested model produces great results and stimulates further investigation. These findings suggest that FOS traits are most suited for creating a DKD diagnostic system, while a combination of diverse textural features provides an extra benefit and high classification accuracy. Analyses demonstrate that an individual's diabetes and renal health status are related to statistical and textural aspects of particular parts of the iris.

Abstract

The global population nowadays is severely affected by various diseases of the soft tissue organs caused mainly because of some infection, heredity, change of lifestyle, etc. The timely detection and accurate diagnosis of these health conditions are of utmost importance in order to improve the chances of recovery and survival. Many medical imaging modalities have proven to effectively diagnose these diseases and their progression in a noninvasive way. Out of all the available modalities, ultrasound is the preferred mode of examination for imaging soft tissue organs for disease prediction because of its ease of use, low cost,

portability, and lack of ionizing radiation. The radiologists manually study these scans for making an accurate diagnosis of the underlying condition. However, ultrasound imaging is highly operator-dependent and its effectiveness is adversely affected because of the presence of speckle noise. Therefore, to overcome these issues and for an efficient disease diagnosis, different computer-aided diagnostic (CAD) systems have been developed by researchers using artificial intelligence techniques along with the metrological characteristics of the diseased part as visible on the ultrasound scan of the organ under study. The main purpose of the present chapter is to shed light on the different types of diseases that affect the soft tissue organs like kidney, liver, thyroid, breast and their sonographic appearances, and characteristics. The chapter further describes methodologies developed in recent existing literature (year 2017 onwards) for the classification of diseases using ultrasound images of these organs through a CAD system using state-of-the-art deep learning and machine learning methods. The chapter also gives an insight into designing an efficient CAD system for the classification of breast tumors. The authors in the chapter have used nonsubsampled contourlet transform (NSCT) for multiresolution analysis of the original tumor images. From the subimages obtained using NSCT, extraction of texture features has been carried out using gray level co-occurrence matrix (GLCM), whereas shape features have been computed from the preprocessed tumor images. The computed feature set (texture + shape) has been used for classifying breast tumors using an adaptive neuro-fuzzy classifier with linguistic hedges (ANFC-LH) classifier based on the optimal features selected on the basis of the hedge values associated with the fuzzy rules.

Introduction

Recent statistics and reports prepared by various organizations show that the diseases of the soft tissue organs like kidney, liver, spleen, breast, thyroid, pancreas have become very common among the people globally and are a major cause of concern. Some of the statistics are as follows: Chronic kidney disease (CKD) has been recognized as a major health risk and is estimated to affect around 37 million people in the United States (Centres for disease control and prevention 2021); over 1 lakh patients are diagnosed with end stage kidney disease in India per year (World kidney day 2019); in India, approximately 10 lakh patients have been diagnosed with liver cirrhosis every year due to lifestyle changes (TNN 2017), whereas nonalcoholic fatty liver disease has affected 25% of the global adult population (Cheemerla and Balakrishnan 2021); as per the report by American Thyroid Association, approximately 20 million people in the United States are affected by thyroid diseases (American thyroid association), and a report published in 2018 claimed that approximately 42 million Indians are affected by thyroid disorders mainly hypothyroidism (DTE Staff 2018); another health report has published that uterine cancer is the 4th most common form of cancer among women in the United States. It is

estimated that approximately 66,000 people will be diagnosed with uterine cancer in 2021 (Cancer.net 2021). According to a report by World Health Organization (WHO), 2.3 million women have been diagnosed with breast cancer globally in the year 2020 (World Health Organization 2021). As per the report given by Cytcare cancer hospitals, in India, breast cancer accounts for approximately 14% of the cancers in women in India, 1 in 28 Indian women is likely to develop breast cancer and it is more prevalent in the women living in urban areas as compared to rural areas (Cytcare cancer hospitals 2022).

As has been observed above, some of these statistics are alarmingly high and most of these diseases do not show any early symptoms; hence, timely detection of these major diseases of the soft tissue organs plays a vital role in efficient treatment planning and improving the recovery rate. Even though the prediction and diagnosis of diseases based on pathological tests remains to be a gold standard, this process is cumbersome and time consuming. In order to overcome this, various imaging modalities like x-rays, ultrasound, computed tomography (CT), magnetic resonance imaging (MRI) can be used to provide an accurate diagnosis of the abnormalities in a noninvasive manner at a preliminary stage. Out of all the available modalities, ultrasound has found use prominently in disease detection and diagnosis because of its associated advantages such as lack of radiation, low cost, portability. Ultrasound imaging includes the transmission of sound waves greater than 20 kHz into the body for the purpose of capturing the live images of the internal organs. Ultrasound imaging modality has been prevalently used for visualizing vessels, organs, and soft tissues in real time without the use of radiations. The image formation takes place on the basis of the reflection of waves from internal body structures. The time taken by sound waves to travel through the body and the amplitude of the wave provides the basic information for image formation. The most common organs to be visualized by an ultrasound are ocular structures, liver, bladder, spleen, kidney, uterus, pancreas, carotid artery, breast, thyroid, fetal heartbeat, etc. The commonly occurring diseases of the soft tissue organs as seen on ultrasound have briefly been described below.

Kidney Diseases

The kidneys in the human body are used for filtering the blood and removing excessive waste and toxins out of the body. The nephrons present in the kidney are affected by the diseases and get damaged, which leads to failure in the kidney function. The most common kidney diseases encountered are renal cysts, chronic kidney diseases (with different stages of severity), and renal cell carcinoma. Renal cysts are most commonly found simple fluid-filled sacs having thin walls. Some cysts further develop to become complex with thick walls and some solid components along with the fluid (Johnson 2018). The formed cysts compress the nephrons or sometimes result in kidney enlargement affecting the renal function, ultimately leading to kidney failure if left untreated (Sudharson and Kokil 2019). Chronic kidney disease means kidney damage over time leading to end stage renal disease

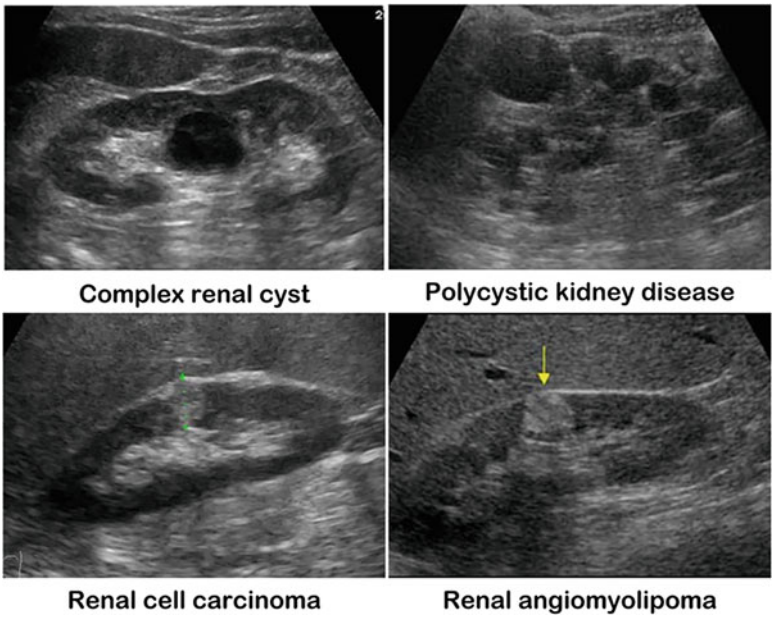

Fig. 1 The sample images of different kidney diseases as seen on ultrasound (Geertsma 2014d)

wherein the kidneys lose their ability to filter out the blood (American kidney fund 2021; Johnson 2018). The diseases of the kidney parenchyma that cannot be precisely determined are called medical renal diseases (MRD), characterized by nonspecific changes in the echotexture of the renal parenchyma which can be determined by ultrasound-guided biopsy (Johnson 2018). Renal cell carcinomas are primary malignant kidney tumors with four grades of severity (grade I to grade IV). These tumors are varying in appearance from solid and homogeneous to cystic changes and heterogeneous. Renal angiomyolipomas (AMLs) are solid tumors composed mainly of adipose tissue. These appear hyperechoic on an ultrasound as compared to surrounding kidney parenchyma. Different kidney diseases as visible on an ultrasound are shown in Fig. 1.

Liver Diseases

The liver is the largest and most vital organ in the human body as it helps in digestion and carrying out various metabolic activities of the body. Broadly there are two types of liver diseases viz focal and diffuse liver diseases. The focal liver diseases affect a small region of the liver parenchyma, whereas in case of diffuse liver diseases, the whole liver parenchyma is affected (Brown 2020; Virmani et al. 2013, 2014). The focal and diffuse liver diseases can further be subcategorized as shown in Fig. 2.

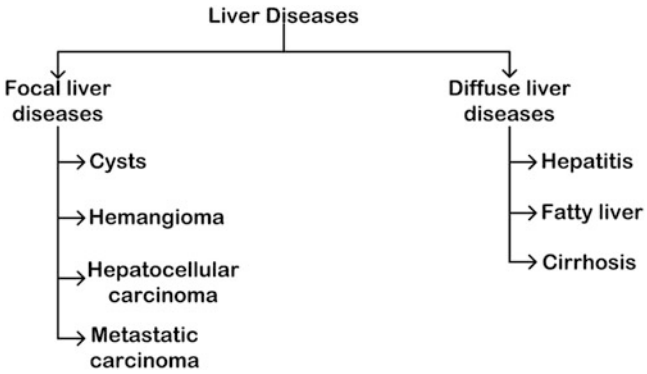

Fig. 2 Different types of liver diseases

Simple liver cysts are thin walled and filled with fluid or solid components and are generally benign. Hemangioma (HEM) is a benign mass formed in the liver due to entanglement of blood vessels and appears as a homogeneous, well-defined solitary mass. Hepatocellular carcinoma (HCC) is a primary malignant liver condition characterized by scarring of liver parenchyma and fibrosis and is considered to be the end stage of liver cirrhosis. Metastatic carcinoma is a secondary malignant liver condition caused due to cancerous cells spreading to the liver from other parts of the body (Virmani et al. 2014).

Hepatitis means inflammation or swelling of the liver due to some infection. Under normal operation of the liver, swelling occurs to fight off any infection, that is, controlled inflammation. However, when this inflammation gets unregulated, infection gets progressed into a disease called hepatitis. Persistent and uncontrolled inflammation leads to deposition of collagen on the liver parenchyma, which gets stiff and replaces healthy cells of the liver leading to fibrosis. Fatty liver disease is characterized by accumulation of fat in place of normal liver tissue, which causes scarring and inflammation leading to fibrosis and ultimately cirrhosis if left untreated as this scar tissue cuts off the blood supply to the liver thus damaging the healthy cells. Liver cirrhosis is an irreversible damage to the liver tissue because of gradual scarring of liver tissue due to inflammation that is caused by hepatitis, alcohol consumption, and progression of fatty liver disease (Virmani et al. 2013). The basic stages of liver disease are summarized as: Hepatitis/fatty liver resulting in fat accumulation around liver leading to swelling. From here the disease progresses to liver fibrosis in which the cells of the liver harden and liver swells further. The next stage here on is cirrhosis in which the liver cells get severely scarred. After this stage if no treatment is taken, the disease progresses into liver cancer ultimately leading to liver failure. The sample images of different liver diseases as seen on ultrasound are presented in Fig. 3.

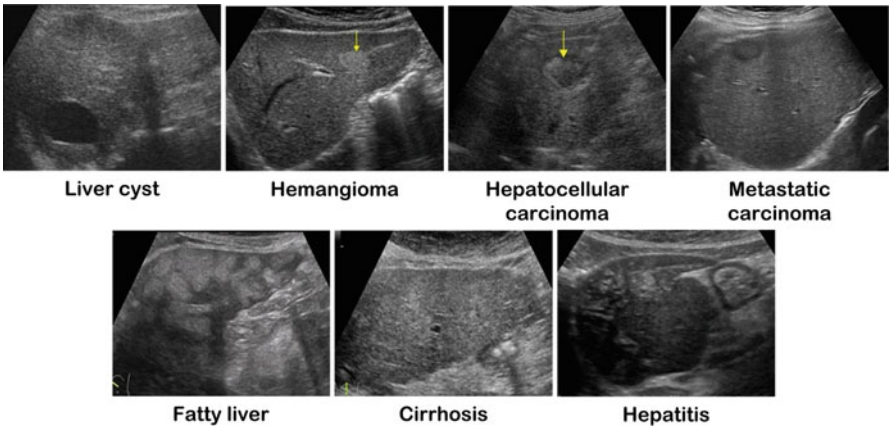

Fig. 3 The sample images of different liver diseases as seen on ultrasound (Geertsma 2014a)

Thyroid Diseases

Thyroid is one of the hormone-forming glands of the human body to control the rate of many metabolic activities. Thyroid diseases prevent the thyroid from generating right amount of hormones required for proper functioning of the body. Most common thyroid diseases are hyperthyroidism (too much hormones), hypothyroidism (not enough hormones), formation of thyroid nodules, and diffused thyroid diseases like multinodular goiter, Hashimoto's thyroiditis, Graves' disease (Chaudhary and Bano 2013; Cleveland clinic 2020; Wallace 2018). Thyroid nodules are solid or fluid-filled lumps with varying echogenicity growing unusually on the thyroid gland.

These nodules can be cancerous or noncancerous and are graded on the basis of Thyroid Imaging Reporting and Data Systems (TI-RADS) into benign, probably benign, borderline, suspiciously malignant, and malignant classes (Pedraza et al. 2015). Malignant thyroid nodules if go unnoticed or left untreated can lead to thyroid cancer. In diffused thyroid diseases, the echogenicity can increase or decrease with coarse texture and lobulated margins. Goitre is the enlargement of the thyroid gland and is mostly benign in nature. It is caused often by hypothyroidism due to deficiency of iodine. Thyroiditis is the swelling of thyroid leading to over or under production of hormones and occurs in cases when body's immune system produces antibodies that attack the thyroid. Hashimoto's thyroiditis leads to hypothyroidism and is prevalent in middle-aged women. Graves' disease occurs predominantly in females leading to glandular enlargement and hyperthyroidism. In Graves' disease, there is an increased blood flow in the thyroid leading to decrease in echogenicity and scalloped margins (Alexander et al. 2020). The sample images of different thyroid diseases as seen on ultrasound are shown in Fig. 4.

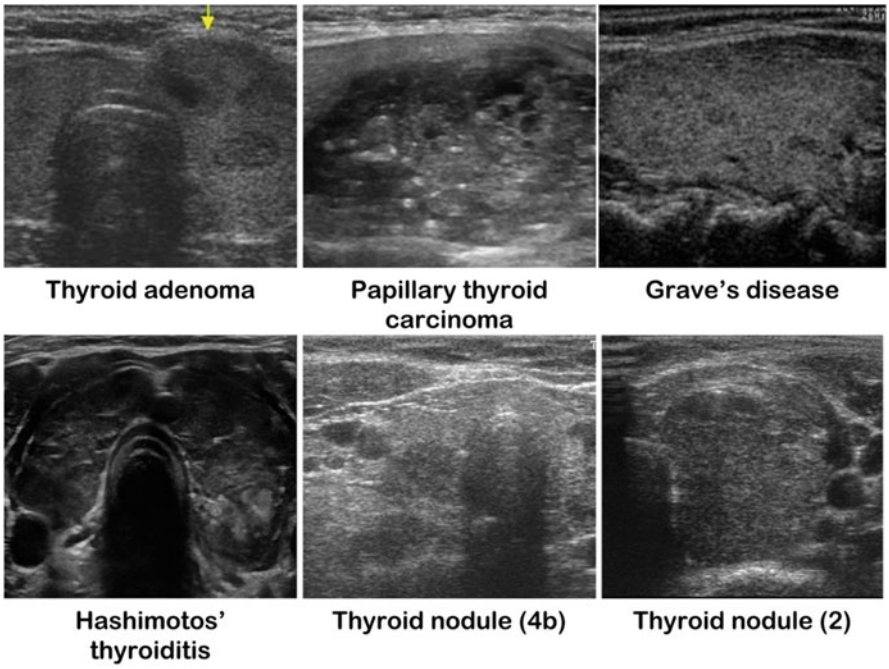

Fig. 4 The sample images of different thyroid diseases as seen on ultrasound (Geertsma 2014c; Pedraza et al. 2015)

Breast Diseases

Breast diseases develop in the breast tissue or milk-carrying ducts. The most common disease of the breast tissue is the development of a tumor that can be broadly classified as (i) noncancerous (benign) and (ii) cancerous (malignant). The benign tumors are considered to be noncancerous as these tumor cells do not spread and grow to other body parts, have a slower growth rate, and are more differentiable. The malignant tumors are considered to be cancerous and can also invade other healthy tissues in the body through the bloodstream (Gokhale 2009). The sample images of subcategories of different breast tumors as seen on ultrasound are shown in Fig. 5.

Breast cysts are firm circular lumps filled with fluid or solid debris. Generally, cysts have a thin, regular border, but due to the presence of solid components, cysts sometimes can have thick walls with irregular margins. Lipomas generally occur in women aged between 40 and 60 years. These are well-circumscribed masses having fat as the major component. Fibroadenomas occur in younger women. These are hard, solid masses having a well-defined shape. Intraductal papillomas are wart like tumors growing within the milk ducts and having a well-defined shape.

Breast carcinomas occur in epithelial tissues of the breast having higher rate of incidence. These are ill-defined masses having irregular contours and varying

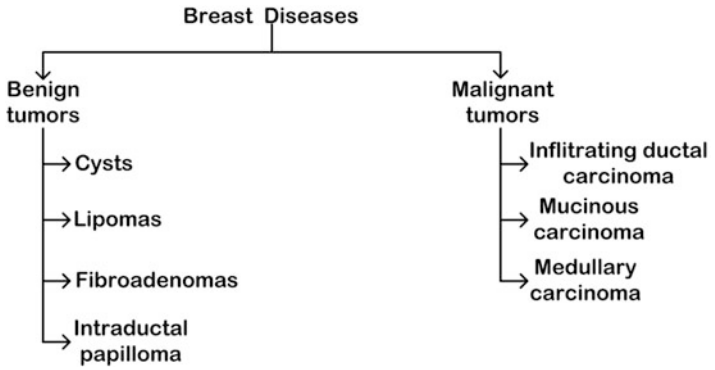

Fig. 5 Different breast diseases

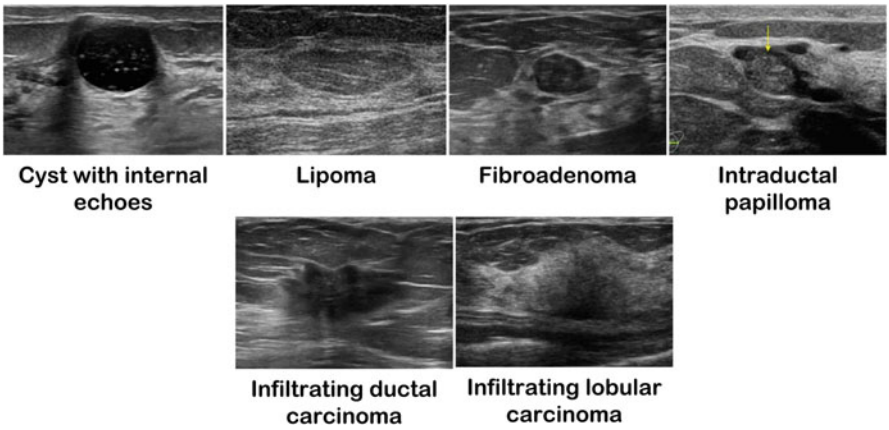

Fig. 6 The sample images of different breast diseases as seen on ultrasound (Geertsma 2014b)

echogenicity (Gokhale 2009; Medline plus 2022). Lobular carcinomas occur in the breast lobules, whereas ductal carcinoma is found in the cells lining the ducts of the breast. The sample images of different breast tumors as seen on ultrasound are presented in Fig. 6.

Other breast diseases occurring in women are as follows: hyperplasia, a medical condition affecting the breasts wherein there are a large number of abnormal-looking cells present in the breasts. Depending upon whether these cells are found in the lobules or the milk ducts of the breasts, the conditions are named atypical lobular hyperplasia and atypical ductal hyperplasia, respectively. Women diagnosed with hyperplasia have a higher risk of developing breast cancer. Fat necrosis is a breast condition that causes round, firm, painless lumps in the breast tissue caused due to any injury or radiation therapy. Breast fibrosis is a common condition causing lumpy breasts and is common in women below 45 years of age. Adenosis is a scar-like

fibrous tissue present in the glands of the breast that can elevate the risk of breast cancer among women manifolds (National Cancer Institute 2019).

Need of CAD Systems for Disease Diagnosis Using Ultrasound Images

For the advancement in disease diagnosis and efficient treatment, an accurate measurement of visual and nonvisual metrological characteristics from the images such as texture, size, and shape is very critical (Patel and Matcuk Jr. 2018). Different imaging techniques like X-rays, ultrasound, MRI, CT, thermography have widely been used for screening of different diseases. Even though the gold standard for disease diagnosis is pathologic staging, the treatment options and management of the diseases are frequently based on imaging and physical examination (Patel and Matcuk Jr. 2018).

Distinct modalities have their own advantages and disadvantages associated with them for measuring different metrological characteristics of the diseases according to past studies conducted by researchers, *for example*, in the case of breast cancer diagnosis, it has been observed that calcifications are better detected using mammography (X-ray images); however, in case of high-density breast tissue, mammography has shown poor detection results of the underlying abnormality. For this case, ultrasound modality is preferred to overcome the density effect and detect the abnormalities of the breast. Accurate measurement of tumor size in multiple planes is also possible with the help of ultrasound. Still, the accurate measurement is highly dependent on the operator's experience and the presence of artifacts also limits the diagnostic accuracy (Davis et al. 1996; Gruber et al. 2013). It is worth mentioning that the type of tumor also affects the accuracy of tumor size measurement and diagnosis, *for example*, malignant tumors have irregular margins and are diffused between collagen fibers, and it is difficult to accurately determine the shape and size information. The formation of ultrasound images includes the transmission of sound waves greater than 20 kHz into the body for capturing the live images of the organs such as the breast, kidney, liver, thyroid and the structures such as joints, tendons, muscles. Ultrasound imaging modality is the first line of treatment in the diagnosis of most of the diseases of soft tissue organs due to ease of use, availability, and zero exposure to harmful radiation. However, the drawback in the use of ultrasound imaging is that it is highly operator dependent and is affected by the presence of speckle noise that masks the important features in images that may be helpful in the diagnosis. This makes it hard for radiologists to clearly predict the disease and its progression. Based upon the points mentioned above, computer-aided diagnostic (CAD) systems have attracted immense attention from the research community to overcome the difficulties in the use of ultrasound imaging for disease prediction by paving a way for removing the effect of noise and artifacts and extracting the underlying learnable features from the ultrasound scans. It is also worth mentioning that these algorithms bring attention to the suspicious areas in the image to decrease the false-negative cases. The CAD systems try to search for the same information in

the images as a radiologist does while manually studying the scans and tries to quantify that information in terms of texture and shape features to achieve high accuracy in diagnosis. Thus, a novel CAD system design can act as a helping tool for the radiologists in gaining confidence in their diagnosis for efficiently classifying the different classes of diseases of the soft tissue organs.

The performance of the CAD systems can be quantified by using the confusion matrix technique that provides information about the true negative, true positive, false negative, and false-positive cases in the dataset depending upon which the parameters of the algorithms can be fine-tuned to decrease the detection of false positives thereby increasing the accuracy of prediction. The confusion matrix can also be used to quantify the accuracy, sensitivity, specificity, recall, and precision of the CAD system along with the AUC-ROC curves.

Based upon the associated advantages of CAD systems for disease prediction and monitoring, a huge amount of interest has been developed in the research community to design various CAD systems based on machine learning and deep learning techniques for the prediction of diseases as seen on ultrasound images of different soft tissue organs.

Further, the chapter has been divided into the following sections: Section "CAD System Designs for Disease Prediction Using Ultrasound Images of Soft Tissue Organs" outlines the different CAD system designs developed by researchers in the recent past for disease prediction using ultrasound images of organs like kidney, liver, thyroid, and breast. Section "Sample Demonstration" describes the methodology adopted by the authors in the present chapter to design a CAD system for breast tumor classification based upon the conclusions drawn in section "CAD System Designs for Disease Prediction Using Ultrasound Images of Soft Tissue Organs." Section "Sample Demonstration" presents the detailed result analysis of the proposed CAD system design and section "Conclusion and Future Scope" presents the conclusion of the chapter.

CAD System Designs for Disease Prediction Using Ultrasound Images of Soft Tissue Organs

This section presents the different CAD systems designed by various researches over the previous years (starting from 2017 to till date) for classification of diseases affecting the kidneys, thyroid, liver, and breast using ultrasound images.

CAD System Designs for Prediction of Kidney Diseases

A brief description of recent CAD systems designed for disease prediction of kidneys using ultrasound images is given in Table 1.

Table 1 describes in detail the studies carried out for the classification of different kidney diseases using artificial intelligence techniques applied to the ultrasound images. It can be observed from the table that most of the studies have been carried

out by using machine learning techniques, while very few studies have utilized deep learning architectures for kidney disease classification. Another point worth noting is that most of the studies have used preprocessed images for analysis.

Mangayarkarasi and Jamal (2017) used median and Gaussian filters for preprocessing 77 kidney ultrasound images. From the preprocessed images, first-order statistics (FOS)-based texture features have been computed, which were fed to probabilistic neural network (PNN) classifier for categorization of images into normal, cyst, calculi, and tumor classes achieving an accuracy of 93.5%. The study by Raju et al. (2018) proposed a CAD system to classify kidney ultrasound images into normal and abnormal classes. From the images Gray level co-occurrence matrix (GLCM), texture features have been computed which were further fed to probabilistic principal component analysis (PPCA) for finding optimal attributes. An accuracy of 98.4% has been reported using feed-forward back propagation neural network (FFNN), whose layers and neurons have been optimized using the gray wolf optimization (GWO) method. The highest accuracy of 99.7% has been reported by Acharya et al. (2019), for classifying the kidney ultrasound images into normal and CKD stages by computing texture feature using cumulants bispectrum and elongated quinary patterns (EQP)-based methods with support vector machine (SVM) classifier. The optimal feature set was computed using locally sensitive discriminant analysis (LSDA), and the ultrasound images were preprocessed using adaptive histogram equalization (AHE). Chen et al. (2019) proposed a methodology to classify kidney ultrasound images into different stages of CKD using GLCM texture features and SVM classifier. Hao et al. (2019) reported the use of a texture branch network model for differentiation between different CKD stages. The proposed model used the amalgamation of deep features extracted using ResNet-34 model with GLCM and histogram of oriented gradients (HOG) features reporting an accuracy of 96.0%. Nithya et al. (2019) in their study used 100 kidney ultrasound images for classification into normal, tumor, and stone classes. All the images have been preprocessed using median filter. From the filtered images, GLCM texture features have been computed, which were subjected to the crow-search optimization algorithm (CSA) for finding the optimal number of features. The study reported an accuracy of 93.4% using artificial neural network (ANN) classifier based on the computed optimal feature set. In a study carried out by Sudharson and Kokil (2020), the kidney images have been categorized into four classes: normal, cyst, stone, and tumor based on an ensemble of deep learning models ResNet101, ShuffleNet, and MobileNet-v2 using majority voting. The study reported an accuracy of 96.5%. In yet another study by Sudharson and Kokil (2019), deep features were extracted from AlexNet and fed to multiple support vector machine (MSVM) classifier to classify 100 kidney ultrasound images into normal and abnormal classes reporting an accuracy of 89.5%. Ahmad and Mohanty (2021) in their study utilized ultrasound images processed by median filter for calculation of GLCM texture features, which were fed to SVM classifier for classifying the stages of CKD, achieving an accuracy of 97.4%. Kim and Ye (2021) used histogram equalization (HE) in their study to preprocess the kidney ultrasound images. From the enhanced images, GLCM features have been computed and fed to artificial neural network (ANN) classifier

for categorizing the CKD stages into normal, mild, moderate, and severe classes achieving an overall accuracy of 95.4%.

Out of the total 11 recent studies selected in the time range (2017 onwards) for CAD systems designed for kidney ultrasound images, it has been observed that approximately 82% (8 out of 11) of studies have been carried out by using machine learning methods, while only 18% (2 out of 11) of the studies have used deep learning methods.

CAD System Designs for Prediction of Liver Diseases

A brief description of recent CAD systems designed for disease prediction of liver using ultrasound images is given in Table 2.

Table 2 presents the studies carried out for classification of liver diseases using ultrasound images. It is seen that a number of attempts have been made to design both machine learning and deep learning-based CAD systems. It can also be noted that most of the studies have used original ultrasound images for processing, while only two studies report the use of preprocessing methods for enhancing the image quality. Acharya et al. (2016) proposed a CAD system for differentiating between normal and fatty liver classes using GIST descriptors. The features were then optimized using marginal fisher analysis (MFA) and Wilcoxon test and fed to PNN classifier, reporting an accuracy of 98.0%. Hassan et al. (2017) preprocessed the liver images using anisotropic diffusion (AD) filter and classified the images into cyst, hemangioma (HEM), and hepatocellular carcinoma (HCC) classes using stacked sparse autoencoder (SSAE) reporting an accuracy of 97.2%. Bharti et al. (2018) developed a method to classify liver ultrasound images into four classes, namely, normal, chronic liver disease (CLD), hepatocellular carcinoma (HCC), and cirrhosis. The authors computed different texture features using Ranklet, gray level difference matrix (GLDM) and GLCM, and convolutional neural network (CNN). Optimal handcrafted features have been computed using RelieF algorithm and sequential feature selection (SFS), which were then combined with deep features and feed to an ensemble model of classifiers, namely, k-nearest neighbor (kNN), SVM, RF-kNN. The study reported an accuracy of 96.6%. Reddy et al. (2018a) in their study proposed a method using VGG-16 network for classification of normal and fatty liver disease (FLD), reporting an accuracy of 90.6%. In another study, Reddy et al. (2018b) proposed a self-designed deep CNN for classification of liver images into different stages of the fatty FLDs reporting an accuracy of 93.4%. The authors Sharma and Juglan (2018) in their study computed texture features from seven different models, namely, SGLCM, FOS, GLDS, SFM, Laws' texture energy measures, Fourier power spectrum (FPS), and Fractal for classification of liver images into normal and fatty classes. The optimal features have been computed using mutual information (MI). The authors have used four different classifiers SVM, IBk, AdaBoostM1, and BF Tree, reporting highest classification accuracy of 95.5% using SVM. Acharya et al. (2018) proposed a machine learning-based CAD system using features computed by bi-dimensional empirical mode decomposition and kNN classifier. The images have been preprocessed using

Note: *MFA* marginal fisher analysis, *PNN* probabilistic neural network, *Ac*. accuracy, *HEM* hemangioma, *HCC* hepatocellular carcinoma, *AD* anisotropic diffusion, *SSAE* stacked sparse autoencoder, *CLD* chronic liver disease, *SFS* sequential feature selection, *FLD* fatty liver disease, *MI* mutual information, *SVM* support vector machine, *B* benign, *m* malignant, *CLAHE* contrast limited adaptive histogram equalization, *PSO* particle swarm optimization, *PCA* principal component analysis, *kNN* k-nearest neighbor, *MGLCM* multi-scale gray-level co-occurrence matrix, *WMCM* wavelet multi sub-band co-occurrence matrix, *GLCM* gray level co-occurrence matrix, *GLRLM* gray level run length matrix

contrast limited adaptive histogram equalization (CLAHE) for classification into normal, benign, and malignant classes. Amin et al. (2019) in their study used frequency domain method-based texture feature extraction using wavelet packet transform. From the decomposed images, different texture features, namely, FOS, GLCM, and Local binary pattern (LBP), were computed and fed to PCA for computing optimal attributes. These attributes were fed to different classifiers like kNN, SVM, and LDA, reporting an accuracy of 91.8% using kNN classifier. Dandan et al. (2019) proposed a method to classify liver images into normal, fatty, and fibrosis classes using multiscale gray-level co-occurrence matrix (MGLCM) and wavelet multilevel subband co-occurrence matrix (WMCM) and deep features based on GoogLeNet. The features were fed to lightGBM achieving an accuracy of 82.6%. Xu et al. (2019) in their study proposed a CAD system for classification of liver cancer, that is, HCC and abscess using GLCM and GLRLM texture features. Optimal features were computed using SFS and fed to SVM classifier, achieving an accuracy of 89.2%. Krishnamurthy et al. (2020) proposed a method based on multilevel and multidomain features for classification of different liver disorders. The images were segmented by authors based on iso-contour segmentation. Different fractal and wavelet-based features were computed from the segmented ROIs and optimal features have been decided by using particle swarm optimization (PSO) algorithm. An ensemble of different classifiers was then used for differentiating between focal and diffuse liver diseases achieving an accuracy of 91.0%. Pasyar et al. (2021) used a hybrid ResNet-50 deep neural network for classification of liver ultrasound into normal, hepatitis, and cirrhosis classes achieving an accuracy of 84.0%.

Out of the total 12 recent studies selected in the time range (2016 onwards) for CAD systems designed for liver ultrasound images, it has been observed that approximately 67% (8 out of 12) of studies have been carried out by using machine learning methods, while only 33% (4 out of 12) of the studies have used deep learning methods.

CAD System Designs for Prediction of Thyroid Diseases

A brief description of recent CAD systems designed for disease prediction of the thyroid using ultrasound images is given in Table 3.

Table 3 presents the different studies carried out for classification of thyroid diseases using ultrasound images. It is observed that most of the investigators have used deep learning-based techniques, while very few studies have reported the use of machine learning-based methods. Also only one study has reported the use of enhancement methods for preprocessing the images. In the study by Chi et al. (2017), the authors designed a hybrid system for classifying benign and malignant thyroid nodules using deep features extracted from GoogLeNet which were further fed to a cost sensitive random forest (CS-RF) classifier achieving an accuracy of 99.1%. The authors Ma et al. (2017) in their study designed and trained two deep CNNs and fused the deep features from these networks using a summation layer. The

fused features were further fed to softmax classification layer for differentiation between benign and malignant thyroid nodules achieving an accuracy of 83.0%. Wang et al. (2017) in their study proposed a method to classify thyroid nodules based on TIRADS standard. The authors combined different texture and shape features computed from ultrasound images and fed them to a semi-supervised fuzzy C-means ensemble (SS-CME) model for classification achieving an accuracy of 77.07%. Zhu et al. (2017) proposed a deep learning approach for classification of thyroid nodules into benign and malignant classes using ResNet-18 network achieving an accuracy of 93.7%. Moussa et al. (2018) used ResNet-50 network to classify thyroid nodules into benign and malignant classes, achieving an accuracy of 97.3%. It can be noted that one study has been reported to use preprocessed thyroid images for classification purposes (Raghavendra et al. 2018). In this study, the authors have adjusted the contrast of the images in the first step and used multilevel elongated quinary patterns to represent the thyroid ultrasound images. From these images, higher order spectral (HOS) entropy features were extracted and an optimal feature set was obtained using particle swarm optimization (PSO). The SVM classifier was used for the classification of thyroid nodules into benign and malignant classes using a public and private dataset obtaining an accuracy of 97.7% and 97.0%, respectively. Liu et al. (2019) used a multibranch CNN for classification of thyroid nodules into benign and malignant classes. The authors also proposed a detection network prior to the classification phase based on pyramidal features and region proposals. The detection-classification network was tested on two different datasets achieving an accuracy of 97.1% and 94.9%, respectively. In the study by Ataide et al. (2020), shape features have been used to differentiate between benign and malignant thyroid nodules with random forest (RF) classifier reporting an accuracy of 99.3%. Nguyen et al. (2020) proposed an ensemble-based deep network model for classification of thyroid nodules. The thyroid ultrasound images were preprocessed for background extraction and then the detected nodules were fed to ResNet and Inception-based deep networks for classification of thyroid nodules into benign and malignant classes. The results of both the classifiers were then combined using different voting schemes like MIN, MAX, and SUM. Highest accuracy of 92.05% has been achieved using the MAX rule. Song et al. (2020) proposed a hybrid feature cropping CNN approach for the classification of thyroid nodules into benign and malignant classes. The proposed deep architecture has two branches: global branch for extracting global features and a feature cropping branch for processing the feature information in ultrasound images. The proposed technique achieved an accuracy of 96.1%.

Out of the total 10 recent studies selected in the time range (2017 onwards) for CAD systems designed for thyroid ultrasound images, it has been observed that approximately 30% (3 out of 10) of studies have been carried out by using machine learning methods, 60% (6 out of 10) of the studies have used deep learning methods, while only 10% of the studies (1 out of 10) have used a hybrid of both deep learning and machine learning methods.

CAD System Designs for Prediction of Breast Diseases

A brief description of recent CAD systems designed for disease prediction of the breasts using ultrasound images is given in Table 4.

Table 4 presents the studies carried out for the classification of breast tumors using ultrasound images. It was observed that most of the studies have used machine learning-based techniques as opposed to deep learning-based architectures for classification purposes. It can also be noted that almost all the studies have used preprocessing methods for enhancing the image quality before further processing. Rodriguez-Cristerna et al. (2017) proposed a technique for classification of breast tumors into benign and malignant classes. The authors used different contrast enhancement and speckle reduction techniques for finding out optimal methods for preprocessing to get efficient classification accuracy. From the preprocessed images, tumor regions have been segmented using watershed transform. Different texture features (like autocorrelation, GLCM and Laws' energy features) and shape features have been computed from the segmented tumor images and fed to Fischer linear discriminant analysis (FLDA) classifier reporting an accuracy of 84.0%. The authors also concluded that Fuzzy enhancement (FEN) followed by inference-based speckle filtering (ISF) produced better quality images for efficient classification performance. The author Singh et al. (2017) in their study reported the use of a hybrid feature selection technique for the classification of benign and malignant breast tumors. The ultrasound images were first preprocessed with a wavelet-based filter. From the filtered images different texture features (FOS, GLCM, GLRLM, Neighborhood gray tone difference (NGTD), statistical feature matrix (SFM), Laws' features, fractal-based features, Spectral features) and shape features have been computed. The computed features were then fed to different feature selection techniques. To determine the relevance of features, a new feature ranking method based on multiple criteria has been proposed. The relevant features were then fed to back propagation artificial neural network (BPANN) and SVM classifiers, reporting a highest classification accuracy of 96.6% using BPANN classifier. Moon et al. (2018) presented an approach to differentiate between metastatic and nonmetastatic malignant tumors. The images have been preprocessed using sigmoid and gradient-based filters and segmented using Level set method. From the segmented tumor images, different texture- and shape-based features have been computed out of which optimum features have been computed using backward feature selection, and an accuracy of 75.1% has been reported using logistic regression (LR) classifier. Nemat et al. (2018) in their study proposed a texture feature extraction method based upon transform domain methods. The authors have used CLAHE for preprocessing the images. From the preprocessed images, tumor regions have been segmented using the combination of manual and computerized techniques. Using the segmented tumor image, texture features based on Gabor transform and shape features have been computed. Optimal features have been computed using Bayesian automatic relevance detection (BARD), which were further fed to sparse logistic regression (SLR) achieving an accuracy of 97.1%. Highest accuracy of 99.3% has been reported by Uzunhisarcikli and Goreke (2018), using images preprocessed by

Gaussian filter and CLAHE. From the preprocessed images, GLCM texture features and shape features have been computed and fed to adaptive neuro fuzzy inference system (ANFIS) classifier. Fujioka et al. (2019) used the fine-tuned GoogLeNet deep learning network for the classification of breast tumors into benign and malignant classes reporting an accuracy of 92.5%. Gonzalez-Luna et al. (2019) presented a comparative study for the classification of benign and malignant tumors using different machine learning techniques. From the images different texture features like GLCM, auto-mutual information-based features and shape features have been computed and fed to seven different classifiers, namely, SVM, kNN, radial basis function network (RBFN), LDA, Multinomial logistic regression (MLR), RF, Adaboost. The study reported the highest accuracy of 89.0% using LDA classifier. The authors have also proposed two CAD system designs in their previous works: one based on machine learning techniques (Kriti et al. 2019) and other a hybrid CAD system using deep features fed to conventional machine learning classifier (Kriti et al. 2020). In both the studies by the authors, detail preserving anisotropic diffusion filter (DPAD) has been used to preprocess the images and the tumor regions have been segmented out using Chan-Vese active contour method (Chan and Vese 2001). In the work Kriti et al. (2019), different texture features, namely, FOS, GLCM, GLRLM, Fourier power spectrum (FPS), Laws' TEM, and 2D Gabor wavelet transform-based features, were computed and combined with shape features. Optimum attributes were computed using PCA and these attributes were then fed to SVM classifier achieving an accuracy of 96.6%. In the other study, Kriti et al. (2020), deep features were extracted using GoogLeNet deep network and the optimal features were computed by using correlation-based feature selection (CrFS) and a wrapper-based method adaptive neuro-fuzzy classifier using linguistic hedges (ANFC-LH). The selected optimum features were fed to ANFC achieving an accuracy of 98.0%. Mishra et al. (2021) in their study proposed a pipeline for differentiation between benign and malignant tumors. Different texture features, namely, HOG, Hu moments, GLCM features, and shape-based features, have been extracted from each segmented tumor image. Out of the extracted features, optimum features have been selected based on recursive feature elimination (RFE). After this, SMOTE oversampling technique has been applied to deal with the imbalanced data. The resultant feature set is then fed to different machine learning-based classifiers, namely, RF, gradient boosting classifier (GBC), AdaBoost classifier, SVM, LR, and decision tree. The highest accuracy of 97.4% has been reported using AdaBoost classifier. Shia et al. (2021) in their study proposed an unsupervised approach for the classification of breast tumors. From the images, a pyramid histogram of oriented gradients (PHOG)-based texture features have been computed to capture efficient edge description in the images. The optimal feature set has then been computed CFS and classification has been carried out using locally weighted learning (LWL) + sequential minimal optimization (SMO) achieving an area under the curve (AUC) of 0.847.

Out of the total 11 recent studies selected in the time range (2017 onwards) for CAD systems designed for breast ultrasound images, it has been observed that approximately 82% (9 out of 11) of studies have been carried out by using machine

learning methods, 9% (1 out of 11) of the studies have used deep learning methods, while 9% (1 out of 11) of the studies have used a hybrid of deep learning and machine learning methods.

According to all the studies presented in Tables 1, 2, 3, and 4, it has been observed that the majority of CAD systems designed for disease classification in ultrasound images of soft tissue organs have used texture descriptors computed in the time domain for the classification task, while very few studies have used transform domain-based texture feature extraction methods (Krishnamurthy et al. 2020; Nemat et al. 2018). Thus, to demonstrate this, an attempt has been made as an example in the present chapter to test the efficacy of transform domain-based texture features for the classification of breast tumors. The texture features were generated in the current work utilizing a transform domain-based method called nonsubsampled contourlet transform (NSCT).

Sample Demonstration

The present chapter explains the basic process of designing a CAD system for classifying breast tumors into benign and malignant classes using adaptive neuro fuzzy classifier (ANFC) based on texture features computed in transform domain amalgamated with shape features. It was validated in authors' previous work that shape and size characteristics of tumors were better represented by using pre-processed images while texture was better quantified from raw images (Kriti et al. 2019). The work was aimed at making the breast tumor classification as efficient as possible by using a combination of the essential features extracted from the original as well as preprocessed images. Therefore, a similar approach has been used in the present chapter also. The workflow adopted in the example is shown in Fig. 7.

The exemplary CAD system design in the present chapter made use of 100 breast ultrasound images which include 40 benign and 60 malignant images that were selected from an openly available, standardized benchmark database of ultrasound images (Geertsma 2014b). These images have been methodically selected to include representative cases of each class from the database. The images contained in the dataset have solitary as well as multiple tumors.

As can be seen from Fig. 7, the images have been preprocessed using the DPAD filter. The DPAD filter belongs to a class of nonlinear iterative filters used to implement the anisotropic diffusion technique used for the removal of multiplicative noise from the images (Aja-Fernandez and Alberola Lopez 2006). Both the original and preprocessed images have been segmented using the Chan-Vese active contour method to obtain the tumor images. This method has been designed to segment the medical images that prove to be a little difficult to segment based on traditional methods of segmentation like thresholding. This method has been formulated as an energy minimization problem. Out of a total of 40 benign images, 43 tumor images have been segmented out, and out of a total 60 malignant images, 61 tumor images have been segmented out. Original segmented tumor images have been subjected to NSCT for multiresolution decomposition, and from the resulting subband images,

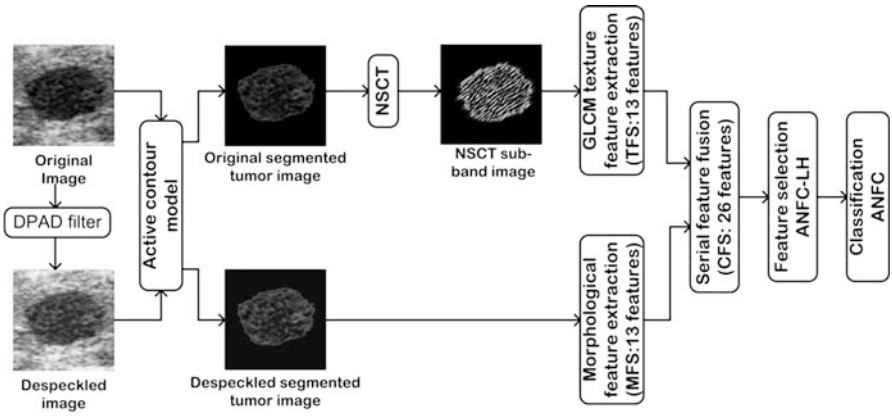

Fig. 7 Workflow adopted to design the NSCT-based CAD system. Note: *DPAD* detail preserving anisotropic diffusion, *NSCT* non subsampled contourlet transform, *GLCM* gray level co-occurrence matrix, *TFS* texture feature set, *MFS* morphological feature set, *CFS* combined feature set, *ANFC-LH* adaptive neuro fuzzy classifier using linguistic hedges, *ANFC* adaptive neuro-fuzzy classifier

texture features based on GLCM were computed. The preprocessed segmented tumor images have been used to compute shape features. Further, the texture features and shape features have been serially fused into a single feature vector. The computed feature vector was then subjected to ANFC-LH classifier for finding an optimal set of features based on hedge values which were further fed to ANFC classifier to classify the tumors into benign and malignant classes.

The NSCT was used to improve efficiency in image representation. It has two building blocks, namely, (a) nonsubsampled pyramid (NSP) structure and (b) nonsubsampled directional filter bank (NSDFB). The result of the multiscale characteristic of NSCT gives a subband decomposition similar to Laplacian pyramid. To obtain this, a two-channel nonsubsampled 2-D filter bank was used. In the computation of such decomposition, à trous algorithm is used giving a redundancy of $J + 1$, where J is the total number of decomposition stages. At the j^{th} stage, the ideal pass band support of the low-pass filter was the region $[-(\pi/2^j), (\pi/2^j)]^2$, whereas for the high-pass filter, it was $[(-\pi/2^{j-1}), (\pi/2^{j-1})]^2/[(-\pi/2^j), (\pi/2^j)]^2$. The upsampling of filters of the previous stage further designs the filters for the consequent stages. This provides the required multiscale property to NSCT without having to design additional filters at each stage (da Cunha et al. 2006). The directional filter banks were constructed using carefully sampled two-channel fan filters and critically analyzed resampling operations (Do and Vetterli 2005). This gives out a filter bank, which is tree-structured that splits the 2-D frequency plane into directional wedges. For constructing nonsubsampled directional filter bank (NSDFB), the shift invariant directional filter banks were made by removing any downsamplers or upsamplers in the two channel filter banks and later upsampling filters accordingly. This gives filter banks, which were nonsubsampled in nature. For an M stage NSDFB, the number of directional subbands that were produced was 2^M.

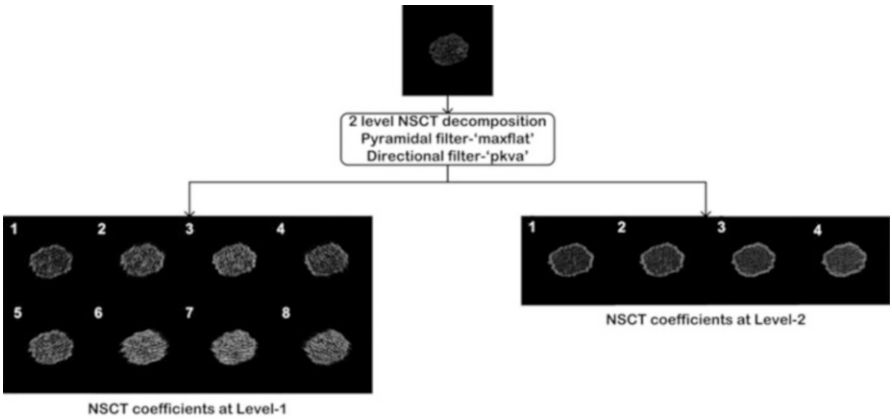

Fig. 8 Shifting of breast ultrasound images to NSCT domain giving out 12 subband images (8 + 4) from both levels to be used for classification purpose

For implementation in the present chapter, the breast ultrasound images were resolved using NSCT into two levels of 8 and 4 directional subbands as shown in Fig. 8. These subband images hold the essential feature characteristics of the breast tumors and were used for classification purpose. Through exhaustive experimentation, it was observed that best accuracy is achieved when features were computed from 5th subband image of level 1 generated using "maxflat" pyramidal filter and "pkva" directional filter.

For computing GLCM texture features, a co-occurrence matrix is first formed by computing the number of times a combination of different pixel pairs has occurred in the image for a particular gray level. This combination occurrence is calculated over a specified direction and inter-pixel distance (d). In the present work, inter-pixel distance (d) is taken to be 5 and the directions are taken to be 0°, 45°, 90°, and 135°. The final feature matrix has been formed by taking out the average of the features taken in all four directions. The different features computed were entropy, correlation, angular second moment (ASM), inverse difference moment (IDM), etc. Shape features like tumor area, convex area, tumor boundary, diameter, Euler number, orientation, eccentricity, circularity, elongation have been computed and fused with the texture features serially.

The classification systems based on fuzzy rules have gained popularity in pattern recognition and machine learning problems as these systems can easily address complex real-world problems. The fuzzy system is based on fuzzy logic such that the vagueness in the data can be handled. The fuzzy system uses membership functions and a set of different *IF-THEN* rules for reasoning and finding the result. The linguistic hedges (LHs) were used to introduce the importance of fuzzy rules in terms of linguistic terms. The LH values were tuned to improve the flexibility of fuzzy sets, thus removing the ambiguity of the overlapped classes. The LHs were defined as the linguistic terms to modify other linguistic terms. The various experimental results established that the LH value near 1 of the fuzzy classification set

indicates that the feature was relevant and significant for that class. For values other than this, the features were considered to be irrelevant and insignificant for that class (Cetisli 2010a, b).

The ANFC classifier combines the various advantages of a fuzzy inference system and the neural network classifier. The fuzzy inference system makes use of a set of fuzzy *IF-THEN* rules that can approximate nonlinear functions to deal with imprecise real-world problems while the neural network classifier had the capability to self-organize and learn adaptively from its environment. The network contains multiple nodes connected to each other by directional links. The output of the nodes was dependent on the parameters of the nodes, which were changed during network training to reduce the error (Kar et al. 2015; Kher et al. 2015; Rawat et al. 2018). The structure of the ANFC-LH classifier is shown in Fig. 9.

In the present chapter, the combined feature set containing a total of 26 features (13 GLCM texture based + 13 shape) was subjected to ANFC-LH, a wrapper-based method of feature selection based on linguistic hedges and ANFC classifier. Out of the total 26 features, seven most relevant features were selected on the basis of linguistic hedge values for the efficient classification of breast tumors. The obtained optimal feature set was then fed to ANFC classifier. The results obtained in the example for efficient breast tumor classification are shown in Table 5.

Table 5 indicates that an accuracy of 88.24% was achieved for the classification of benign and malignant tumors with individual class accuracy (ICA) values of 85.71% and 87.09% for benign and malignant cases, respectively. It was observed that only six testing instances out of a total of 51 instances were misclassified where three instances belonged to the benign class and three instances belonged to the malignant

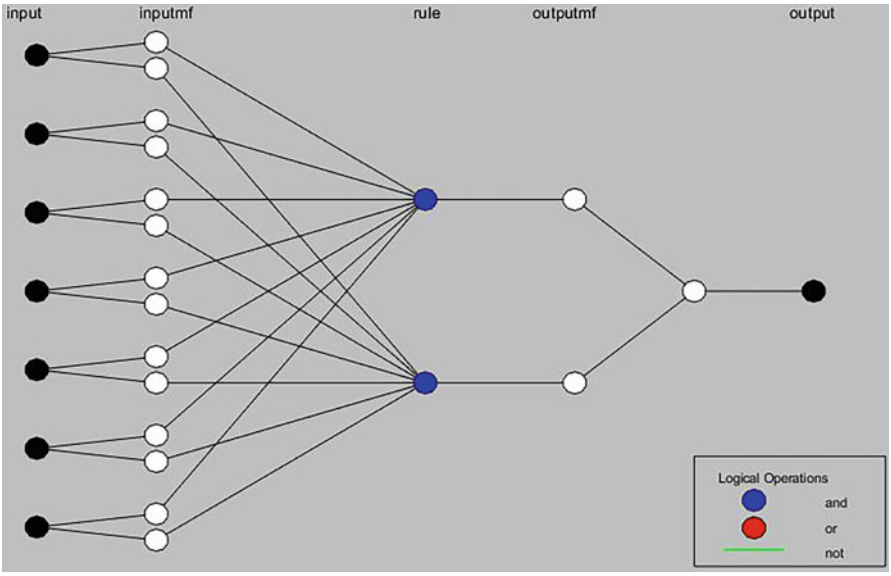

Fig. 9 The structure of the ANFC-LH classifier

Table 5 Results obtained in the present work for efficient breast tumor classification

class. The performance of the ANFC-LH classifier was also measured using the ROC curve as shown in Fig. 10, with an AUC value of 0.879 (Fawcett 2006).

As discussed previously, for early disease detection to manage its progression and improve chances of survival, imaging-based screening tools are predominantly used. However, the conventional approach is that the offline scans are available to the radiologists for interpretation and the results of the CAD system are also available to the radiologist in offline mode. This constraint on the CAD system can be overcome by real-time interaction between the radiologist and the CAD system used for classification purposes. One approach for this task is to provide a CAD server that has the proposed CAD system design integrated in it and is configured to interact with the radiologist in real-time, that is, accept real-time data and generate the diagnosis result for the radiologist (Zhang and Heffernan 2012). Another approach for real-world implementation of the proposed CAD system design is integration of the CAD system with the ultrasound machine, wherein the radiologist marks the region of interest for interpretation and simultaneously the software analyzes the ultrasonographic features and produces the final assessment (Kim et al. 2017). Depending upon the need, the radiologists can use the proposed CAD system design as an interactive 2nd opinion diagnostic tool for differential diagnosis between breast abnormalities, giving the radiologists a confidence in their interpretation and diagnosis.

Conclusion and Future Scope

The present chapter sheds light on the importance of the ultrasound imaging technique for the diagnosis of diseases of soft tissue organs. The chapter also presents a brief review of the literature on the classification of diseases of the soft tissue organs as seen on ultrasound images. Based on the conclusions drawn from the literature, a design of CAD system has been demonstrated as an example for the classification of breast tumors into two classes, namely, benign and malignant. For this classification of the breast ultrasound images, the texture features, that is, the textural characteristics of the region inside the tumor, and the morphological features, that is, characteristics of the tumor-associated with its shape, were considered essential. The work applies DPAD filtering algorithm to the original images for the morphological feature extraction. Since texture features get distorted by DPAD filtering, NSCT and GLCM were applied to the original images for the texture feature extraction from original images. The ANFC-LH focuses on efficient feature selection, thereby resulting in the maximum accuracy obtained by the ANFC classifier. The literature review in this chapter has been included with an aim to provide a comprehensive review of recent trends in the development and design of CAD systems that can be of significant importance to students and researchers starting to work in the field. The survey also tries to highlight the algorithms that have still been unexplored and can be applied for the disease prediction in soft tissue organs.

Abstract

The global trade has existed for ages, but in recent decades, global trade has become extremely important as it has been immensely influencing the world economy and society. The inflation in global trade over the ages has resulted in globalization, which has helped in increasing the cross-border activities and capital flow in the market. There are many factors such as the economy of the country, social factors, technological advancement, consumer needs and demands, legislative framework, and political scenario of the nations which have stimulated the global trade. The legal metrology also has a paramount role in influencing the world trade as the legal metrology establishes and imposes standards for weight and measurements, which is one of the most important

parameters in global trade as the global trade involves numerous commercial transactions and measurements of commodities which are exchanged between nations and thereby it has a predominant role in promoting global trade. The legal metrology laws ensure and maintain the accuracy and fairness in the global trade, it aids in production optimization, it helps in building consumer and corporate trust for the products and services being globally traded, and it also causes the evolution of new technologies and innovations. It also played a remarkable role in consumer protection and fair trade promotion. At present, every industrialized nation has a government agency in charge for monitoring the measurement accuracies, and they also put mandates for complying with legal metrology laws and other technological standards. This research paper attempts to analyze the importance of legal metrology laws in promoting world trade.

Introduction

A customer in India who wishes to buy the latest electronic gadget released in Europe or America can simply place an order on a leading e-commerce marketplace, and within a short period, he will receive his order at his doorstep thousands of miles away. This has become possible with the evolution of global trade. Global trade is an exchange of goods or services for consideration between the national or the individual entities across the international borders. Global trade eliminated borders of the national for trade and commerce. Global trade has its existence since the ancient time, and according to Peter Watson, the first long-distance trade extends back to almost 1500 BC (Watson 2012). Global trade involves exchange of products and services between two or more nations. As compared to domestic trade, carrying out global trade is a much more challenging operation as the trade has to comply with the regulations of both the markets (Tyc 2021).

Prior to conducting a global trade, many factors are to be considered, which include cultural and social impacts, demographic trends, legal concerns, and political situations of the nations in which the trade is to be carried out, and global trade can also be influenced by the changes in the natural environment and due to technology advancement (Kelly 2021). Today's world economy is characterized by international interdependence, and thereby no nation can exist in isolation or claim to be self-sufficient. All the economies are interdependent and aim to be self-sufficient. All the economies are interdependent on each other in some way or the other for goods and services. Global trade and the capital flow in the market have a huge role in promoting the nation's economy. Since the production and supply chain covers almost nations and continents, the country's commodity supply is highly reliant on economic activity in several other countries, and hence all the nations are highly

interdependent on each other (What is Globalization? 2021). The main aim of the international trade is to boost the economy of the nations and to raise people's living standards; it also allows the inhabitants of one country to consume and enjoy commodities that are produced in another country, and it also helps in promoting healthy competition in the market, which will in return facilitate in fair trading. The nations have also taken various measures and steps for obtaining financial stability and economic growth and for improving the living standards of people of the nations by establishing an organization which would help them in promoting and encouraging fair trade globally. The World Trade Organization (WTO) (1995) has been established to deal with all the trade-related aspects on a global level. WTO's (Plummer et al. 2005) main aim is to ensure to remove obstacles in international trade and negotiate trade rules and help in settling disputes.

Global trade, on the other hand, has further strengthened the role of legal metrology as it creates trust and confidence between the parties to the trade, and states/governments, being the promoter of trade and commerce, shall establish necessary standards and mandatory requirements to create trust and confidence. History of weights and measures can be traced over the last 5000 years, and it has evolved from time to time as nonstandard measures are the root cause of economic exploitation, and to address the issues faced by the consumers and the other stakeholders, respective nations have regulated laws, rules regarding weights and measures.

Importance of Global Trade

Global trade involves the transferred capital in exchange for commodities and services across international borders or territories. It also allows consumers and the countries to be exposed to the commodities and services that are not accessible or available in their own countries. The need for cross-border trade is felt as it is not possible for one particular country to be able to manufacture all the goods or provide all kinds of services, and thereby countries need to be interdependent on each other for goods and services, and therefore the countries cannot disregard or ignore the symbiotic trade relationship which they share with the other countries (Stobierski 2021). The global trade of products and services is very important for economic growth and the overall development of society (Kirton 2009). Global trade is a far more complicated operation as compared to domestic trade as because international trade involves many enormous factors such as regulatory frameworks, government policies, economic factors, exchange rate, political scenario, and market influences. In most of the nations, global trade is accounted as a significant component of the elevation of their country's GDP (Ross 2021).

The significance of global trade has been understood from prehistoric times (McKenzie and Coppolaro 2013). Global trade enables the nations to make better use of their assets and natural resources, such as land, labor, capital, and technology, in a wiser manner basically, and the global trade helps the nations to invest in their assets and resources in a more systematic and a strategical manner. Global trade

helps to promote and maintain healthy competition in the market, and thereby it results in more competitive pricing and in providing the best possible quantity and quality of commodities and services for consumption**.** One of the most basic advantages of competition is that it promotes innovation (Engagement and competition: how tech can help small businesses 2016). The competition among corporates or businesses may lead to the production of new or improved commodities, as well as more efficient services**.** The cross-border trade also aids in disregarding the domestic monopolies in the market, and it promotes and maintains fair trade and competition in the market. Trading in the international market can be done either by exports or importing commodities in the market. Importing basically implies a transfer of economic ownership between residents and nonresidents, and exports are taking away goods from domestic markets to international markets (Bernard 2011). Imports and exports are the major factors behind the growing interdependency between the actors on the stage of the world economy (Alexander 1986).

Global trade allows the countries to achieve economic progress, and it also helps the countries in improving their access to physical capital and export markets (Baylis and Smith 2021). As per the World Trade Organization report, the global trade is decreased by 9.6% in the year 2021, but it rose by 8%, and the value of merchandise exported is USD 17.58 trillion among all the nations of the world (Global trade rebound beats expectations but marked by regional divergence 2021). Over many years, the countries have formed economic alliances to enable the flow or transfer of goods and services from one country to another. Over the period of time, such cross-border trade resulted in a considerable increase in the globalization process. Globalization is considered as a process that is based on the international approaches, and it aims to expand trade and commerce on a global level (Kaur and Kaur 2017). Although many researchers attribute that globalization began in the contemporary era, many historians write that globalization dates back to the European age, and evidence is also found that global trade existed during the third century BCE (Vanham 2019). The term globalization was coined in the early twentieth century, but it evolved into its modern meaning and became popular in the 1990s, but the large-scale globalization had already begun in the 1820s, and it had caused a dynamic development in the late nineteenth and early twentieth centuries; it resulted in the world's economy developing rapidly and interdependent with each other country (Gopinath 2011). Globalization has resulted in the opening of the economy and has also aided in promoting cross-border trade. Analyzing from an economic perspective, it can be stated that globalization holds a huge impact on the exchange of commodities, services, data, technology, and other economic resources on a global level (IMF Staff 2008).

Global trade leads to the globalization of products and services, and it has certain advantages (Ozer 2019). Global trade provides the consumer a greater array of options for the same commodity from various places available for consumption, and this helps to not only improve their standard of living but also helps the country prosper. Global trade gives a country a comparative advantage by enabling it to specialize in the production of goods with lower opportunity costs of production

than its competitors. Global trade also aids in the allocation and utilization of resource in a more efficient manner as the countries tend to produce or offer goods or services in which they have a competitive advantage. Global trade enhances production efficiency because nations would endeavor to adopt better manufacturing processes in order to keep costs down and remain competitive. Countries who are able to create a product at the lowest feasible cost will be able to earn a greater market share, and as a result, there is an incentive to manufacture efficiently, and this will assist in raising product standards, and this will enable the consumers to have access to a high-quality product. Globalization allows a country to consume goods that are either unavailable or prohibitively expensive to manufacture inside its boundaries, and as a result, importing from other nations via international commerce becomes less expensive. International trade helps various nations to utilize their excess or surplus products by selling those to other countries for obtaining capital, and it would also help the nations to prosper economically (Klasen 2019). Global trade decreases trade volatility by increasing the size of the market with vast supply and widespread demand, and the goods pricing tends to be more consistent in international trading. Global trade would promote international peace, goodwill, and mutual understanding between the nations, and it would also promote the economic interdependence between countries, which frequently leads to deep cultural ties and also in preventing conflict between the nations (Melitz et al. 1998).

Global trade and the financial transactions that accompany it are often conducted to provide nations with products that they lack in return for those that they produce in excess. Such transactions, when combined with other economic measures, tend to increase a nation's standard of living (Thomas Warren Hertel 1997). The countries make attempts to promote reasonably fair trade among them.

Evolution of Global Trade and the Importance of Trade Route

Trade is a fundamental economic concept that entails the act of buying and selling goods and services for a valid consideration. Trade was also a boon for human interaction, which helped in building cross-cultural contact and economic prosperity, and it also raised the living standards of people. Trade is as long as the existence of civilization, and evidence reveals that mercantile business existed for the last 5000 years (Anne Osborn Kruege 2020). The emergence of trade over the centuries has helped in the evolution of trade routes, which have been used to establish connections between the civilizations from where the goods are manufactured to places where goods are consumed. Trade confine within the boundaries of a country is called domestic trade, and international trade is exchange of good and services across two or more countries which is known as the global trade. Trade can create job opportunities and economic prosperity of the nations and can increase the standard of living of its citizens (Smith 2013).

Trade and civilization are practically inseparable. The traders have travelled across the globe far and wide in pursuit of trade and commerce; they used every available mode of transport and reached new territory and offered goods and services

over the centuries. Among the most notable trade of the past is the oldest long-distance trade that took place around 3000 BC and was between Mesopotamia and the Indus Valley (Lamberg-Karlovsky 1972) (which is now located in Pakistan). This long-distance trade was exclusively limited to luxury goods such as spices, textiles, and precious metals, and in those early days, the cities that were rich in these products were monetarily wealthier and financially benefitted because of these long-distance trades, and also the cities along with these trade routes later have been developed into manufacturing and trading hubs, and consequently the economic standards of the locals had improved. Another most significant trade took place around 2000 BC (Journal of ancient History 2017) on the island of Cyprus, which had at that time become a major player in the Mediterranean region, and the region had been transporting huge amounts of copper resources to the Middle East and Egypt, and this region has its own natural resources such as papyrus and wool (Frankopan 2015). This trade also led to prospering of other countries like Phoenicia, known for its maritime prowess, which traded rich cedar wood and linen across the Mediterranean. China flourished as it traded in jade and spices and eventually started trading in silk, and Britain thrived in its economy as it traded in tin.

The Chinese started trading in silk in Europe in consideration which they received gold, silver, and wool from Europe. In the past, one of the major trade routes was the Silk Route (Elisseeff 2000); it started operating during the second century BC, and it enabled trade between China and the Far East, as well as the Middle East and Europe, easier (Lally 2021). Later, due to the lack of appropriate roadways and facilities, the maritime trade routes emerged and were believed to be the most efficient means of transporting goods from one region to another. The trade routes helped in trading everything from silk and spices to glassmaking methods and gunpowder, and it made its way from the East to West. The most recent archaeological discovery confirms that the classical international trade, known in ancient Indian history as "Indo-Roman trade," existed long ago.

The trade route helped in building the trade network worldwide; it included roads between points which included not only the transportation of goods along these roads but also knowledge, ideas, religious practices, etc.

The emergence of trading led to the evolution of different trade routes, which had emerged with time. The Silk Route/Silk Road was one of the most well-known and historic trading routes. It emerged in 130 BCE and it existed until 1453 AD. This trade route was first originated during the ruling period of the Han dynasty by Zhang Qian (Chandra and Banerjee 2008). The Silk Route was a historic trade route which mainly aided in connecting China's main civilizations with the Roman Empire (Philip 2020). Along with this trade route, silk was one of the principal commodities which were traded as the traders discovered that ferrying merchandise along this route was profitable. This route aided in exporting silk from China to Europe; in return it received wool, silver, and gold for such exchange. With time the trading hubs began to spring up along this trade route, and it served as a gathering place for individuals to share their knowledge and interests. Later, with the fall of Roman Empire in the fourth century CE, gradually it decreased the use of Silk Route, and the route was barely used, and later it was resurrected by the Mongols in the thirteenth

century, and Marco Polo (1300) used it when he became one of the first Europeans to travel to China. Later, in 1453 AD, the route again lost its significance. Another most notable trade route in the past was the Spice Route, and this was a maritime route; it generally connected the eastern part with the western part. This maritime route was used by the Arabian as they traded spices through this route to Europeans, and the Spice Route (Keay 2006) was also known as the Maritime Silk Route. The spices which mainly traded through this route were pepper, cinnamon, nutmeg, cloves, cassia, turmeric, and star anise and were hugely traded through this route. Prior to the fifteenth century, the trading in spices was extremely uncommon and expensive, and during that period, the spice trading was controlled by the Arabs and North Africans between the East and the West. So, during the Age of Exploration in the fifteenth century, it became possible for people to travel long distances and establish new global trade links; thus, Europeans began sailing and establishing new global trade relations with people in China, Japan, and Indonesia. Even some scholars also claimed that the spice trade spurred the growth of international trades and encouraged the exploration of new areas, and it has also helped foster new diplomatic connections between the East and West. The Incense Trade Route (Unesco Journal 2005) was a historic trade network of significant land and sea trading routes which connected the Mediterranean area to the eastern and southern parts. This route also extended from Mediterranean ports through the Levant and Egypt to India and beyond. The Incense Route (River 2019) was mainly created to export frankincense and myrrh, which are only found in the Arabian Peninsula's southernmost regions (which is now in modern Yemen and Oman). Later as trade along the Incense Route flourished, it was observed that almost 3000 tons of incense were transported each year (Karl Reinhold Haellquist 1991). Another most important trade route was the Amber Route which linked the Baltics with Europe, and this route was relevantly used for trading in 3000 BCE, with archaeological data suggesting that Baltic amber beads were traded through this way. The Romans built an Amber Route (2011) between the Baltics and in the rest of Europe, as the Romans valued amber for its medicinal and its aesthetic qualities. Later, in the twelfth and thirteenth centuries BC (Claire Cock-Starkey 2016), the Baltic Sea was ruled by the knights, and it became a very important source of capital for the Teutonic Knights. Another majorly important trade route is the salt route (Cartwright 2017) as for generations salt has been in great demand, and it is a precious commodity as it can be used for multiple purposes. The salt-rich locations grew into major trade hubs as it helped in transiting of salt to regions that lacked it. The salt route connected Rome with the Adriatic coast. Another prominent trade route was the Trans-Saharan trade route (The Metropolitan Museum of Art 2000); this is one of the oldest trade routes; it began its significance in the fourth century CE. This route mainly connected North and West Africa. In the eleventh century, this route also aided in transporting of the caravan with over a thousand camels, and various commodities across the Sahara Desert were transported. The gold, slaves, salt, and fabric, as well as ostrich feathers and European weaponry, were exchanged along the route. Another most relevant trade route was the Tin Route (Flower Philip William 2017) which transformed from the Bronze Age to the Iron Age; the Tin Route was one of the most crucial routes that enabled people

to the export of tin. This route stretched from the tin mines in Cornwall's extreme southwest, over the sea to France, and then down to Greece and beyond.

In the history of ancient trade, the significance of the trade route is immeasurable. It had immensely contributed to make the transportation of goods and services in a much easier and more flexible way, which had been exceptionally helpful for carrying out global trade. It also helped in building the trade network worldwide; it included roads between points which included not only the transportation of goods along these roads but also knowledge, ideologies, and religious practices.

The global economy has grown rapidly in recent decades, and an enormous portion of this expansion has been fueled up by the fast-growing world trade. Integration into the global economy has been a very significant way for nations to promote their economic growth, development, and poverty reduction. However, trade has traditionally been a source of the economic prosperity of the nations. According to the data, the world trade has grown at a rate of 6% per year on average over the last 20 years, twice as fast as global output. Therefore, with rapidly growing trade, the governments have acknowledged the need for regulating the global trade; it was basically due to the economic pressure that had pushed the countries to impose trade regulations to promote free and fair trading in the market.

In the year 1947, the first global multilateral agreement was signed by 23 nation-states at Geneva, and this agreement is known as the General Agreement on Tariffs and Trade (GATT). This agreement was aimed to reduce the trade barriers by abolishing or decreasing quotas, tariffs, and subsidies while retaining considerable restrictions. The GATT was created to help the world economy to recover after World War II by rebuilding and liberalizing global commerce, which would help to promote economic prosperity. One of the most important notions of the GATT was trade without discrimination, which meant that each member country opened its markets to everyone equally, and this also meant that once a country and its main trade partners agreed to lower a tariff, the duty reduction was immediately applied to all other GATT members. Another core principle was that protection should be provided through tariffs rather than import quotas or other quantitative trade restrictions. Another fundamental requirement of the GATT was the consistent customs laws, and each signatory nation had a commitment to negotiate the tariff reductions upon another's nations request. The contracting nations might change agreements if their domestic producers incurred disproportionate losses as a result of trade concessions, according to an escape clause. The GATT (1947) agreement remained in force from 1948 to 1994. The GATT mainly was established to provide the framework for much of international trade and presided over some of the fastest-growing periods in history. The GATT agreement appeared to be well-established, but it was a temporary agreement. Later the GATT was replaced by WTO in the year 1995 (Autar Krishan Koul 2005).

Later, in the year 1995, the World Trade Organization was established, and it has 164 member nations. It is an international organization that regulates and liberalizes global trade. The main principles of the World Trade Organization (WTO) agreement (1995) is to build on the idea of eliminating trade barriers and adopting nondiscriminatory norms and raising the standard of living by creating jobs and

improving lives. These ideas are enshrined in the core principles of the WTO agreements. The World Trade Organization oversees the worldwide system of trade rules and aids developing nations in increasing their trade capacity. The WTO's goal (Landau 2006) is to guarantee that global trade is being carried out in a free, transparent, and predictable manner. As per the WTO report, the global trade in goods and services amounted to US$ 22 trillion in 2020.

OECD Role in Promoting Global Trade

The Organization for Economic Cooperation and Development (OECD) is an international standard-setting body that provides important impartial research and information on a wide range of economic and trade policy concerns. The OECD has 38 member states, and it was formed in the year 1961 to promote the economic development of the nation and to promote global trade. The Organization for Economic Cooperation and Development (OECD) evolved out of the Organization for European Economic Cooperation (OEEC), which was founded in 1948 to supervise American and Canadian contributions to the Marshall Plan (Kenton 2020).

The OECD convention's three main objectives were (Woodward 2009) to contribute to the development of the world economy by achieving maximum sustainable economic growth, employment, and improved living standards in member countries while maintaining financial stability, to contribute to rational economic expansion in member and non-member countries in the process of economic development, and to contribute to global trade expansion. This organization's main concern is to find a solution for international concern, establish the international standard, and share information, and it also tries to find the best-practiced solution in order to support improved policies that will improve people's lives.

The OECD mainly assists in promoting global trade between the nations by providing trade facilitation indicators which help the nations to evaluate their trade facilitation advantages and shortcomings, prioritize action areas, and more effectively deploy technical support and capacity building. The trade facilitation indicators use a variety of quantitative measurements on key areas of the border process to assess not only the actual amount to which nations have enacted and implemented trade facilitation measures in absolute terms but also their performance relative to others. The OECD also provided protection to the consumers as the consumers encounter more complex financial market situation; therefore, such measures are very much important, and it also aids in the development and maintenance of consumer confidence and trust in financial markets, hence improving efficiency and stability and assisting both financial institutions and their customers in achieving favorable results. The OECD aims to improve financial consumer protection by assessing what is needed to assist consumers to achieve the trust, knowledge, information, security, and choices they need to fully engage in financial markets. There are certain guidelines which has been provided by OECD to protect the consumers. The guidelines take into account existing legislative protections for consumers in more traditional forms of trade; it fosters private sector initiatives

that include customer engagement; it also emphasizes the need of collaboration among governments, corporations, and consumers.

The OECD has estimated that around 80% of the global trade is in compliance with some standards or regulations. The OECD encourages global trade by promoting robust rule-based international trading framework to keep the momentum for more trade liberalization going while also contributing to long-term development. It also promotes mutually beneficial integration of developing and emerging economies with the trading system by strengthening trade policy.

Legal Metrology: "Once Measured, Accepted Everywhere"

In the twenty-first century, our life has become inconceivable without measurement. Measurement makes our lives much easier and more comfortable. Measurement is a vital instrument that we all use in our day-to-day life. Basically, every aspect of human existence is influenced by measurement in some way or the other way. Some of the important measurements we come across on a daily basis and without which we cannot even imagine our lives are time, temperature, pressure, sound, weight, volume, distance, speed, and direction. Simply measurement is basically a technique for determining an object's properties or qualities by comparing it to a standard object. Measurement's scope and applicability are determined by the context and expertise.

Measurement also plays a significant role in promoting trade. Every day in some way or the other, we all are engaged in some or the other commercial transactions which involve buying or selling of commodities or services for a particular sum of money, and therefore, it becomes important for us to know whether the measurement and weights used in the commercial transaction or for the delivering the goods or services are proportionate to consideration; we are paying for it, and therefore it brings in the need for a standardized measurement which will ensure accuracy and transparency; it will also enable the consumers to make an informed choice, and it will also protect the consumers for loss or damages which can be caused (Legal metrology and trade 2021).

As the globalization causes interdependence of the economies and the exchange of goods and services at the international level has become imminent, it becomes really important to use standardized system of weight and measurement for selling and buying of these commodities or services at the global level, and this will also promote fairness and transparency, adapt various means to remain competitive and compete with each other, and will help consumers to make a better and informed choice.

The weights and measurements and the standard of measurement are the yardstick for the exchange of commodities. The measurements adapted in the trade, which is once standardized and certified, shall be accepted across worldwide. The nation at the international level has taken enormous steps to maintain transparency and to establish standards to promote global trade by establishing an organization; the International Organization for Standardization (ISO) (Murphy and Yates 2009)

has an important role in encouraging global trade by developing international standards.

Evolution of Unitary System of Measurement

The practices relating to weights and measurements is not new, and its significance can be traced from the past; the oldest and the most primitive known weights and measures systems date back to the third millennium BC. The concept of weights and measurement, on the other hand, would be neither innovative nor contemporary in practice; it has been in use since the dawn of civilization (Hallock and Wade 1906).

The Egyptian system of measurement was founded on bodily measurements, and they used "cubit, figures, and spans" for measurement of length; they used the unit "hekat" for measuring volume, and for measuring weight, they used "deben (Swango 1957)." The Babylonian measurements (Mina unit of weight, Britannica 1998) were determined from an examination of the Senkereh tablet, which is estimated to have been inscribed about 2500 BC. The Babylonian first discovered the unit for weight measurement called as "mina," and it is one of the earliest known units for weight; the unit for measuring capacity is known as "Qa" or "Ka" which was also discovered by the Babylonian (Lawrence James Chisholm, Britannica 2018). The Roman standard for all weight measurements was the "as," "Old Etruscan," or "Oscan pound."

The Indus Valley emerged in 7000 BC. In the Indus Valley, the Harappa and Mohenjo-Daro civilizations were both prominent civilizations. During 1800 BCE the traders of the Harrapan civilization used to trade through barter or exchange system for goods and services as the Harrapans did not have money as their exchange system. It was based on binary and decimal systems and was used to measure weights. Later, in 2500 BCE, during the emergence of the Mohenjo-Daro civilization, the weight and units played a significantly major role, and one of the major units that were used at that time was Dhanurgraha (which was equal to four Angula) (Mauryan empire, Britannica 1998).

In the Middle Ages, during the emergence of the Maurya dynasty period around 321 BCE, they used a complex weight and measuring system, and the unit system used at that was for the measurement of basic length was Angulam. Therefore, it can be stated that the weights and measurements and standardization of units could be referred from an immemorial time. Later, during the fourth century BC, Chanakya authored a famous book named *Arthashashtra* in which he mentioned the units for measuring lengths and distance which was known as Dhanushas and Angulas (McIntosh 2008) which were commonly used for measuring the distance.

During the period of Ramayana and Mahabharata as during that time, there was a standard unit for measurement known as yojana (Yojana standard length of measure evidence from Ramayana and Mahabharata 2018). In the past, there were various practices which could be recognized as per the custom and usage, which were later adopted by the society for measuring and in producing various food items, metals, and other commodities. But after the legislations pertaining to weights and

measurements came into force, customs, usage, and practices lost their enforceability and significance, and presently after the enactment of the legislation, the weight and measurements were governed under the said law. During the Late Middle Ages, with the emergence of the Mughal Empire in 1526 CE, there was a reform in the weight and measurement system, and the standard measure (unit) that was used to measure the land was Gaz and bigha (Karl 1981). Later, during the British colonial period, the British imperial units of measurement were adopted in India (British Imperial System 2019).

In 1795, France was the first country to adopt the metric system (Free 1976) which is now formally used in almost all nations. The metric system is a decimal weight and measurement system that is used all throughout the world. The metric system uses the "meter" as a unit for measuring length, and it uses the "kilogram" as a mass unit.

Evolution of Legal Metrology Laws

The term metrology means the science of measurement, and the legal metrology laws refer to all applied metrology that is regulated by legislation or by decrees. The legal metrology laws are framed to basically guarantee correctness and equity in commercial transactions and to protect the consumers from financial loss and promote fair trade. Previously there was no codified law which dealt with the trade-related aspect like standardization of weight and measure, fairness, and the offense associated to it. Furthermore, since years have passed, there has been technical advancements and societal shifts that have occurred; the economic changes and political changes have made us to understand the need for a standardization of weight and measurement. Later, with time, the government understood the importance of standardization of weight and measurement as there was no particular law which governed the weight and measurement at that time.

The measure was taken at the international level to promote world trade and for standardization of weight and measures. The late nineteenth (International Trade Centre, Legal Metrology and International Trade 2004) century witnessed a significant expansion in international trade, prompting metrology to take steps to improve measuring uniformity throughout the world. The most significant of these metrological initiatives was the 1875 Treaty of the Meter, which enabled the establishment of the International Committee of Weights and Measures (CIPM) and the national measurement institutes (NMIs) in developed countries to maintain national standards of measurement and provide traceability to these standards. This intended to offer one of the fundamental infrastructures for science and technology progress throughout the century. The International System of Units (SI) was developed to replace a plethora of national, craft, and industrial units. The SI units were formed to ensure international consistency of trade and regulatory measurements, as well as to "resolve internationally the technical and administrative problems raised by the use of measuring instruments," which led to the establishment of a second metrology

treaty organization, the International Organization of Legal Metrology (OIML), in 1955, and it focused on trade-related aspects.

In India, in 1956, a central act was formulated called the Standards of Weights and Measures Act 1956. This piece of legislation was passed with the aim of implementing a metric-based universal standard unit for weights and measurements. It intended to facilitate and regulate interstate trade and commercial conduct through the enforcement of a uniform measurement system for commercial goods. Later, in the year 1976, the act was repealed by another act known as the Standard of Weights and Measures Act 1976; this act addressed concerns such as the establishment of standard weights and measures, regulating trade and commerce in terms of weight measurement and other commodities, it also dealt with the approval of models, it also established standards for the commodities which were packed for the intention to be sold or distributed in an interstate trade or commerce, it also emphasized on verification and stamping of weight and measure which were to be traded in interstate, and it also emphasized on the duties of exporter and importer and their mandates on their registration process.

In the year 1985, the Standards of Weights and Measures (Enforcement) Act 1985 was formed, which supplemented the previously formed act on standard weight and measure known as the Standard of Weights and Measures Act 1976. This was an enforcement action which was formed to ensure the uniformity in the enforcement procedures relating to weight and measures; it also had a legal control on weights and measures and on its instruments; the act had a uniformity of procedure; it aimed to protect the consumers in a better way; and there was no much scope for exploitation by the unscrupulous users; the act also authorized the state government to appoint controllers of legal metrology for the states and a required number of additional, joint, deputy, or assistant controllers, inspectors, and other officers to carry out the objectives of the act efficiently, and the act, on the other hand, protects them from liability for actions performed in good faith when exercising any authority or performing any obligation under this or the Standards Act.

With the changes in the society due to the sheer of fast growth of science and technology, as well as the globalization of economies, weighing and measuring procedures have vastly improved, and the scope of weights and measures has been expanded, so therefore, the need was felt for a new law with the intent of establishing standards for weights and measures, regulating trade and commerce in weights and measures and other commodities sold or distributed by weight, measure, or number, and for matters connected with or incidental thereto. In the year 2009, the Legal Metrology Act was enacted. This was enacted as the need was felt to integrate the contents of the two previous acts to eliminate inconsistencies and simplify the legislation.

The Legal Metrology Act 2009 consists of 5 chapters and 57 sections. This act is procedural law in nature. This act regulates interstate trade and commerce relating to weights and measures; it provides mandates on the manufacturer, repairer, and dealer of weights and measures to obtain license compulsorily; it imposes the obligation of declarations on the manufacture, packaging, sale, import, distribution, delivery, offer, exposure, or possession for sale of any prepackaged commodity. In order to

deal fairness for the goods packed in the absence of the consumers, packaging commodities rules are framed under the Act of 2009. These rules stipulate the requirements of labeling declaration on the prepacked commodities.

Legal Metrology Laws of India, the United States, and the United Kingdom with Reference to the Package Commodity

In India, the Legal Metrology Act 2009 and Packaged Commodity Rules 2011 govern weights, measures, and packaged commodities. These rules are applicable to packages containing a quantity of less than 25 kg or 25 liters, and no package shall be sold without proper declaration as per the rules (Rule 3 of Legal Metrology 2011). For cement and fertilizer bags, this rule will be applicable if the quantity is more than 50 kg.

"Prepackaged commodity" is a commodity that, without the purchaser being present, is placed in a package of whatever nature, whether sealed or not so that the product contained therein has a predetermined quantity (Section 2(l) of The Legal Metrology Act 2009). If any predetermined quantity is packed in the absence of the purchaser, then it shall comply with the provisions of the Packaged Commodity Rules 2011. Every package shall contain a label, and all the mandatory declarations as per the rules shall be declared on the label, and the label shall be securely affixed to the package. According to rule 4, no one may prepack any commodity for sale, distribution, or delivery unless the package in which the commodity is prepacked has labels carrying the necessary declaration.

The rules also prescribe the size of the label and the size of the package with reference to the volume of the package. The units are expressed in SI system and expressed "kg" or "g" for mass, "cm" or "m" for linear measurement, and "ml" or "L" for liquid volumes. The total surface area on which this mandatory declaration was made is defined as a principal display panel (PDP) (Section 2(h) of the Legal Metrology Act 2011). These rules also mention the size of the font on the packaging.

Some of the prepacked products, like baby foods, bread, biscuits, weaning food, tea, coffee, etc., are to be packed in specified quantities; however, in November 2021, these restrictions are withdrawn, and now the products can be packed in any quantity. However, the unit sale price of the product is to be mentioned on the pack.

Whereas in the United States, the legislation which mainly deals with the packaging of commodities is the Uniform Packaging and Labeling Regulation under regulation 1. These regulations are applicable to all packages except the packages that are not intended for individual sale and packages intended for exports. A package is defined as enclosed in a container or wrapped in any manner in advance of wholesale or retail sale or whose weight or measure has been determined in advance of wholesale or retail sale (Section 2 United States Uniform Packaging and Labelling Regulations 1952). Uniform Packaging and Labeling Regulation states that the principal display panel is the area of a label that is most likely to be seen,

presented, exhibited, or inspected under the normal and typical display and purchase conditions. All standards relevant to the "primary display panel" should apply to all such principal display panels in the package when a principal display panel occurs more than once. These regulations also prescribe size of the font for making the mandatory declaration. In the United States, the Uniform Unit Pricing Regulations are in place to declare a commodity per kilogram or per gram and the price to be declared in dollars or in cents.

Whereas in the United Kingdom, Weights and Measures (Packaged Goods) Regulations 2006 governs regulations regarding prepackaged commodities. These regulations are applicable to packaged commodities that are intended for sale in constant unit nominal quantities, which shall be not less than 5 grams or 5 milliliters and not more than 25 kilograms or 25 liters (Regulation 3 UK The Weights and Measures 2006). This regulation applies to bread that is sold either unwrapped if it has a predetermined constant quantity and is intended for sale in constant unit nominal quantities of not less than 300 grammes per loaf and not more than 10 kilograms per loaf. The marking or labeling declaration shall be made in specific unit measurement in metric units, i.e., kg, g, L, ml, and cl. These regulations also prescribe the size of the font for making the mandatory declaration. In UK metrology law for packaged commodities, there is no specific mention of the principal display panel.

The Declaration Is to be Made on the Packages

A customer shall have the right to know the contents of the prepackaged product in order to make an informed decision. The regulations made a bounden duty on the manufacturer/packer/importer to make a declaration about the product. The following is the comparative statement on the declaration of prepackaged products in these following countries.

Declaration	India	UK	USA
Name of the product	Generic name to be mentioned	To be declared	Identity to be declared
Name and address of the manufacturer and packer, and for any imported package, name and address of the importer	To be mentioned	To be mentioned	Responsibility to be declared by state-corporate name of the packer along with the address
Date of manufacture/ packed	**Yes.** In case of food items, expiry date also to be mentioned	To be mentioned. In case of food items, expiry date also to be mentioned	To be mentioned. In case of food items, expiry date also to be mentioned
Net quantity	Yes. Quantity to be mentioned in SI units	Yes. Quantity to be mentioned in SI units	Yes. Quantity to be mentioned in SI units

(continued)

Declaration	India	UK	USA
Maximum retail price	Price to be mentioned in rupees	Not mentioned in the regulations	
Consumer care cell	Name, telephone number, and email address to be declared on the pack	Not mentioned in the regulations	
Principal display panel (PDP)	All mandatory information to be grouped together and to be declared on PDP		All mandatory information to be grouped together and to be declared on PDP
Height of the numerals	To ensure the heights as mentioned in the rules	To ensure the heights as mentioned in the regulations	To ensure the heights as mentioned in the regulations

Offense and Penalties

Under criminal jurisprudence, a punishment or penalty is levied on the wrongdoer in order to deter him/her from doing the act again, and this also prevents others from committing any offense. In Indian legal metrology laws, the punishment varies from penalties starting from Rs. 2000 to Rs. 50,000 per person, and second and subsequent offenses can lead to imprisonment.

Whereas in the United States according to Uniform Weights and Measures Act, the punishment varies from civil penalties to criminal penalties. In civil penalties, the amount of fine increases on the second and subsequent offenses.

In the United Kingdom, any noncompliance will be penalized based on a graded scale. The punishment or penalties for most of the offenses are fines at various levels on a scale of 1 to 5. As per Criminal Act 1982, the standard scale of fines is L1, 200; L2, 500; L3, 1000; L4, 2500; and L5, 5000 pounds; and imprisonment is for fraud or intentional tampering of the weighing scales.

Advantages of Legal Metrology in Trade Practices

Global trade of products and services is significant for economic growth, societal well-being, and maintaining global financial stability. The legal metrology laws are framed to uplift the economy and to benefit the society, which would lead to social and economic development. The legal metrology laws are framed with an objective to simplify and consolidate the laws relating to weight and measurement, and it also

promotes fairness and transparency. The following are the advantages of legal metrology law in trade practices (International Organization of Legal Metrology 2002):

Upliftment of economy. Legal metrology has immensely helped in uplifting the economy by escalating the trade and commerce of the country as from the very beginning measurements have always been recognized as foremost criteria for trade and commerce, and therefore the need was felt for standardization of weights and measures to elevate its precision, transparency, and authenticity which would promote fair trade in the market, and it would entice investors to invest in the market, and that would positively impact the economy as the government collects its revenue through excise duties imposed on products produced, sold, imported, and exported and also via taxes levied on measurement and weight of the commodities. The Legal Metrology Act also ensures that no injustice is done to both the consumers and businesses in the matter related to trade and commerce.

Protects and builds consumer trust. The legal metrology laws standardize rules and regulations to protect the consumers from fraud and significantly reduce disputes; it increases the efficiency of the marketplace, and when customers realize, they acquire the product that has been confirmed in accordance with standards and rules, which increases their trust in the brand or company, resulting in a solid trading relationship between the trader and the customer. In the current area of Internet revolutions, the role of legal metrology is indispensable as these consumers interact and trade globally.

Promotes fair trading and healthy competition. Legal metrological regulation guarantees fair trade by limiting the use of short measures to gain a commercial advantage over competitors in the market and by preventing the manufacture and sale of many trade measuring instruments that are not fit for purpose and do not meet internationally recognized standards through pattern approval and certification.

Reduces technical barriers to trade. The Legal Metrology Act reduces technical constraints and enhances measurement confidence and clarity. Fewer barriers boost national morale and encourage citizens to participate in the global commercial system, resulting in increased national economic growth. Using the Legal Metrology Act, a trader can avoid needless obstacles in the adoption, use, and evaluation of technical regulations, standards, and conformity assessment procedures.

To promote global trade. The establishment of International Recommendations for Pattern Approval of Measuring Instruments contributes to the worldwide market

for measuring instruments that meet globally recognized standards. The Legal Metrology (Packaged Commodities) Rules 2011 has a provision that deals with exporting of packaged commodity, and it also sets certain guidelines for the way the exporting shall be done and leads to promoting the global trade.

OIML Role in Stimulating the World Trade

The International Organization of Legal Metrology (OIML) is an international organization founded on a diplomatic agreement signed in Paris on October 12, 1955. Currently, 124 countries are members of OILM (of which 61 are full member states and 63 are corresponding members). The OIML has developed a number of guidelines to assist members, particularly developing countries, in drafting appropriate legislation relating to metrology in all aspects of society, as well as certification and calibration requirements for new products, especially where such calibration has a legal impact, such as in trade and taxation.

The OIML (International Legal Metrology Documentary Standards, NIST 2016) was established with the goal of promoting worldwide harmonization of legal metrology processes and to encourage world trade. The aim of the OIML is to assist economies in developing mutually compatible and globally recognized legal metrology infrastructures in all domains where governments are responsible, such as in trade facilitation and standardizing consumer protection norms throughout the world.

The International Organization of Legal Metrology (OIML 2015) has an objective to promote world trade, which would automatically help to promote the global economy. It generally tends to reduce the trade barriers by standardizing and harmonizing the regulation, which would help in facilitating global trade; it provides standard laws and regulations concerning the measurement and weight, which would build the confidence and the trust of the consumer and would tend to promote global trade and also consumer protection norms which would encourage the customer to invest more in global trade.

Conclusion

With the advent of transportation, communication, and technology, the world has become a global village without boundaries for trade. The global economy has shown significant rise in recent years, and much of this development has been fueled by the huge rise in global trade. A recent analysis by the world bank group shows that economic growth has been enormously boosted by trade liberalization and that there has been a 20% increase since the 1990s (Trade, World Bank Group 2021). Internet technology revolution is largely influencing global trade. Further consumer needs and coordinated attempts by nations for eliminating trade barriers by making a

significant effort to standardize their regulations concerning the global trade are increasing. Some of the developing nations have opened their economies to take full advantage of trade-related opportunities for the economic growth of the nation.

The legal metrology also has an enormous role in promoting global trade as they mainly aim in establishing and enforcing standards of weights and measures and regulating trade and commerce activities relating to weights, measures, and other goods which are sold or distributed; it promotes fairness and transparency, and it also protects consumer interest.

Trade and legal metrology are very much interconnected with each other as both are associated with the use of weight and measurements. In today's globalized trade environment, most of the commercial transactions require measurements, and they must be able to be considered "acceptable" in order to assure fairness to all parties and thereby legal metrology in promoting world trade. Further, the roles of legal metrology are increasing in health care and medical devices and environment. The OIML is working toward global consistency in measurements.

economies. It is happening because India has already established a suitable institutional mechanism and is continuously striving to develop a robust domestic Quality Infrastructure (QI). The QI mainly comprises Metrology, Standardization, and Accreditation. Historically, the journey of India was started with the foundation of the Indian Standards Institution (ISI) and National Physical Laboratory, India (NPLI), in the year of 1947. Further, it passes through pre- and post-days of globalization; reform initiatives taken up by the Government; the impact of ever-changing technology and industry/business trends, and comprehensive changes in global trade due to the advent of the World Trade Organization (WTO) regime. Further, the progress is going on in the context of contemporary advancements. The chapter is an effort to get a holistic overview of major verticals which influence trade and economic growth across the globe, exploration of existing institutional mechanisms for Indian QI, ongoing activities to maintain sustainable economic growth, and futuristic challenges in this arena.

Keywords

Quality infrastructure · Standardization, Regulatory ecosystem

Introduction

Globalization has connected economies and cultures worldwide. Interdependence and interoperability are becoming an integral part of the global ecosystem. For example, a car sold in Canada can be designed in France, with parts manufactured in Australia or China. It becomes possible by adapting suitable standards (i.e., *something established by a competent authority, custom, or general consent as a model, example, or point of reference*) and their proper implementation. However, over time, the use of Standards has emerged as one of the magical tools to control international trade dynamics. The developed economies have pre-assessed the situation at an early stage. They have taken control of the world economy by establishing a robust and effective QI ecosystem (Quality Infrastructure 2018; McDermott 2019; UK Quality Infrastructure; Quality Infrastructure: UNIDO's). The QI broadly encompasses Metrology (i.e., *the science of measurement*), Standardization (i.e., *the process of making something conforming to a standard*), and Accreditation (i.e., *third-party attestation by a designated authority confirming the competence of the assessment body to carry out specific conformity assessment tasks*). On contrary, developing economies are still facing challenges.

According to (The Importance of Standardization – benefit and advantages 2020), the standards/specifications stand for knowledge in the form of regulations and guidelines. These are written documents (printed and digital formats) that can be easily distributed among interested parties or end users. Generally, such types of documents remain accessible to everyone. The aim is to help people/industries across the globe to understand each other better so that they can react faster and act accordingly. Irrespective of the nature of the organization (whether it is a private

or public sector), nearly in every area of life, there is generally at least one standard that plays an important role. ISO (International Organization for Standardization) rightly states that the future belongs to standards (https://www.iso.org).

The Standards (i.e., defined to be per se Voluntary) become mandatory when implemented as Technical Regulations/SPS measures. Generally, the Government in developing economies takes such initiatives in the interest of the country and its people. A report by OECD (Organisation for Economic Co-operation and Development) (Singh and Mitra 2022) indicates that, generally, regulation is an attempt to control or influence private behavior in the desired direction by imposing costs on or proscribing undesirable behavior. Since regulation can have significant consequences for economic efficiency and private incentives, it is usually justified only under specific conditions. There are three sets of justifications for regulatory interventions, i.e., (i) prevention of market failures, (ii) restriction or removal of anti-competitive practices, and (iii) promotion of public interest. Post-independence, India experimented with a "socialist mixed economy model." In this model, the government retained control over the heavy industries and utilities and tried to command the activities of the private sector through licensing and quotas regarding intermediate goods imports and outputs. Such types of controls were complemented by high tariff walls. However, after 1985, the Indian economy embarked on a process of domestic reform involving steps like delicensing of industries, abolishing quotas, permission for private entry into sectors which were hitherto the monopoly of the government, and liberalization of quotas and tariffs on capital goods imports. Further, from 1991 onwards, the liberalization of the external sector resulted in tariff reductions in almost the entire spectrum of merchandise trade, simplifications, and liberalization in the conditions for foreign investments, etc.

Side by side, to achieve sustainable economic growth, India has strived hard to cultivate its unique kind of QI ecosystem. Historically, the journey was started with the establishment of ISI on 6 January 1947. This institute was initially concentrated on standardization activities; subsequently, it was replaced by the Bureau of Indian Standards (BIS) on 26 Nov 1986. Further, BIS became the Standard Development Body (SDO) of India. Moreover, the National Physical Laboratory, India (NPLI, which is also referred to as CSIR-NPL), was founded on 4 January 1947, which was the first milestone in the field of Metrology for India. Subsequently, under the Act of Parliament, Legal Metrology, it becomes the National Measurement Institute (NMI) in 1956. NPLI establishes and maintains all the seven basic SI units (International System of Units) and their derivates, except the ionization radiation. In 2003, the Bhabha Atomic Research Centre (BARC), Mumbai, was declared a designated institute (DI) to deal with ionization radiation.

Further, in this sequence, the Quality Council of India (QCI) (https://www.qcin.org) was established as the national body of accreditation in 1996. Subsequently, the council came into existence in 1997 through a Cabinet decision as an autonomous non-profit organization under the Department for Promotion of Industry and Internal Trade (DPIIT), Ministry of Commerce and Industry. QCI's role is to establish and operate a national accreditation structure and to promote quality through the National Quality Campaign. It plays the role of the National

Accreditation Body (NAB) as per the ecosystem of quality around the world with the task of creating a mechanism for third-party assessment of products, services, and processes.

Recently the Indian QI has been investigated in the context of the QI of the United States and indicated that all the basic three pillars (i.e., metrology, standards, and accreditation) are well established in India; however, the strengthening of QI is still an area where further attention/improvement is required (Aswal 2020). However, the topic has vast scope to look into it; thus, it would be interesting to carry out an independent 360^0 investigation and analysis of the Indian standardization and regulatory ecosystem. The QI of developed economies like the United States, EU, etc., is almost mature, while the developing economies like India are still coping with typical challenges to maintain sustainable economic growth.

This chapter is an effort to visualize the existing Indian ecosystem of standardization and regulation. Onset, we review the verticals like industry revolutions, ever-changing trade dynamics, QI ecosystem adapted by large economies, and the role of major key players (i.e., WTO, SDOs, etc.) in the international arena. Afterward, we evaluate the domestic ecosystem of standardization and regulation and will conclude by presenting views on growth avenues and challenges for India.

Industry Revolution and Trade Dynamics

The standard, standardization, and regulatory activities are an integral part of our lives; however, things get altered with the changes in the requirements. Indeed, the orientation of industry, trade, and interaction among people across the borders significantly transformed over time. The ever-changing trade dynamics are one of the root causes of significant transposition in the country-specific regulatory/standardization requirements to maintain sustainable economic growth. One of the best ways to visualize the changes is in the context of the revolution in industry developments, trade liberalization, and globalization that influenced the trade dynamics.

Industry Revolution over Time

Figure 1 illustrates the metamorphosis of the industry over time. It summarizes the developments starting from 1784 to till date (https://www.desouttertools.com/industry-4-0/news/503/industrial-revolution-from-industry-1-0-to-industry-4-0).

The figure is self-explanatory. However, a brief overview of the stepwise progress is as follows:

(i) **The First Industrial Revolution (Industry 1.0)**: It was the start of mechanization. It is understood to begin in the eighteenth century with the implementation of steam power and automation of production. The use of steam for

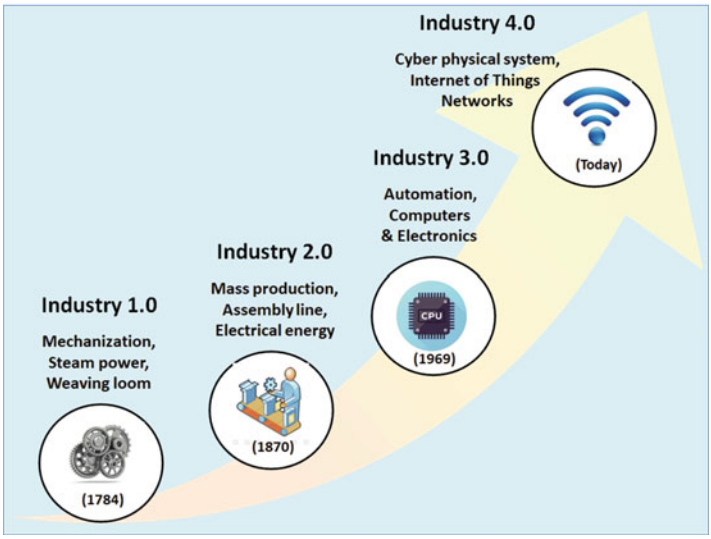

Fig. 1 Industry revolution over time

industrial purposes was a significant breakthrough in increasing human productivity.

(ii) **The Second Industrial Revolution (Industry 2.0)**: It started in the nineteenth century after the invention of electricity and assembly line production. It was a boost in mass production by implementing automation using electrical energy. Earlier only one station assembled an entire automobile. However, after the introduction of the assembly line, the vehicles were produced in partial steps on the conveyor belt – significantly faster and at a lower cost.

(iii) **The Third Industrial Revolution (Industry 3.0)**: It began in the twentieth century through partial automation using memory-programmable controls and computers. Electronics came into the picture, and by implementing such technologies, automation of the entire production process became possible without human assistance. Known examples of this period are the development and use of robots that perform programmed sequences without human intervention.

(iv) **The Forth Industry Revolution (Industry 4.0)**: Presently people are talking about Industry 4.0. It is marked by the application of ICT (Information and Communication Technology) to industry. It builds on the developments of Industry 3.0. The computerized production systems are expanded by a network connection and the Internet. These allow communication with other facilities and the output of information about themselves. It is the next generation of production automation, and the concept of "smart factories" (Weyer et al. 2015) comes up. In such factories, the production systems, components, and people communicate via a network, and production is nearly autonomous. The implementation of such new technologies together resulted in the concept of "cyber-

physical systems" – which are networks in the "Internet of Things (IoT)." These developments brought significant improvements, such as enhancement in automation, and shortened the time between the development of a new product and its market launch. Notwithstanding, the novel technologies pose typical challenges, e.g., cyber security issues, data privacy, security, etc. Standardization in this segment has emerged as one of the major challenges.

Trade Liberalization

Trade liberalization is a deterrent process of protection. Trade liberalization takes place when the government decides to support free trade. Trade liberalization may take place unilaterally. Initially, around the second half of the twentieth century, significant trade liberalization occurred among developed economies. However, it was reciprocal and multilateral. The liberalization decisions taken up by the countries' governments reciprocated among the trading parties. The liberalization was non-discriminatory in applying to all liberalizing trading partners. The trade liberalization aimed to facilitate cross-border trade among the trading partners who support the concept. The trade liberalization was followed by the liberalization of international capital markets and substantial international migration (both legal and illegal). International agreements and conventions also unified rules of conduct concerning the protection of property rights, including intellectual property rights related to proprietary knowledge. The outcome of these liberalizing and integrating processes is known as globalization (Hillman 2008). The trade liberalization was started in developed economies but gradually spread throughout the world. However, it posed negative as well as positive impacts across the globe.

Impact of Globalization

According to a report (Globalization), it was a general conception that globalization is working selectively. It was beneficial for some economies while not for others. It has been observed that poverty reduction in China was one of the impressive impacts of globalization, while In India, the message was more mixed. India has a typical socio-economic environment; the challenge before it is unique in many ways. An India-specific report (Kishore 2002) indicates that inter-regional inequality appears to have widened during the era of globalization. India is a country rich in knowledge and the production of technology. Over the years, it has changed in many ways, and knowledge is now recognized as a commodity. India is rapidly increasing its integration with the global economy and has emerged as a global player. Even the World Bank has judged India to be one of the world's "fast globalizers." It is well known that ICT became important in new-age industry evolution, i.e., Industry 4.0. Noticeably, India is progressing very fast in this segment.

Globalization and Standardization

The interconnection between globalization and standardization is one of the significant areas of research. In this regard, an analysis report has been published (Purcell and Kushnier 2015). Interestingly, according to the said report, more than 100 individuals and standards organizations who are experts in the field of globalization and standardization (academic, private sector, and public sectors) were approached to submit their views and comments on this critical issue. Surprisingly they only received inputs/comments from two standards organizations, i.e., the International Electrotechnical Commission (IEC) and DIN (the German national standards organization). It indicates that standards have strategic value and are a bridge between the market and technologies. They control access to virtually every market in global commerce and directly affect more than 80% of world trade. The conclusions of the views of IEC and DIN are investigated in the report. The analysis concludes that the relationship between globalization and standardization is, or should be, a critical area of understanding for policymakers across the world.

Quality Infrastructure (QI)

The term QI has nicely been explained in a Blog wherein the author cited different definitions by the subject experts and has elaborated the concept (Harmes-Liedtke 2002). The term, "Quality Infrastructure" is made of two words, i.e., "Quality" and "Infrastructure." "Quality" is inherently a subjective concept. For instance, from the manufacturer's point of view, quality is "freedom from deficiencies or defects," whereas, from the customer's perspective, the definition of quality can be "fitness for use." The quality management standard ISO 9000:2005 defines the term "as the degree to which a set of inherent characteristics of an object fulfills requirements." The product quality depends solely on the extent to which the standard-defined requirements are met. The word "infrastructure" mainly described the immobile buildings and facilities that served to mobilize and keep the armies ready. Indeed, the QI (as a whole) describes a system of institutions that guarantee the definition and control of quality criteria. These institutions can also be seen as the underlying foundation of international trade. The functions of QI include the development of standards and the control of conformity.

The International Network of Quality Infrastructure (INetQI) (INetQI) is a consortium of 14 international organizations which promotes the significance of QI activities (i.e., metrology, accreditation, standardization, and conformity assessment) as a tool for sustainable economic development. This group of international organizations includes the International Bureau of Weights and Measures (BIPM), International Accreditation Forum (IAF), IEC, Independent International Organisation for Certification (IIOC), International Laboratory Accreditation Forum (ILAC), International Certification Network (IQNET), ISO, International Trade Centre (ITC), International Telecommunication Union (ITU), International Organizations of Legal Metrology (OIML), United Nations Economic Cooperation for Europe

(UNECE), World Bank Group (WBG), WTO, and United Nations International Development Organisation (UNIDO).

To understand the interrelationship between different entities involved in QI activities, we may cite the model of National QI by PTB (Fig. 2) (https://www.ptb.de/cms/fileadmin/internet/fachabteilungen/abteilung_9/9.3_internationale_zusammenarbeit/publikationen/102_National_QI/PTB_Q5_National_QI_EN.pdf). The figure shows the central components of the QI are accreditation, certification, standardization, testing/inspection, and metrology. It would be pertinent to mention that the certification and testing/inspection are integral parts of conformity assessment. The individual components exchange services and form an overall system. In the model, on the right-hand side, international recognition is represented by membership in international professional organizations. While on the left-hand side, the users of the system are demonstrated in the form of a value chain. Nevertheless, similar models are being used/adopted by all the large economies. Let us have a quick look at each component of the QI activity.

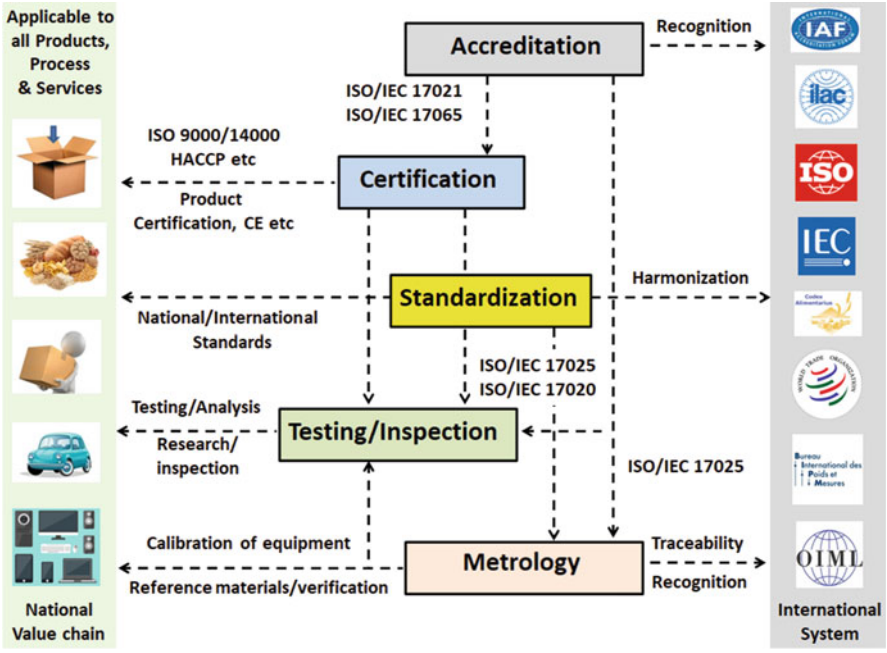

Fig. 2 Entity relationship in QI. (Retrieved from the model given in (https://www.ptb.de/cms/fileadmin/internet/fachabteilungen/abteilung_9/9.3_internationale_zusammenarbeit/publikationen/102_National_QI/PTB_Q5_National_QI_EN.pdf))

Metrology

The BIPM (BIPM 2022) defines metrology as "the science of measurement, embracing both experimental and theoretical determinations at any level of uncertainty in any field of science and technology." It can be further split up into three subfields, i.e., scientific metrology, applied metrology (sometimes also termed industrial metrology), and legal metrology.

(a) **Scientific metrology**: It is the base of all other subfields. It covers the development of new measurement methods, R&D activities in standards, the realization of measurement standards, and the transfer of these standards to users. For this work across the globe, all countries have their NMIs. For example, in India, CSIR-NPL, New Delhi performs this task.
(b) **Applied metrology (or industrial metrology):** In this subfield of metrology, the science of measurement is advanced in production and other processes, ensuring the suitability of measurement tools, their calibration, and quality control. Accurate and accurate measurements improve the quality of the product and, therefore, its market. The power of industrial metrology, therefore, controls the economic and industrial development of the country.
(c) **Legal metrology:** It deals with regulatory requirements for well-established standards and measurement tools (compliance with standards) for consumer protection and fair trade. These regulatory requirements arise from the need for public health and safety, consumer rights, favorable taxes, the environment, and fair trade by competent organizations.

Standardization

Standardization is the process of making something conform to a standard. Indeed, the ultimate aims of standardization include making a product, process, or service fit for its purpose, controlling diversity by using the optimal number of types/sizes, protecting the environment, and ensuring compatibility of various products, health, safety, etc.

A study for the Department of Business, Innovation and Skills and the British Standards Institution (BSI) throws light on the role of standardization in support of emerging technologies. The report inter alia indicates that to escalate competition for industrial activity, the government recognizes the new technologies as one of the significant driving forces in the growth of the national economy. One may describe the emergence of technology as a complex and dynamic phased journey, by which, the applied science ideas turn into workable technologies, then viable applications, and marketable products; fostering the right environment for each stage of this journey has become a priority for the government. Over time, there has been an increasing interest in the understanding of the effect of standards on emerging technologies, appropriate roles for government, innovation system actors in support of standardization activities, etc. (O'Sullivan and Brévignon-Dodin 2012).

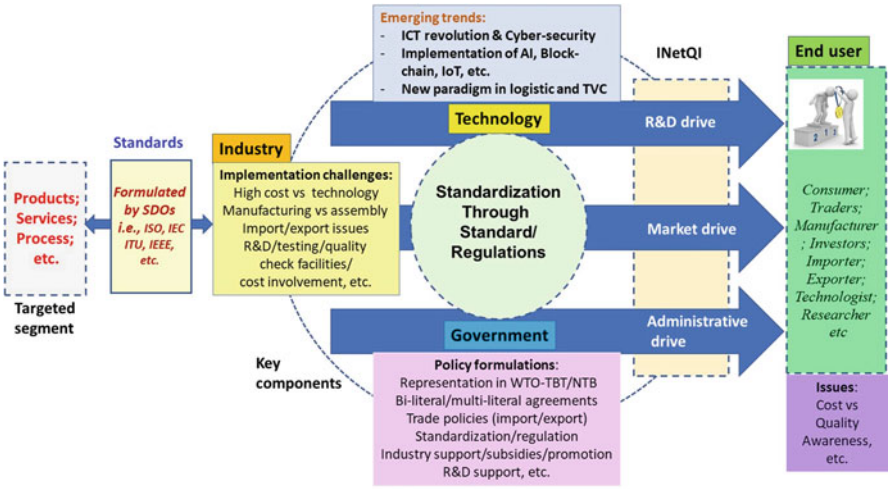

Fig. 3 Schematics of standardization through standards/Regulations with involved key entities

Altogether, these entities develop a complex ecosystem in terms of interactions among them and their interrelationship.

A self-explanatory Fig. 3 gives a glimpse of the process. It includes the targeted segment (e.g., products, service, process, etc.), SDOs (e.g., IEC, ISO, etc.), Industry, government, technologies, and prominent drives (e.g., R&D, market, administration, etc.), and finally, the end user. Ultimately, the whole ecosystem revolved around three major components, i.e., commodity, standards, and the end user. The illustration indicates the interrelationship among involved entities, their concerns/expectations, and linkages of the components with the driving forces. For instance, a manufacturer/company/industry of any product wants to adopt standards to improve its quality, safety, fitness for the global market, etc.; however, they face various challenges like conformity issues, taxation matters, costing, the impact of government policies, etc. The government formulates policies to control as well as facilitate the trade; it has to cope with multiple challenges in the domestic as well as international arena. Technology, which is one of the significant components of the process, keeps on changing over time and its demands/requirements. The end user may generally have concerns like cost versus quality issues.

Standard

Standards provide individuals/organizations with a basis for understanding and are used as tools to facilitate communication, measurement, trade, and productivity (https://research.lib.buffalo.edu/standards). As we already have emphasized in section "Globalization and Standardization," the Standards control the world economy. Its major functional components are as follows:

- Facilitates business communication.
- Allows companies/organizations to comply with applicable laws and regulations.
- Accelerates the introduction of new products to the market.
- Provides interoperability between new and existing products, services, and processes.

Since standards play a pivotal role in international trade, their development process is also quite typical. According to ISO, standard development is like a symphony; it takes a lot of people working together to develop a standard. The standard development process includes many steps. The process starts by evolving a draft according to the market requirements within a specific area. Thereafter, it is shared among interested parties for commenting and further discussion. Voting is carried out to get a consensus. Once it is achieved, the draft becomes a standard. In case, the agreement doesn't reach, then the under-consideration draft is modified again, and the whole process gets repeated till the consensus. The standard development process (from the first draft to final publication) usually takes about 3 years. Standards are the distilled wisdom of people with expertise in their subject matter (e.g., manufacturers, sellers, buyers, customers, trade associations, users, or regulators) who know the needs of the organizations/market. Some of the areas where a majority of standards are coming out are as follows:

Type of standards	Requirements
Quality management:	To help work more efficiently and reduce product failures.
Environmental management:	To help to reduce environmental impacts, reduce waste, and be more sustainable.
Health and safety:	To help to reduce accidents in the workplace.
Energy management:	To help cut energy consumption.
Food safety:	To help prevent food from being contaminated.
IT security:	To help to keep sensitive information secure.

Technical Regulation

According to WTO, the technical regulation is a government document that describes product characteristics or their related processes and production methods, including the applicable administrative provisions, with which compliance is mandatory (https://www.wto.org/english/tratop_e/tbt_e/tbt_info_e.htm#:~:text=The%20difference%20between%20a%20standard,different%20implications%20for%20international%20trade). No consensus is necessary for the establishment of the regulation. The technical regulation may also include or deal exclusively with terminology, symbols, packaging, marking, or labelling requirements as they apply to a product, process, or production method.

The main difference between a standard and a technical regulation lies in compliance. Conformity with standards is voluntary, while in the case of technical regulation, it remains mandatory. Since they are different by nature, thus, their implications for international trade are also dissimilar. For instance, if an imported

product does not meet the requirements of a country-specific technical regulation, it will not be allowed to be put on sale in that country, although the situation is quite different in the case of standard. In this scenario, the non-complying imported products will be allowed on the market; however, then their market share may be affected if consumers/end users prefer products that meet local standards such as quality or color standards for textiles and clothing.

Ideally, the government interferes when products can affect the health or safety of the consumers or the environment or that might encourage deceptive practices; consumers need protection from faulty or dangerous products or the conscienceless behavior of suppliers. The technical regulation is introduced as a legislative measure to assure a reasonable level of protection for the consumers. According to ISO, the technical regulatory system includes the following (ISO Guide to Good Practices):

Elements of regulatory system	
A regulator:	A public body (ministry, department, etc.), identified to administer technical regulations.
A suite of technical regulations:	It normally includes both administrative and technical provisions.
A supplier of the product:	The supplier of the product (e.g., designer, manufacturer, importer, distributor, retailer) is responsible for marketing safe products and monitoring their products in the marketplace.
A conformity assessment infrastructure:	It is required to enable the regulator to make decisions about compliance or non-compliance.
A range of sanctions:	It can be applied by the regulator in the event of proven non-compliance.

According to the experts, the technical regulations have to be the same for imported and locally manufactured goods. WTO strives for non-discriminatory treatment for all trade partners, thus, encouraging countries to adopt international standards as Technical Regulations/SPS measures. Enacting any technical regulation is one part of the story, while enforcement is the most crucial part of the system. Regulators and suppliers need strict monitoring to ensure compliance with any technical regulation. However, the approach may be different. Market surveillance is one of the best mechanisms by which compliance can be ensured. The market surveillance is either carried out by the regulator/supplier itself or authorities/agencies appointed by them. According to the requirements, one may initiate market surveillance before or after the product is placed on the market.

Market Surveillance (MS)

As mentioned earlier, MS is an essential part of any regulatory system. It refers to the activities carried out and measures taken by public authorities to ensure that products comply with the requirements embarked in the relevant technical regulation and do not jeopardize the health, safety, or any other aspect of public interest protection. It includes both pre-market and post-market surveillance activities. It is a complex

process. In principle, one can broadly categorize it into two segments, i.e., (i) active market surveillance and (ii) reactive market surveillance.

(v) **Active market surveillance**: this type of MS pertains to the authority's initiative, sometimes referred to as (pro)active market surveillance. It is performed for appropriate checks (a) on an adequate scale, (b) based on adequate samples, and (c) to take account of established principles of risk assessment, complaints, and other information. Sometimes it is also referred to as routine surveillance.
(vi) **Reactive market surveillance**: it is initiated when (a) product problem is clear, e.g., non-conformity is claimed, occurrence hazard by the product, etc.; (b) extent of the investigation follows from the complaint/accident report.

The MS activities shall be planned based upon an evaluation of existing information about (possibly) unsafe products/product groups (scope), or in case of any investigation has to be determined. One of the ideal MS models is EU (European Union) model (Market Surveillance in the European Union and Germany: Perspectives for India, Indo-German Working Group on Quality Infrastructure – Knowledge Series 5, Editors: Dhundia H, Singh K, Moser V A, Jan 2020), the process of the said model is illustrated in Fig. 4 to understand the process at an abstract level. Each component of the process is self-explanatory. The aforesaid process is a basic system

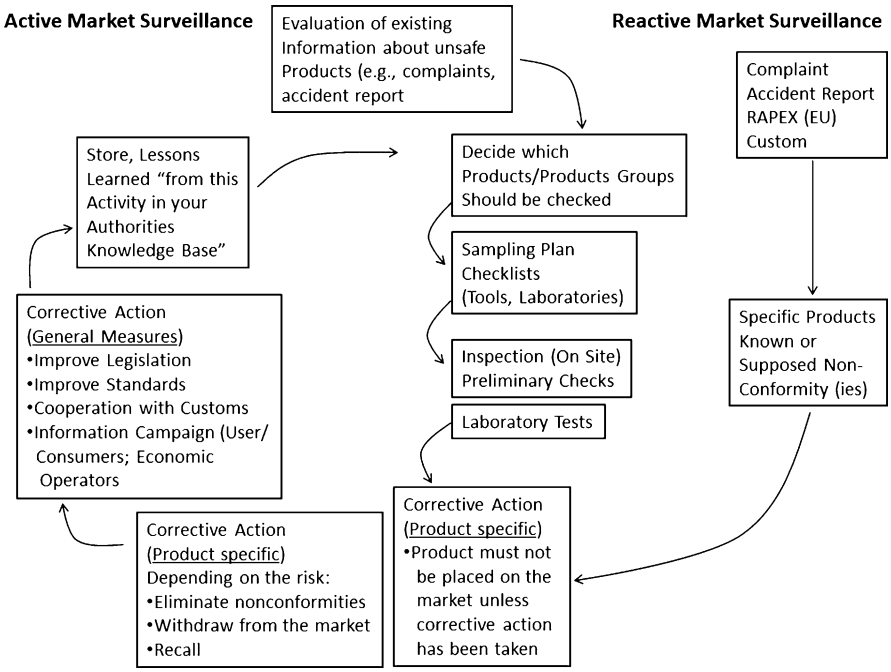

Fig. 4 Process of market surveillance. (Retrieved from presentation by Hans-Georg Niedermeyer in Indo-German Workshops on Market Surveillance, New Delhi, 2018 and 2020)

of market surveillance; however, it varies from country to county based on their regulatory ecosystem, market intelligence potential/capability/infrastructure, level of user awareness, etc. Many developed economies including the EU have their stringent regulatory framework to implement market surveillance.

Conformity Assessment

Merely meeting the regulations and standards is however not enough. The industry has to gear up to face challenges beyond compliance to Technical Regulations/SPS Measures and Standards. Demonstration of compliance to these is also equally important. Demonstrating compliance means that an organization is committed to conducting business in conformity with the regulations and standards that apply to them. It is ensured by Conformity Assessment (CA) which involves a set of processes that manifest that your product, service, or system meets the requirements of a standard. There are a variety of Conformity Assessment Procedures (CAPs) or routes available starting from the least stringent one, i.e., SDoC (Self-Declaration of Conformity), used extensively by the EU in its regulations for CE Mark to the intensive third-party assessment. Similarly, for instance, in India, BIS uses compulsory registration for electronics products, solar energy products, etc.

Conformity assessment is growing in importance both in regulated and voluntary sectors. A WTO study (https://www.wto.org/english/res_e/reser_e/ersd201609_e.pdf) carried out in 2016 on Specific Trade Concerns (STCs) raised by the TBT Committee inter alia indicates that:

- Conformity Assessment Procedures (CAPs) of any country generate equally more trade concerns for Members than technical regulations. It implies that following harmonized (or equivalent) technical regulations in practice is not necessarily the best solution for facilitating international trade. Notwithstanding the degree of symmetry between regulations, CAPs are still appraised by WTO Members as a decisive hindrance to market access. Post investigation of different CAPs, the analysis finds that testing and certification are the procedures that give rise to considerable concern during bilateral and multilateral trade negotiations.
- CAP-related STCs elaborate on a full range of issues regarding consistency with the TBT Agreement; out of these concerns, the most significant issues are related to transparency and unnecessary trade barriers.
- The data on STCs raised by different economies indicates a volumetric exchange of STCs between China, the EU, and the USA. China is the WTO Member most frequently challenged in CAP-related STCs, and 93% of these STCs were brought by the EU or the USA, or both together.

The situation is understandable because more and more countries today are adopting and implementing International Standards and then cease to be an issue; however, their CAPs differ and will continue to diverge since there is no single internationally accepted model. Since the conformity assessment includes testing, inspection, and certification, thus, it is crucial to suppliers, consumers, and regulators.

Accreditation

As the importance of conformity assessment has grown with the regulators increasingly relying on independent, third-party inspection and certification bodies or labs to carry out inspection/certification/testing on their behalf and number of voluntary schemes coming up globally who needed third-party bodies to scale up adoption of their standards, a need arose of assuring the competence of conformity assessment bodies and facilitating cross-border acceptance of test reports, inspection reports, and certifications. This has led to the development of a system of accreditation to establish the technical competence of inspection/certification bodies and labs for which ISO has laid down several standards. ISO 17000 defines accreditation as "third-party attestation related to conforming assessment body conveying formal demonstration of its competence to carry out specific conformity assessment tasks."

WTO and SDOs: The Key Players

The WTO (https://www.wto.org) is the organization that deals with global trade. It ensures seamless, free, and predictable trade flow across the globe. It originated on 1 January 1995 under the Marrakesh Agreement (Marrakesh Agreement) after the Uruguay Round of Multilateral Trade Negotiations. It would be pertinent to mention that earlier, General Agreement on Tariffs and Trade (GATT) (General Agreement on Tariffs and Trade (GATT)), which commenced in 1947, governed the international trade. GATT was replaced by WTO agreements (Agreement on Technical Barriers 2022), and the agreement was signed initially by 123 nations. The agreement is popularly known as TBT Agreement (Technical Barriers to Trade Agreement). India has been a WTO member since 1 January 1995 and a member of GATT since 8 July 1948. The purpose of the TBT agreement is to assist manufacturers of goods and services, exporters, and exporters to conduct their business.

The Role of the WTO

The WTO is run by member states and its main functions are:

- **Trade negotiations**: WTO agreements include goods, services, and intellectual property. They specify the principles of freedom and permissible diversity. It includes each country's commitment to lowering commodity prices and other trade barriers as well as opening and maintaining open market markets.
- **Implementation and monitoring**: WTO agreements require governments to make their trade policies transparent by informing the WTO of applicable laws and measures.
- **Dispute resolution**: The WTO process for resolving trade disputes under Dispute Settlement Understanding is essential for enforcing laws as well as ensuring fair trade.

- **Capacity building**: WTO agreements contain a special provision for developing countries, including long-term implementation of agreements and commitments, measures to increase their trade opportunities, and support to help them build their trade power, deal with conflicts, and apply technical standards.
- **Public relations**: The WTO maintains dialogue with non-governmental organizations, members of parliament, other international organizations, the media, and the general public on various aspects of the WTO.

The WTO regime recognizes that governments have the right to protect their people for reasons such as health and safety and therefore can legally enforce product requirements – so-called technical regulations or sanitary and phytosanitary (SPS) measures in the agricultural food sector. It describes, under the TBT Agreement, reasons such as health (food, drugs, medical equipment), safety (toys, electronics, LPG cylinders), environment (vehicle exit rates, environmental regulations, lead content in paint), fraudulent trade practices (damage to cement or gold jewelry) and national security (telecom) controls, i.e., the product requirements set by law. This has led to an increase in the number of technical regulations, national and international volunteer standards, and compliance assessments applicable to all sectors in products, services, processes, management systems, or personnel. Indeed, the WTO regime has created two distinct domains: sectors amenable to technical regulations/SPS measures and sectors that are driven by Standards (Jauhri 2020).

Trade Dynamics and WTO

According to a study (Bastos and Cabral 2007), based on data from 20 OECD countries for the period 1980–2000, it shows that trade transitions between industries that contradict previous international knowledge are often the best way to increase trade. Economic analysis shows that the perceived changes in trading patterns were explained by the first gifts of individual and financial transactions in a particular productivity of labor and labor costs. The results also suggest that trade liberalization has led to an increase in the pre-existing specialization of large OECD economies in industries with a growing profitability scale. Indeed, economic status, technology, and factor endowments are important factors in changing trade patterns.

One of the most important factors affecting trade is FDI (Foreign Direct Investment). According to the discussion paper (Riccardo 2004), in the past, FDI was primarily directed to establish a manufacturing facility in foreign markets in order to cater to foreign buyers and to cross trade barriers. Similarly, the increase in trade barriers would be associated with an increase in FDI. In particular, therefore, trade and FDI were areas of concern. More recently, however, global investment decisions seem to be driven by a different set of considerations. The development of telecommunications and transportation technologies allows firms to achieve significant cost reductions by cutting value-added chains between companies located in different areas as a function of pricing. Therefore, trading costs play a very different role in this context. In particular, the increase in trade restrictions will not only influence

trade, but will also reflect negatively on the motives of multinational firms to invest abroad.

Generally, International Trade is dominated by two types of trade barriers, namely, Tariff Barriers (TB) and Non-Tariff Barriers (NTB). TB is a related tax imposed by governments to control the import and export of one or more products from a particular country. On contrary, NTBs are government policies and actions without tax restrictions. Figure 5 shows the year-wise status of TB/NTB. In Geneva (Tokyo round) conventions, NTB has registered its presence (Fig. 5a) (https://view.officeapps.live.com/op/view.aspx?src=https%3A%2F%2Fwww.wto.org%2Fenglish%2Ftratop_e%2Ftbt_e%2Fprogram_fiji06_e%2Fs3_conc_def_princ_e.ppt&wdOrigin=BROWSELINK). Trade barriers often protect domestic companies by imposing restrictions on the distribution of goods between nations. With the advent of the WTO regime, TB in international trade has declined (see Fig. 5b), and NTBs have arrived to take the central stage in the arena. The major barriers between NTBs (commonly known as TBT) are generally accepted as those related to standards and compliance assessments.

Figure 6 illustrates the SPS/TBT notifications in WTO from 1995 to 2022 (till march 2022) (https://epingalert.org/en/FactsAndFigures/Notifications); the year-wise data shows that the number of TBT notifications almost keeps on rising (Fig. 6a) while ups and downs may be observed in SPS (Sanitary and Phytosanitary) notifications; in case, we analyzed the economy-based TBT data (Fig. 6b), the facts are quite interesting; the developed economies have not raised TBTs substantially while the developing and emerging economies keep on raising the numbers. On the other hand, in least-developed economies, it is also showing increasing trend in recent years. In case, we see the data of TBT notifications by objectives, the maximum TBT notifications were come up in the segment of protection of human health or safety. The quality requirements and prevention of deceptive practices have taken second and third position, respectively (Fig. 6c). It would be pertinent to mention here that we are exploring TBT data more than SPS data because we are more concerned in TBT notifications than SPS to remain in the scope of the chapter. The data/information implies that:

- TBTs are showing a raising trend than NTBs. However, socio-economic condition is one of the major deciding factors for implementation of such trade barriers.
- Developed economies have raised TBT initially, but soon after a certain period they have started to curb the growth. It indicates that somewhere it has been understood that raising the number of TBT may adversely influence the flow of their international trade. Moreover, largely they have already protected their market, and they now have only to maintain the pace with the contemporary changes in the trade dynamics.
- WTO provides provisions to enact TBT national security requirements; the prevention of deceptive practices; protection of human health or safety; etc, as a result, maximum TBTs get notified by different countries in this segment.

SDOs and Their Role

There are thousands of SDOs (Standard Development Organizations) worldwide. They can standardize almost anything to make life easier, safer, and more productive. Generally, these bodies have cooperative agreements. They may be supportive of each other's standards, building on them, or deliberately avoiding repetition. The

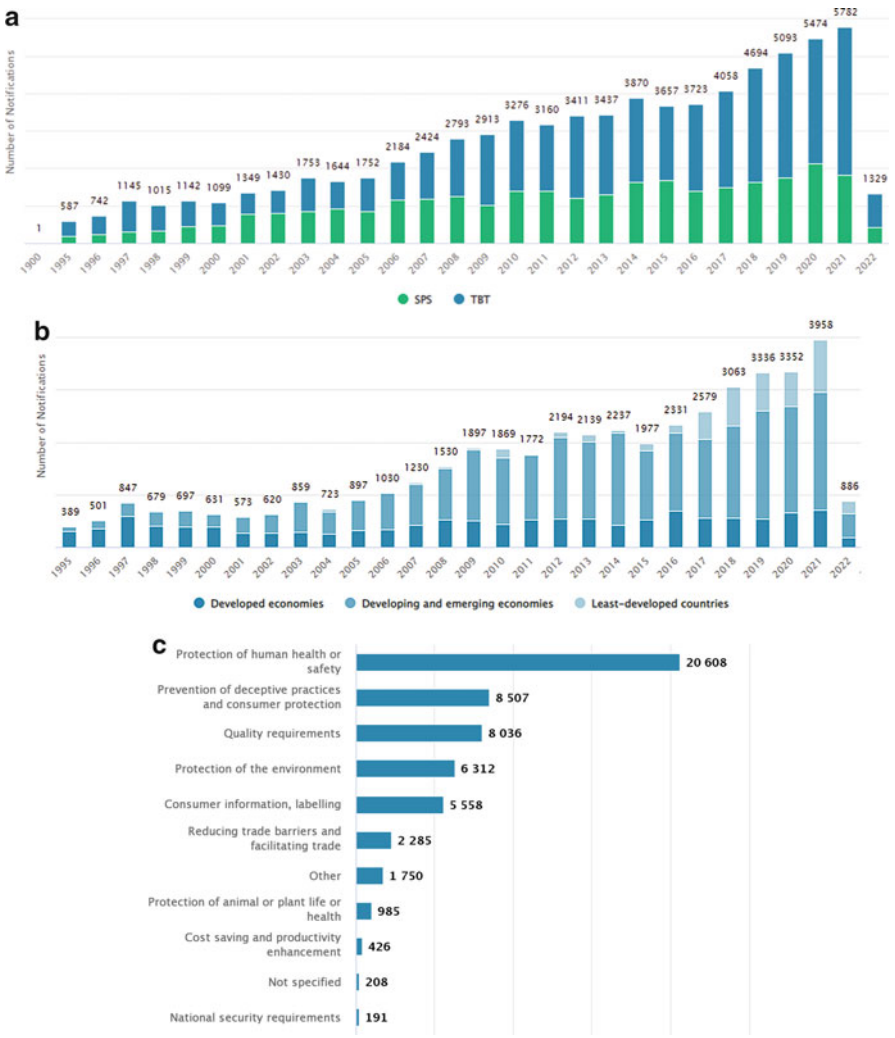

Fig. 6 WTO notifications as on 31.03.2022. (Retrieved from (https://epingalert.org/en/FactsAndFigures/Notifications))

year-wise establishments of the most influential SDOs in the field of standard formulations are summarized in Table 1. An interested reader may visit their official websites to explore more about them.

The IEC (https://www.iec.ch/homepage) is one of the preferred standard development organizations recognized by the WTO and is responsible for monitoring national and regional organizations that agree to use the IEC international standards as the basis for national or regional standards as part of the WTO-TBT Agreement. IEC and ISO and ITU (https://www.itu.int/en/Pages/default.aspx) have built

Table 1 Establishments of International standard bodies

S. no.	Institution	Year
1	International Telecommunication Union (**ITU**) Geneva, Switzerland	1865
2	International Bureau of Weights and Measures French: *Bureau international des poids et mesures (***BIPM**) Sèvres, France	1875
3	National Institute of Standards and Technology (**NIST**) Maryland, U.S.	1901
4	International Electrotechnical Commission (**IEC**) Geneva, Switzerland	1906
5	American National Standards Institute (**ANSI**) Washington, D.C., USA	1918
6	(i) International Organization for Standardization (**ISO**), Geneva, Switzerland. (ii) Association for Computing Machinery (**ACM),** New York, USA. (iii) Indian Standards Institution (**ISI**), New Delhi, India.	1947
7	Joint Electron Device Engineering Council (**JEDEC**) Arlington, Virginia, USA	1958
8	European Computer Manufacturers Association (**ECMA**) Geneva, Switzerland	1961
9	Institute of Electrical and Electronics Engineers (**IEEE**) New York, USA	1963
10	European Committee for Electrotechnical Standardization (**CENELEC**) Brussels, Belgium	1973
11	Bureau of Indian Standards (**BIS**), New Delhi, India	1986
12	Japan Electronics and Information Technology Industries Association (**JEITIA**) Tokyo, Japan	2000

strategic partnerships with the WTO. The IEC has established many standards in various fields; however, the Institute of Electrical and Electronics Engineers (IEEE) (https://www.ieee.org/) is one of the major contributors in standard development for OWC (Optical Wireless Communications) and relevant technologies.

It can be observed that the establishments of influential SDOs were started in 1865, and even India has registered its appearance in 1947 by establishing ISI which subsequently became BIS in 1986.

Standardization and Regulatory Ecosystem in India

For the understanding purpose, the overall ecosystem of standardization and regulations may be divided into three parts, i.e., (i) Acts and regulations, enacted so far to govern the system; (ii) Domestic QI, developed over the years in this arena; and (iii) Indian key players, role of BIS, QCI, NMIs, Regulators, line ministries/departments, etc.

Acts and Regulations

A comprehensive list of principal trade-related Acts/laws is given in Table 2.1 of the Trade Policy Review by WTO for India published on 16 March 2021 (Trade policy review 2021). Just for a look, the information is presented in graphical form in Fig. 7. Figure 7a illustrates the sector-wise number of Acts while Fig. 7b shows year-wise Act notifications. One can observe that maximum acts came in the segment of intellectual property rights and SPS and banking sector are having the second place. If we see the year-wise distribution, a maximum number of Acts/regulations were notified during 1992–2002 and 2002–2012 (6 Acts in the bracket of 10 years). The information indicates that we have sufficient Acts/Regulations, almost in every significant area; however, the scope of the chapter remains around Technical Regulations and related matters.

Table 2 Quality Infrastructure (QI) of India

Govt./ regulator	National standard bodies (NSBs)	Accreditation bodies (ABs)	Metrology	Conformity assessment bodies (CABs)
MoC&I	–	QCI (NABL and NABCB)	–	–

Domestic QI and Institutional Mechanism

The American National Standards Institute (ANSI) has tried to visualize the Indian institutional mechanism for Standards and Conformity Assessment Bodies (https://share.ansi.org/Shared%20Documents/Standards%20Activities/Country%20Charts%20-%20Standards%20and%20Conformity%20Assessment%20Systems/India.ppt). However, it does not capture the entire image of the system. To understand the existing ecosystem, a comprehensive ER (Entity-Relationship) diagram is depicted in Fig. 8. The figure is self-explanatory and illustrates the domestic institutional mechanism of Indian QI ecosystem with mapping of various government bodies/Regulators (R), Accreditation Bodies (ABs), Conformity Assessment Bodies (CABs), and their affiliations with international standardization organizations. Linear mapping of different major entities concerning QI components is also given in Table 2. It shows the relationship of line ministries/departments and their associated organizations/institutes, affiliation with international bodies, and WTO contact/query points.

The ecosystem indicates that a sustainable QI has been flourishing for many years; however, it was felt in Government that a concrete policy framework is required. Therefore, in this connection, a strategic development took place when India introduced the "Indian National Strategy for Standardization (INSS)" in 2018 (Indian National Strategy for Standardization 2018). It not only gives a roadmap to the policymakers or stakeholders but also indicates a strong willingness of India to emerge as a nation with zero tolerance of substandard products, processes, services, etc.

Indian Key Players

To understand the functioning of Indian quality infrastructure and conformity assessment system, one has to have a close look of its key players, i.e., BIS, QCI, NMIs, line ministries/departments, etc. Let us briefly explore some of the major entities.

Quality Council of India (QCI): For Accreditation

The QCI is an autonomous non-profit organization registered under the Registration of Societies Act. It has been established by the joint initiative of the Government of India and the Indian Industry. It is administratively and financially independent and is governed by a Council having a fair representation of the Government of India, Industry (through its associations), and other stakeholders like non-government organizations (NGOs), CABs, institutions, etc. QCI is governed by its own rules and regulations. The operational expenses of QCI and its Boards are generated through the services offered. The QCI has established the National Accreditation Board for Certification Bodies (NABCB) (https://nabcb.qci.org.in) as per the decision of the Cabinet in Feb 1996 and the Memorandum of Association of Jan 1997 to carry out accreditation of Conformity Assessment Bodies (CABs). The terms for

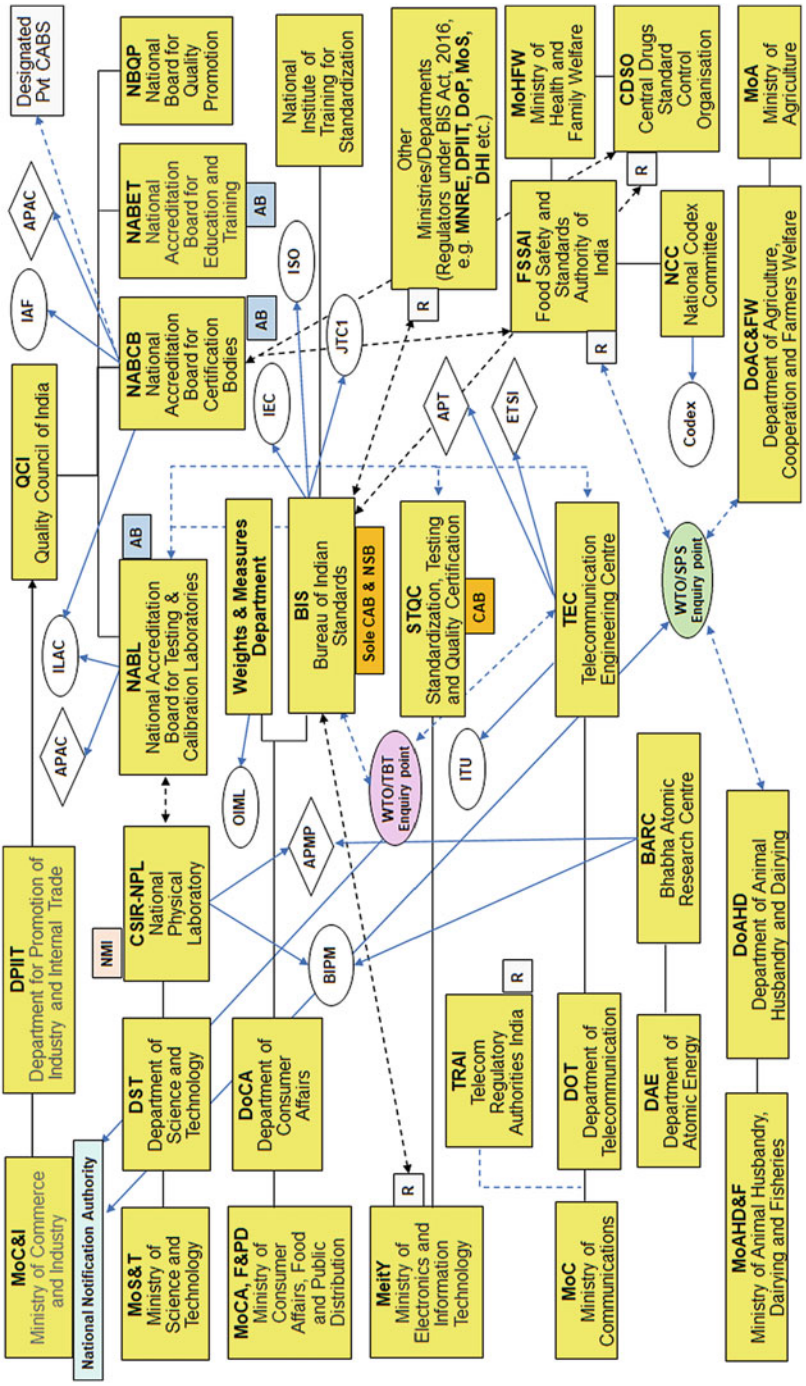

Fig. 8 Indian ecosystem of Standards and Conformity Assessment Bodies

accreditation for the various schemes are developed based on national and/or international standards or guidelines. Accreditation is generally carried out as per common international standards of ISO, some of which are listed below:

- Laboratories as per ISO 17025.
- Inspection Bodies as per ISO 17020.
- Product (which includes Process) certification bodies as per ISO 17065.
- Management systems such as ISO 9001 certification bodies as per ISO 17021-1.

Table 3 depicts a sector-wise number of certification bodies accredited by NABCB. Figure 9 illustrates the statistics graphically; one may note that maximum certification bodies are come up in the Inspection sector (Fig. 9a) while year-wise data indicates that in 2021 (Fig. 9b), the maximum number of certification bodies got accreditation.

On the other hand, National Accreditation Board for Testing and Calibration Laboratories (NABL) (https://nabl-india.org) was founded in 1988, and it is an accreditation body, with its accreditation system established following ISO/IEC

Table 3 Sector-wise number-wise certification bodies. (as on 30.03.2022, data source (https://nabcb.qci.org.in))

S.No.	Sector	Number of certification bodies
1	Environmental Management Systems (EMS)	**15**
2	Energy Management Systems (EnMS)	**5**
3	Food Safety Management Systems (FSMS)	**21**
4	Inspection Body (IB)	**85**
5	Information Security Management Systems (ISMS)	**8**
6	Information Technology Service Management Systems (ITSMS)	**2**
7	Occupational Health and Safety Management System (OHSMS)	**11**
8	Product Certification Body (PCB)	**24**
9	Certification of Persons (PrCB)	**7**

	Total =	**258**

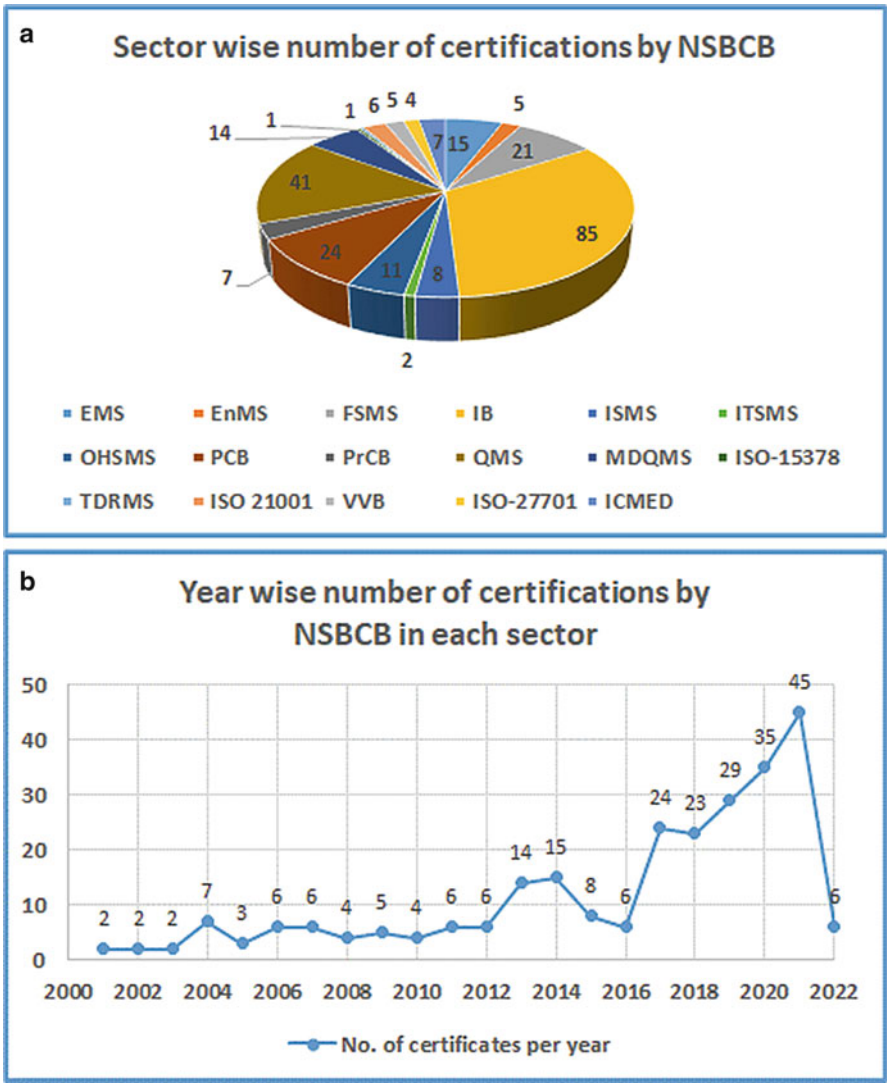

Fig. 9 Statistics of accreditation carried out by NABCB. (**a**) Sector-wise number of certification bodies. (**b**) Year-wise number of certification. (As on 30.03.2022, data source (https://nabcb.qci.org.in))

17011. "Conformity Assessment – Requirements for Accreditation bodies accrediting conformity assessment bodies." NABL provides voluntary accreditation services to different bodies in accordance with relevant standards, for instance:

Segment	Standard
Testing laboratories	ISO/IEC 17025 "General Requirements for the Competence of Testing and Calibration Laboratories"
Calibration laboratories	ISO/IEC 17025 "General Requirements for the Competence of Testing and Calibration Laboratories"
Medical testing laboratories	ISO 15189 "Medical laboratories -Requirements for quality and competence"
Proficiency Testing Providers (PTP)	ISO/IEC 17043 "Conformity assessment — General requirements for proficiency testing"
Reference material producers (RMP)	ISO 17034 "General requirements for the competence of reference material producers"

NABL has signed Mutual Recognition Arrangements (MRA) to ILAC and APAC for accreditation of Testing and Evaluation Laboratories (ISO/IEC 17025), Medical Testing Laboratories (ISO 15189), Professional Test Providers (PTP) (ISO/IEC 17043), and Reference Materials Producers (RMP). Till 2021, NABL has accredited more than 5600 labs in different fields and played an important role in creating quality infrastructure in the testing sector. Indeed, a voluntary system of accreditation has developed worldwide under the aegis of the International Accreditation Forum (IAF) for certification and International Laboratory Accreditation Cooperation (ILAC) for inspection and testing and India responded to these developments by setting up a national accreditation system in the form of the NABCB and the NABL. NABCB is undertaking accreditation of certification, and inspection bodies as per applicable international standards while NABL is devoted to accreditation of testing, calibration, and medical laboratories and related bodies. NABCB is a member of both IAF and ILAC, and NABL is a member of ILAC, and both have achieved international equivalence for their accreditations.

BIS: For Standardization

One can see in Table 1 that the Indian Standards Institution (ISI), in New Delhi, India, came into existence in 1947. In the early years, the organization focused on the standardization activity. In order to provide benefits of standardization to ordinary consumers, ISI began implementing the Certification Marks Scheme under the *Indian Standards Institution (Certification Marks) Act, 1952*. The system, officially launched by ISI in 1955–1956, enabled it to issue licenses to manufacturers who produce goods in accordance with Indian Standards and use ISI Mark in their products. To meet the requirements of the Certification Marks Scheme, the nucleus of the laboratory was introduced in 1963. While product validation was conducted under the *Indian Standards Institution (Certification Marks) Act, 1952*, however, formulation of standards and other related functions were not governed by any law. The Bill for this purpose was therefore introduced in Parliament on 26 November 1986. The BIS came into being, with an Act of Parliament dated 26 November 1986, on 1 April 1987, expanded with additional powers taking over staff, assets, liabilities, and functions of former ISI. Through this change, government aims to create a quality culture, understanding, and increased consumer participation in the formulation and implementation of national standards. The Bureau is a 25-member Body

Corporate organization representing both Central and Provincial governments, Members of Parliament, industry, science and research institutes, consumer organizations, and professional organizations. The Union Minister of the Ministry of Consumer Affairs, Food and Public Distribution (MoCA, F&PD) holds the position of President while Minister of State, MoCA, F&PD works as Vice-President (https://www.bis.gov.in).

The BIS was established under the BIS Act of 1986 for the harmonious development of the standardization activities, marking, and quality certification of goods and related matters. The BIS has been providing traceability and tangibility benefits to the national economy in many ways – providing safe quality goods, reducing health risks for consumers, promoting exports and imports substitute, controlling the growth of diversity, etc. through standardization, certification, and testing. The BIS is also known as the National Standard Body (NSB) or Standard Development Organization (SDO) of India. The BIS is involved in a variety of activities as provided below:

- Standards Formulation.
- Product Certification Scheme.
- Compulsory Registration Scheme.
- Foreign Manufacturers Certification Scheme.
- Hall Marking Scheme.
- Laboratory Services Laboratory Recognition Scheme.
- Sale of Indian Standards.
- Consumer Affairs Activities.
- Promotional Activities.
- Training Services, National and International level.
- Information Services.

The role of BIS has changed over the time; however, its primary role is to formulate and develop standards, harmonized with international standards. Interested user may explore further details on various websites of BIS. BIS has formulated 21,750 Indian standards till March 2022. Figure 10a illustrates technical division-wise published standards (data source (https://www.services.bis.gov.in:8071/php/BIS_2.0/eBIS/). Production and General Engineering Department (PGD) has the maximum number of BIS standards. To observe the trend of year-wise standard development at BIS, Fig. 10b shows statistics of standard formulation that took place during the period of 2014–2015 to 2020–2021 (Jan 21). From the data, the CAGR (Compounded Annual Growth Rate) comes to 4.62% for the period of the years 2014–2015 to 2019–2020 for total formulated standards; similarly, for the same period, the CGAR for new standard formulation comes to 7.55% and for revised standards remains 0.44% (data source (https://consumeraffairs.nic.in/sites/default/files/ReformsBIS.pdf). The data/information given in Fig. 10 indicates that we are moving fast in the standardization activities.

	2014-15	2015-16	2016-17	2017-18	2018-19	2019-20	2020-21 (Jan 21)
Total Standard formulated	746	609	722	742	881	978	613
New standards	407	336	371	450	484	630	343
Revised standards	339	273	351	292	397	348	270

Fig. 10 Status of BIS standards. (**a**) Technical division-wise published standards. (**b**) Standard formulation statics

Technical Regulations: Major Key Players Are Ministries/Departments

A technical regulation is a government document that sets out the features of a product or process that are consistent with the production processes, including operational management provisions, for which compliance is mandatory. Although compliance with standards is voluntary, technical regulations are by nature mandatory. For instance, you may have noticed that on most of the products (on their

packaging or both), apart from other information, there are specific markings (see Fig. 11). Whether it is an appliance, good products, or electronic gadgets, one can observe ISI mark, vegetarian or non-vegetarian mark, and several other symbols or marks. Why are these symbols or marks printed on the product label? What messages do these signs convey to consumers? A careful buyer knows the value of these marks when buying any item. For example, Fig. 11 illustrates the standard marking on the cable (Fig. 11a) of a microwave oven, food containers (Fig. 11b), and electronic gadgets like bluetooth speaker (Fig. 11c), laptop (Fig. 11d), and mobile phones (Fig. 11e, f).

A standard mark (https://www.thecro.in/wp-content/uploads/2017/03/Standardization-Marks-.pdf) is a mark/symbol given to a product, which meets certain quality standards in terms of materials, production methods, labelling, packaging, safety, and performance. In order to obtain a standard mark, the manufacturer/importer must follow the process of conformity (i.e., conformity assessment procedure) in the country when they want to sell/import products. Product conformity is assessed by

Fig. 11 Standard marks/symbols of different products

accredited national/international organizations before being marketed. It needs to show that all legal requirements (i.e., testing, testing, certification, etc.) are met. The process for each product is specified in the applicable product law. In other words, these standard marks/symbols reflect specific management/regulatory measures taken by a particular country/region to ensure the quality and safety of products exported/sold locally or internationally.

Let us take a sector-specific example. Table 4 depicts different popular standard marks issued from different countries/international regulators/standard bodies specifically for electronics and IT products. Figure 11d, e shows the background view of two popular electronic gadgets, namely, laptop and mobile, respectively. In Fig. 11d, some international standard marks/logos can be viewed on a laptop. In Fig. 11e, one can observe the CRO (Compulsory Registration Order notified by MeitY) marking on the lower part of the mobile. The cut-off part of the marker is also displayed in the inset to clarify details. Figure 11f shows an example of e-labelling in mobile phones.

Table 4 Standard marking in the ICT world, as a symbol of quality and safety

Sr. No.	Marking/ Legal status	International body/ Country	Year	Products group
1	"Underwriters Laboratories" (*Voluntary*)	American safety consulting and certification company (USA)-Private, LLC	**1894**	Standards for Electrical and Electronic Products
2	(*Voluntary*)	Canadian Standards Association (Canada) -Standards Council of Canada	**1946**	Electrical and Electronics
3	"European Conformity" (*Mandatory*)	European Commission (EU)-Govt.	**1985**	Low voltage (*all electronics goods*)
4	"Federal Communications Commission" (*Mandatory*)	FCC Declaration of Conformity (USA)-Commission	**1998**	Electronic products
5	"China Compulsory Certification" (*Mandatory*)	China Compulsory Certification (China)-Bureau	**2002**	Low voltage & IT products
6	"Compulsory Registration Order" (*Mandatory*)	Electronics and Information Technology Goods (Requirement for Compulsory Registration) Order, 2012	**2012**	Electronic & IT products
7	**EMC** "Electromagnetic compatibility" (*Voluntary*)	European Commission (EU)-Govt.	**2014**	Electronics equipment

The "*Electronics and Information Technology Goods (Requirements for Compulsory Registration) Order, 2012 (CRO)*" was notified by the Ministry of Electronics and Information Technology (MeitY) on 03 Oct. 2012 under the provision of "Compulsory Registration Scheme (CRS)" notified by BIS under BIS Act, 1986 & Rules, 1987 (now CRO – 2021 has suppressed the Order under BIS Act 2016, Rules & BIS (Conformity Assessment) Regulations, 2018). The order was aimed at addressing consumer safety issues in India and curbing the entry of substandard electronic products into the country. The product categories are covered under CRO in a phased manner. To date, 63 product categories have been covered under the ambit of the Order, and it has come into effect for all the notified product categories. In accordance with CRS, a manufacturer seeking registration of notified goods must get tested its products in BIS recognized laboratories and is required to apply for registration at BIS along with test report and required documents. Once his registration has been granted under CRS, BIS issues a unique registration number (R. No.). Thereafter, the manufacturer can affix standard BIS marks on its products. An example is shown in Fig. 11e where "R-xxxxxxxx" shows R. No. and "IS xxxxx, which" reveals a certain "Indian standard" (e.g., a real world standard marking is shown in Fig. 11f) for which the product complies. A list of all notified products and other scheme details can be viewed on the MeitY website (https://www.meity.gov.in/esdm/standards). It would be pertinent to mention that the CRO is the first registration scheme which is based on self-declaration of conformity for goods notified by MeitY.

The BIS Act, 2016, enables various Ministries/Departments to notify theirs own regulations, which are also termed as QCOs (Quality Control Orders). Figure 12 illustrates the year-wise product coverage and number of notifications of QCOs. In this regard, it is pertinent to mention that most of the QCOs are notified under BIS Act 2016. According to the information available at (https://www.bis.gov.in/index.php/products-under-compulsory-certification), around 104 QCOs have been notified till March 2022 covering 460 product categories. Figure 12 indicates that the maximum number of QCOs was notified in 2018 while the maximum number of products covered under QCOs in 2020. Figure 13 depicts the scenario of sector-wise yearly QCO notifications and product coverage. One can observe that the maximum number of products covered under QCOs pertains to the segment of Steel and Iron products while the electronics and IT and Chemicals, Fertilizers, Polymers, and Textiles hold second and third positions, respectively. Figure 14 shows product category-wise number of operative licenses granted by BIS till March 2022, i.e., total, 19,968 (Nos.) for 64 countries (https://www.crsbis.in/BIS/publicdashAction.do?hmode=getProductCategory).

Apart from the above, "Mandatory Testing and Certification of Telecom Equipment (MTCTE)" launched by the Department of Telecommunications (DoT), Ministry of Communications in 2019 mandating certifications for telecom products under the provision of *The Indian Telegraph (Amendment) Rules, 2017* (https://www.tec.gov.in/mandatory-testing-and-certification-of-telecom-equipments-mtcte) covering around 53 product categories till Sept 2021.

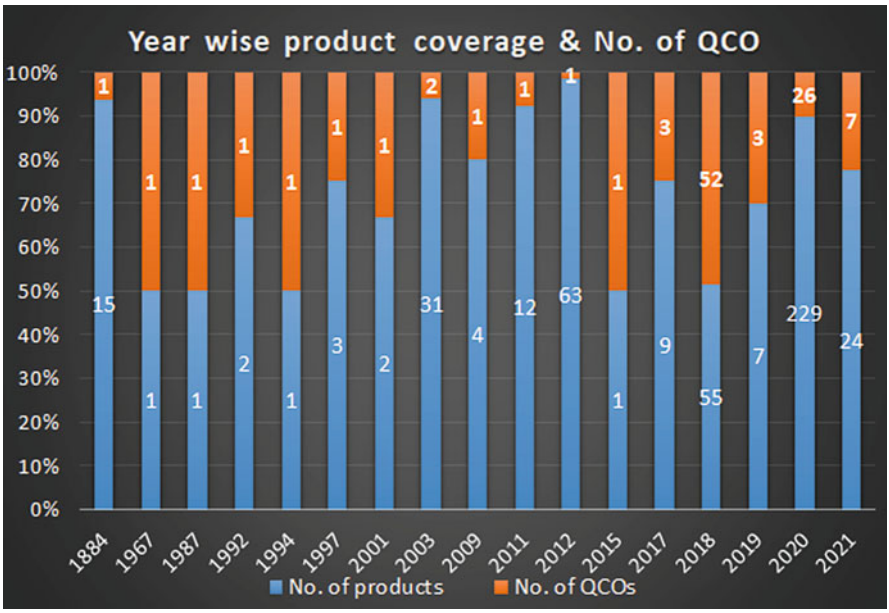

Fig. 12 Year-wise product coverages and no. of QCOs notifications. (*Data source: The number of products and QCOs are counted from the publicly available data on BIS website* (https://www.bis.gov.in/index.php/products-under-compulsory-certification)

Market Surveillance in India

Market surveillance (MS) is one of the major challenges in implementing any regulation. The emergence of eCommerce platforms has made the situation more complex for all regulators across the globe. The architecture and implementation mechanism of MS depends on various factors, country/region-specific administrative structure, socio-economic conditions, adoption of technologies, etc. Since, earlier we have drawn reference from the EU model (see Fig. 4) of MS, for understanding purpose, we may compare the system with the domestic ecosystem of MS on certain parameters.

Parameter	MS model of EU	India (generic view)
Administrative architecture	Group of countries	Single country having Central and State governments
Cartelized or distributed system	Centralized, using RAPEX	Distributed
eCommerce compatibility	Not observed in the publicly available model	Still, it is a challenge
Type of legislations for standardization	EU Directives are used by all members	Technical Regulations have been enacted under different Acts, e.g., BIS Act, 2016, Indian Telegraph Act 1885, etc.

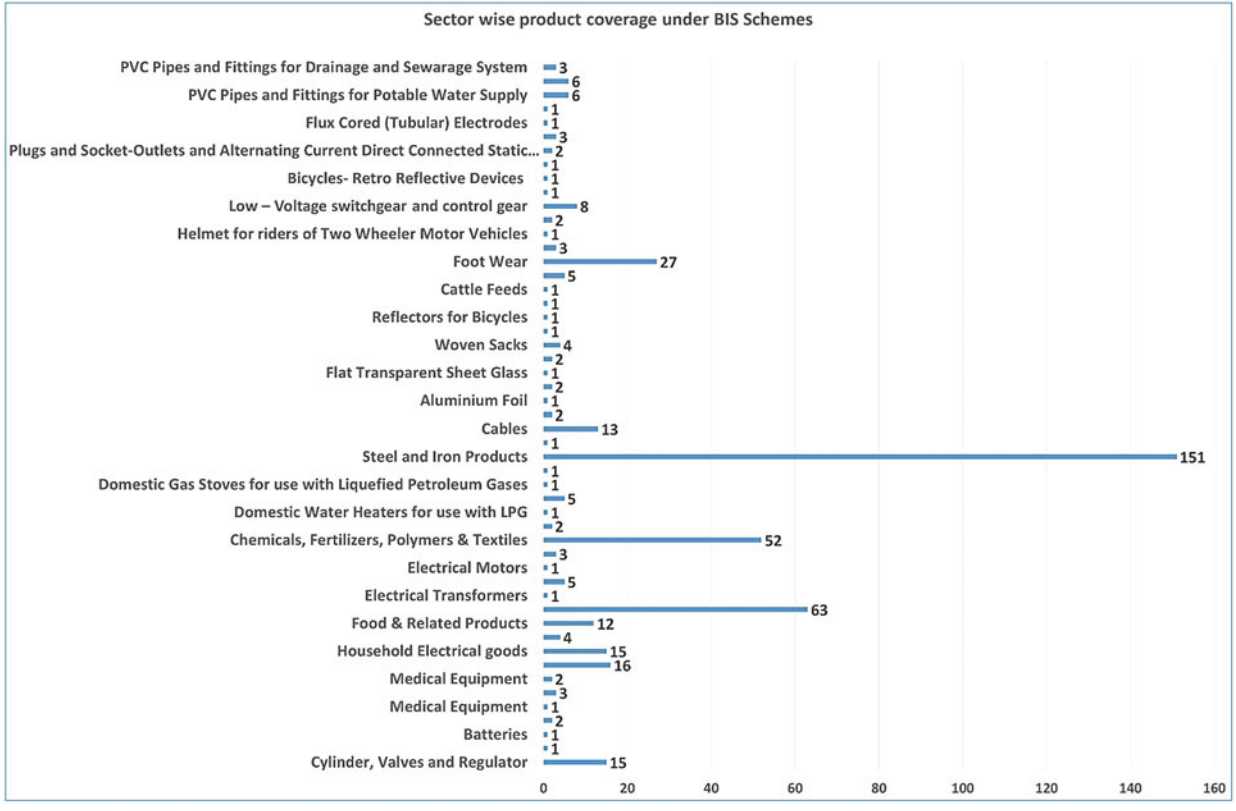

Fig. 13 Sector-wise product coverages and no. of QCOs notifications. (*Data source: The number of products and QCOs are counted from the publicly available data on BIS website* (https://www.bis.gov.in/index.php/products-under-compulsory-certification))

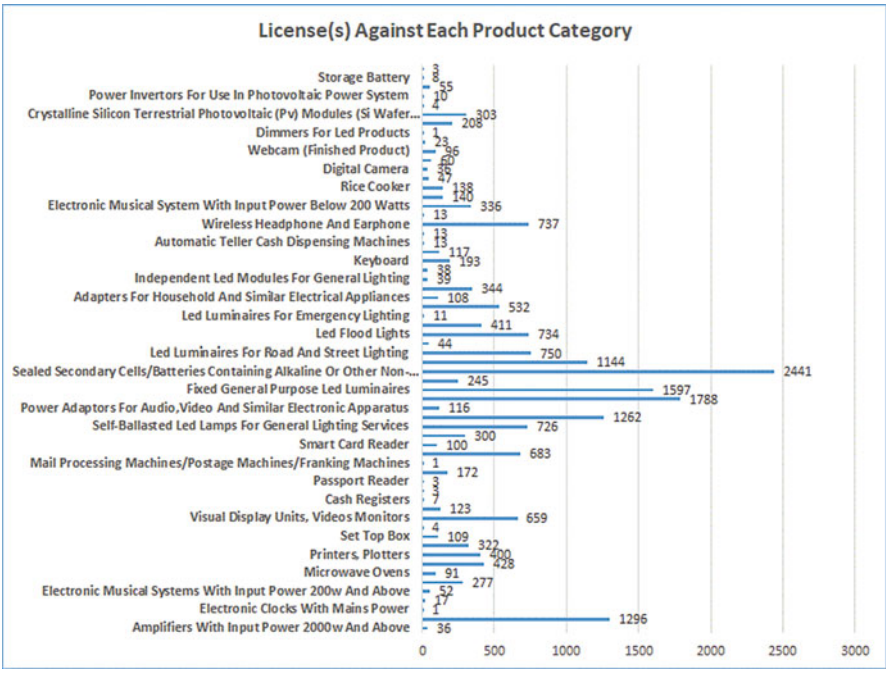

Fig. 14 Product category-wise number of operative licenses granted by BIS till March 2022. (Data source (https://www.crsbis.in/BIS/publicdashAction.do?hmode¼getProductCategory))

The above comparison is self-explanatory. There is a difference in administrative architecture between the EU and India. The MS model of the EU is a centralized system, controlled by RAPEX. The RAPEX is a comprehensive EU wide-ranging program for exchanging quick information on products (other than food, medicine, and medical equipment) that are found to endanger health and/or safety. The product list is reviewed by the European Union weekly, and previously issued warnings may be reviewed. Such type of system does not exist in India.

Unlike in the EU, in India, since the technical regulations have been enacted and implemented under different Acts, their implementation and market surveillance mechanism are non-identical and taken care of by respective authorities. For example, most of technical regulations are notified by sector-specific ministries/departments/authorities under BIS Act, 2016. Except for a few instances, for all these technical regulations, the market surveillance activity is carried out by BIS. As per the provisions of the BIS Act 2016, the BIS becomes the authority by default to initiate market surveillance; notwithstanding, it may delegate powers to the concerning line ministry/department to do so. Accordingly, in some cases, the sector-specific line ministries/departments/authorities also do market surveillance for their notified products, e.g., MeitY has its surveillance mechanism for the products categories notified under CRO.

Other Indian Acts are also being used to enact technical regulations, for example, in the Telecom sector, MTCTE has been established by DoT mandating certifications for telecom products under the provision of the Indian Telegraph (Amendment) Rules, 2017; its implementation part is taken care of by them only.

CSIR-NPL/BARC and DoCA: For Metrology

The CSIR-NPL (or NPLI) (https://www.nplindia.org/) is the National Measurement Institute (NMI) of India. It was created in 1956 by an Act of Parliament, Legal Metrology, Government of India. It operates on all seven basic SI units and their derivates, excluding ionization radiation. Bhabha Atomic Research Centre (BARC) (http://www.barc.gov.in/) was established as a DI (Designated Institute) in 2003 to deal with ionization radiation. The CSIR-NPL is a member of BIPM, a signatory to the International Committee of Weights and Measures – Mutual Recognition Agreement (CIPM MRA) (https://www.bipm.org/en/cipm-mra/) – and a founding member of the Asia Pacific Metrology Program (APMP) (http://www.apmpweb.org/), one of the six Regional Metrology Organizations (RMO). The role of BIPM and RMOs is to homogenize accurate and precise global measurement capabilities with NMIs. The Joint Committee of RMOs and BIPM (JCRB CIPM) analyzes the CMCs (Calibration and Measurement Capabilities) of NMIs and posts the information on the BIPM Key Compatibility Database (KCDB-BIPM) website (https://www.bipm.org/documents/20126/43742162/CIPM-MRA-G-13.pdf/f8b8c429-42e0-4cf1-dc6c-bc60ab7f371a). CMCs have a very high standard of measurement and calibration, guaranteed by the institution to clients of their metrological services, in the form of extended uncertainty of measurement results.

Legal Metrology is the application of legal requirements to measurement and measurement tools. Indeed, a clear and effective legal metrology system promotes confidence in businesses, industries, and consumers and provides a harmonious environment for doing business. In India, this work is being done by the Department of Consumer Affairs (DoCA) (https://lm.doca.gov.in/index.aspx#). The Legal Metrology Act, 2009, received the President's approval on 13 January 2010 and came into effect on 1 April 2011. Details of the measuring instruments are set out in the Legal Metrology (General) Rules 2011. The DoCA performs various metrology functions through its attached/sub-offices, namely, Regional Reference Standard Laboratories (RRSLs) and the Indian Institute of Legal Metrology, Ranchi. Figure 15 illustrates the major components of the legal metrology.

Growth Avenues and Challenges for India

Despite being a developing economy and having a typical socio-economic environment, India has shown tremendous social and economic growth year by year. A similar pattern of such advancement can be observed in the cultivation of standardization and the regulatory ecosystem of India. Some viewpoints in this regard are as follows:

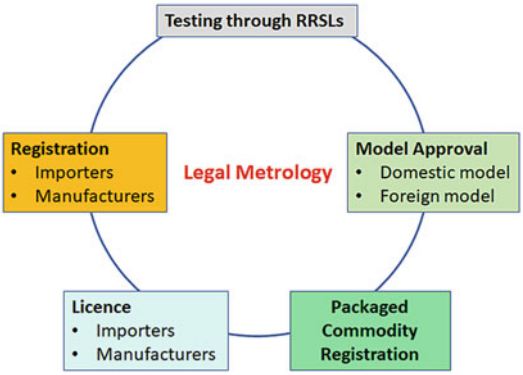

Fig. 15 The major components of legal metrology

Major Positive Nodes

(a) In case, one evaluates the progress under the ambit of the Industrial revolution, i.e., Industry 4.0, where the advancement of ICT is at its core. In this department, India has registered remarkable progress. Digital India is one of the major schemes of the Indian government, having a motto of "Power to Empower" (https://digitalindia.gov.in/content/programme-pillars).

(b) Indian progress has been noticed by IMF (International Monetary Fund). According to its report on "Global Trade Liberalization and the Developing Countries," the progress of integration has been very impressive in a number of developing countries in Asia, and, to a lesser extent, in Latin America. These countries have been successful because they have chosen to participate in international trade, helping them to attract a large portion of FDI. This is especially true of China and India as they embrace trade liberalization and other market-based reforms (https://www.imf.org/external/np/exr/ib/2001/110801.htm).

(c) The World Bank Group (WBG)'s Doing Business Report (DBR) sets the standards for business regulations in 191 economies. The DBR measures regulations that promote business activity and those that oppress them. The Easy of Doing Business (EoDB) index is a standard program developed by WBG where "higher rankings" reflect the best, usually the simplest, regulations for business and strong protection of property rights. India's rank in DBR-2015 was 142 out of 190 economies. This reached at 63rd Position in DBR-2020 released in October 2019. This is a considerable improvement of 79 positions from DBR-2015. In addition, in the ECI (Enforcing Contracts Indicator), India gained 163th position in DBR-2020, an increase of 23 positions from 186th in DBR-2015. One note that ECI is critical to the success of the Doing Business. It measures the time and cost of resolving a trade dispute and a series of good judicial processes (https://doj.gov.in/eodb/).

(d) The progress of the domestic QI ecosystem has been acknowledged by international agencies. For example, a study conducted by the German side for the

Global Quality Infrastructure Index (GQII) has placed India in seventh position for standardization, ninth position for accreditation activities, and 19th position for Metrology-related activities. India has scored 95.6 points out of 100 and is ranked tenth in the global list for overall QI ecosystem development (https://pib.gov.in/PressReleaseIframePage.aspx?PRID=1798826#:~:text=India%20scored%2095.6%20out%20of,infrastructure%20environment%20in%20the%20country).

(e) Awareness level is gradually increasing; people are now noticing the standard marks (e.g., ISI, BIS, FSSAI, etc.) on the products/appliances they are purchasing.

Major Challenges

(a) According to an India-specific report, the latest WTO data indicates that India's average bound tariff rate is 48.5%, while its simple MFN (Most Favoured Nation) average applied tariff is 13.8%. Therefore, it has a higher tariff rate than any other major economy. Despite its target to match the ASEAN (Association of Southeast Asian Nations) tariff rates (approximately 5 percent on average), the basic customs duty is not reduced systematically by India in the past 6 years (https://www.privacyshield.gov/article?id=India-Import-Tariffs#:~:text=According%20to%20the%20latest%20WTO,WTO%20latest%202017%20data%20available). Notwithstanding, subject experts believe that India is not a tariff king (https://economictimes.indiatimes.com/news/economy/foreign-trade/india-is-not-a-tariff-king-has-the-right-to-protect-specific-sectors-under-wto-experts/articleshow/68974070.cms). Whatever the contradictions and differences in opinions, at least one thing is clear this segment requires rationalization without harming the interests of domestic industry.

(b) A recent report by ICEA (India Cellular & Electronics Association) indicates that high import tariffs can negate PLI (Production Linked Incentive) and adversely impact competitiveness and scale (https://icea.org.in/wp-content/uploads/2022/01/Report-by-ICEA-on-Detailed_Tariffs-Drive-Competitiveness-and-Scale_06022022.pdf). One may note that the PLI Schemes are the most ambitious schemes of the Government. A calibrated approach needs to be taken up to be comparative in the world trade arena.

(c) As we have discussed in section "Trade Dynamics and WTO" that NTBs are taking over TBs in international trade, TBTs are raising in developing economies than in developed economies (Fig. 6b); a similar pattern may be observed in the Indian scenario (Figs. 12 and 13). The raise in NTBs is mounting pressure on the government and implementing agencies. Moreover, it is increasing STCs in WTO.

(d) QI has been flourished in India; however, nevertheless it becomes complex system (Fig. 8). Robust coordination among different entities is challenging task.

(e) Enforcement of any regulation at the root level remains a challenge for any regulator/enforcement agency. Robust coordination among Central/State,

autonomous bodies, and other implementing agencies requires more attention and an effective mechanism.

(f) Surveillance is an essential part of any regulatory activity. Developed economies like the EU have implemented RAPEX (Rapid Alert System for dangerous non-food products) to provide a means for the rapid exchange of information between the Member States and the Commission on preventive and restrictive measures taken concerning consumer products posing a serious risk to the health and safety of consumers. On contrary, such a system or similar mechanism is missing in India. The surveillance is either done by BIS or in some cases by line ministries/departments/authorities. This section of the regulatory activities requires more attention and a rubout and effective mechanism.

(g) Surveillance of eCommerce platforms is another emerging challenge across the globe.

(h) Largely it is understood that conforming to International/national standards may resolve a majority of issues. However, it is not completely true. One of the important issues is compliance with different conformity assessment procedures adopted by various countries. It remains one of the major challenges while doing bilateral/multilateral FTA (Foreign Trade Agreement). QCI is working hard to strengthen the accreditation system but has a long way to go.

(i) Centralized data resource is one of the issues where immediate attention is required. For example, the data related to incident reporting for health hazards from any product/appliance, service, or process is one of the helping tools to carry out a risk assessment before taking any regulatory measure. In such a situation, either the data is not available at all or not accessible as and when required. Similar scenarios may also be observed for production data, which is one of the basic components for impact analysis for FTAs under consideration.

Conclusion

The chapter not only provides a holistic overview of major verticals and components which are instrumental in the standardization and regulatory ecosystem but also illustrates the unique strength of India and its hard willingness to cope with challenging conditions and flourish in dynamic situations. India is one of the biggest democracies in the world and striving hard to establish itself as a responsible trade player in the world arena without compromising its heritage value system.

Abstract

Sanctity of calibrations is essentially required to produce products of reliable quality at affordable prices for the international market. India has to compete with the global players in every field of export of goods right from medical equipment to test and measuring instruments to military armaments to agriculture produce. The western countries including the United States, Russia, China, Japan, Eastern and Western Europe, and the United Kingdom are much ahead of India in producing higher quality of products. The Government of India has established coordination among the National Physical Laboratory, the Quality Council of India, the Bureau of Indian Standards, and the National Accreditation Board for Testing and Calibration Laboratories to create quality infrastructure in the country to enable and empower the private, public, industrial, and defense organizations

to produce internationally accepted quality products for augmentation of foreign exchange through export of made-in-India products. This chapter also discusses the gray areas in calibration and measurement domains which needs earnest attention of all the stakeholders.

Introduction

The contours of global trade and commerce are witnessing a metamorphic transformation in the wake of increasing demand for quality and reliable products at affordable prices. It has compelled every nation in the world to strengthen its quality infrastructure to enable the industry to manufacture and produce globally competitive quality products. Metrology – the science of measurement – involves calibration and standardization of measured results of the measuring instruments used in the production processes. The International Organization for Standardization (ISO) at Geneva, Switzerland, has established ISO/IEC 17025:2017 (ISO 2017) Standard which stipulates General Requirements for the Competence to carry out tests/calibrations including sampling. This standard stipulates the protocols for carrying out various tests pertaining the strength of materials, material microstructure examinations, electrical insulation, and other relevant testings required for ensuring the reliability and safety of electrical installations, food, food grains, soil, water, and environmental parameter testings to determine the levels of toxicity arising out of heavy metals or their traces existing in food grains or edible products and water table contaminations, levels of toxic gases in the atmosphere to determine the levels of air pollution, and calibration of all measureable physical scalar and vector parameters like AC/DC voltage, current, temperature, mass, weight, pressure, flow, force, etc. employing both standard and nonstandard methods. The nonstandard methods are those methods which have been developed by the laboratory itself and can demonstrate repeatable and verifiable results inside an accredited laboratory and all the organizations engaged in the production of products. The primary objective of establishing ISO/IEC 17025:2017 standard is to establish a process which can ensure and deliver quantifiable quality product.

Looking into the emerging trends in international co-manufacturing in various countries on 16 November 2018, during the 226 *Conference Generale des Poids et Mesures* (CGPM) Meeting held at Versailles, France, 60 member states voted for a landmark revision of the SI units on the basis of fundamental constants that describe the natural world (Aswal 2017). The seven SI units which have been considered and ratified in the CGPM are (1) second (*s*), cesium hyperfine frequency (v_{Cs}); (2) meter (m), the speed of light in vacuum (c); (3) kilogram (kg), the Planck constant (*h*); (4) ampere (*A*), the elemental charge (*e*); (5) temperature (*T*), the Boltzmann constant (*k*); (6) mole (*mol*), the Avogadro constant (N_A); and (7) Candela (*cd*), the luminous efficacy of a defined visible radiation (Kcd). According to the CGPM mandate, the values of these natural constants have been fixed without any uncertainty by all the national metrology institutes (NMIs) all over the world (Fig. 1).

Fig. 1 SI unit

Accordingly the National Physical Laboratory in tandem with the Bureau of Indian Standards (BIS), the Quality Council of India (QCI), and the National Accreditation Board for Testing and Calibration Laboratories (NABL), the Government of India, New Delhi, have generated a synergy to strengthen the quality infrastructure in India. In order to ensure the acceptance of test/calibration certificates issued by the accredited conformity assessment bodies (CABs) around the world, NABL has endeavored to establish linkages with the international bodies, viz.

- International Laboratory Accreditation Cooperation (ILAC)
- Asia Pacific Accreditation Co-operation (APAC)

As such, now NABL is a fully fledged member of ILAC and APAC and periodically participates in the meetings of ILAC and APAC.

The NABL is Mutual Recognition Arrangement (MRA) Signatory to ILAC as well as APAC for its accreditation programs – Testing and Calibration (ISO/IEC 17025), Medical (ISO 15189), Proficiency Testing Providers (PTP) (ISO/IEC 17043), and Reference Material Producers (RMP) (ISO 17034).

Such international arrangements/MRA are based on peer evaluation and acceptance of other MRA partner accreditation systems. MRA facilitate acceptance of test/calibration results between countries which MRA partners represent (NABL).

The Mutual Recognition Arrangement accords the acceptance of NABL Calibration Certificates issued by the CABs all across the world which inter alia provides a definite degree of reliability stating and affirming the quality of the product through measurable calibrations and testing through reliable tests mentioned in the test and calibration certificates, compliant to ISO 17025:2017 Standard accompanying the product.

It is worthwhile to mention that the export worthiness, acceptability, and visibility of Indian products in the western markets have certainly improved because of their compliance to international standards and affordable/competitive prices. Concurrently the confidence of the manufacturers and investors of the western world has

considerably enhanced toward the capacity and capability of the Indian manufacturing capacity and infrastructure. They are increasingly shifting their manufacturing plants from China to India. Some of western companies have now their plants either in free trade zones in India or the industrial estates in various states (FinEmergia).

In consonance and continuation of the efforts to strengthen the quality infrastructure in India, the Government of India has established four Electronics Regional Test Laboratories (ERTLs) in the eastern, western, northern, and southern parts of India, the India National Test Houses in different parts of India, host of Electronics Test and Development Centers (ETDCs) at the state levels, the defense laboratories of the Defence Research Development Organisations (DRDO), and the laboratories of the Bureau of Indian Standards (BIS) to offer and provide testing and calibration facilities for the master calibration standards used in the accredited calibration laboratories (CABs) in India.

There is a high number of laboratories in the country to generate accurate and precise measurement values beginning right from the National Physical Laboratory, New Delhi – the NMI of India down to the ERTLs, ETDCs, DRDOs, BIS, NABL-accredited testing and calibration laboratories, and the calibration laboratories at the shop floor level in a large number of industrial and business organizations engaged in the production and trading of products. To generate awareness about the significance, relevance, and validity of the unbroken chain of traceability, the NPL has established a landmark traceability pyramid as a beautiful landmark right inside the campus of the NPL. Figure 2 demonstrates the purpose of establishing the traceability pyramid. Similarly another landmark the wall of SI units has been established at the campus of CSIR-NPL, New Delhi, showing the relationship between the SI units of measurement and fundamental constants (Wikipedia). In fact, the NPL is conducting all these initiatives to fulfill the core mandate given to the NPL to maintain the fundamental and derived units and to further conduct research, design, and development activities to develop new products which shall be relevant and commensurate to the Indian conditions. Such NPL-developed products shall lead India to the Mission of Self-Reliance (Atmanirbhar Bharat) mandated by Mr. Narendra Modi, Honorable Prime Minister of India, to make the nation self-reliant in the production of instruments, equipment, armament, food grains, fruits, and various industrial and commercial products and to further empower Indian industry to export its products to overseas countries which are affordable and command world-class quality. It is extremely important to recognize the rich availability of potentially strong skilled, qualified, young, and brilliant human resource in India. Today no other country in the world has such a large reservoir and demographic dividend of young Indian citizens that can match India. Further this initiative and thrust on self-reliance shall earn foreign exchange revenue and minimize dependence on the imported products.

The NPL has mentioned that the measurement traceability can be obtained through two routes: (i) calibrate the measuring instruments through working standards at the shop floor level, reference standards, and secondary and primary standards to the SI units. In simpler terms, an instrument making, measurements at

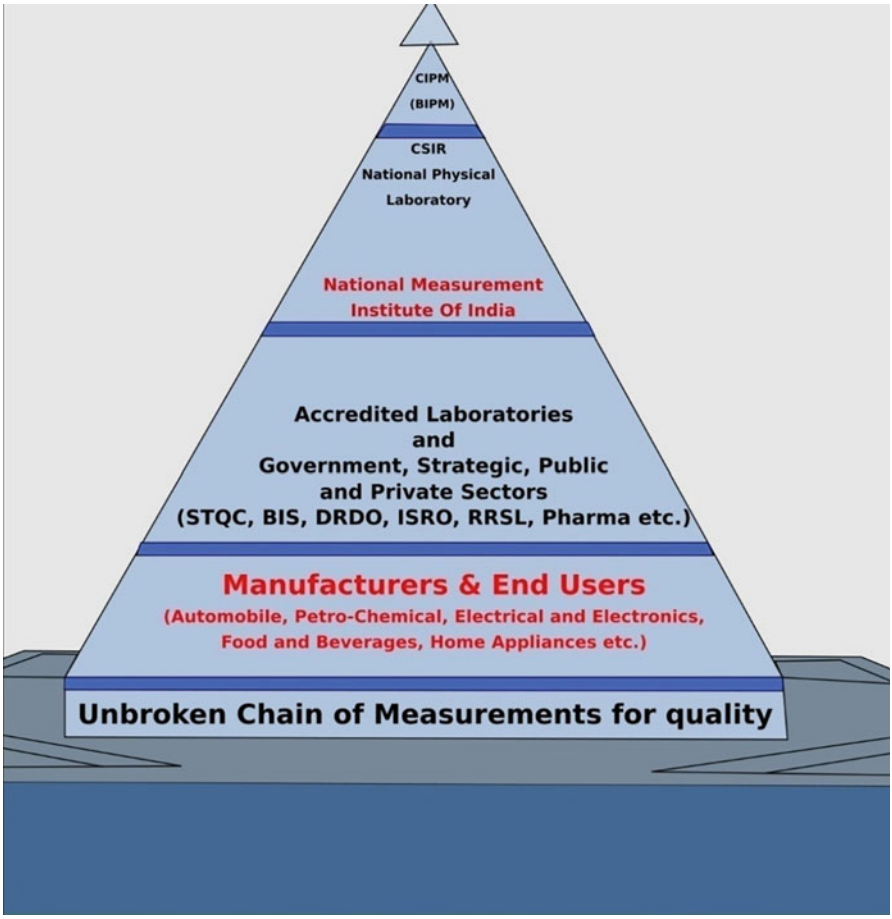

Fig. 2 Traceability pyramid

the shop floor in an industry can ensure the uncertainty in its measurements which are traceable to the SI standards maintained at the international level (Aswal 2020).

Currently the international perception on quality of Indian products is very low as against the other developed nations of the world. This fact is amply proven that the present calibration and measurement capabilities (CMCs) (BIPM) of India are much lower as against the National Metrology Institutes (NMIs) of select developed countries. For example, the CMCs of NMIs of the United States (1889), China (1554), Japan (1126), Germany (1563), the United Kingdom (1137), and India stand at 236. The larger the number of CMCs, the greater is the measurement capabilities of a nation of international equivalence in different areas of science and technology. Thus, India has to go a long way in establishing the credentials of its capacity to produce goods of international standards of quality and reliability which inter alia means that the sanctity of calibration and testing as per ISO 17025:2017 Standard

shall directly determine the quality of our export-worthy products both in terms of revenue and volumes.

Accordingly the NPL has calibrated its response, initiatives, and thrust to fulfill the Atmanirbhar Bharat Mandate. It is extremely important to recognize the rich availability of potentially strong skilled, qualified, young, and brilliant human resource in India. Today no other country in the world has such a large reservoir and demographic dividend of young Indian citizens that can match India. Further this initiative and thrust on self-reliance shall earn foreign exchange revenue and minimize dependence on the imported products.

Today India has already become the exporter of armaments to various countries. India has conventionally been one of the largest importers of armaments from Russia, France, the United States, and the United Kingdom, but this scenario is changing very fast. Now India is registering consistently rising progress in exports of armaments to developing as well as developed nations of the world like Finland, Germany, Sweden, France, Australia, the United States, and South Africa.

Minister of State for Defence, Shripad Naik (2019–2021) in a written reply to Rajya Sabha has mentioned in Parliament that the "cost of the items and quantum of foreign exchange earned varies from company to company."

Indian Ordnance Factories are supplying 5.56 × 45 mm Ball MK N (SS 109) cartridges, hard armor plates, and protective head gears for police and armed personnel to counter enemy in the battlefield and for police to control mob attacks. Of late the light combat aircrafts and the BrahMos missiles are among the highly sophisticated airborne warfare equipment (Fig. 3).

Indian exports to Qatar, Lebanon, Iraq, Ecuador, Uruguay, Japan, and Egypt primarily comprised body protecting equipment, said the Minister in his written response to Parliament.

Under the "make-in-India" flagship program in 2014, the Government of India has been emphasizing the need to increase the production of defense equipment in India and to create and strengthen the country's manufacturing infrastructure to provide more employment and to reduce foreign exchange import bill of India. It is noteworthy that India is the second largest importer of defense equipment next to Saudi Arabia in 2019, according to the Stockholm International Peace Research Institute.

Fig. 3 BrahMos missile and light combat aircraft. www.timesofindia.com

Prime Minister Shri Narendra Modi has told that the export of defense equipment from India stood at ₹2000 crore in 2014. Right from 2018 onward, the Indian export of armaments has gone up to ₹17,000 crore, and by 2024, India aims to hit a target to export of US $5 billion worth of military hardware which is about ₹35,000 crore (Roche 2020).

Calibration and Its Role in Industry

Calibration is an activity performed under the stated environmental conditions and adhering to the relevant ISO standards by a set of trained, skilled, and qualified personnel who are engaged in comparing a device under test (DUT) of an unknown value with a reference standard of a known value. The primary objective of calibration is to assess and estimate the error or determine and verify the accuracy of device under test in terms of measurement value of an unknown value.

Sanctity of Calibration: Case Study Pressure Gauges (PTB 2014)

Here is the example of calibration of a pressure gauge demonstrating how to maintain the sanctity of calibration as per the standard DKD-R-6-1 and obtain precision measurement results with known uncertainties.

This procedure of calibration is followed at an ISO 17025:2017-compliant NABL-Accredited Calibration Laboratory for the calibration of pressure gauges as per DKD-R-6-1 standard. The details provided for the working instructions have been carefully written to take care of every element and protocol of DKD-R-6-1. It will be observed that each and every step starting from the preparing the system/priming the system to start calibrations has been clearly specified. The necessary instructions and environmental conditions have been stipulated. Then, during the process of calibration, whatever requisite care is to be maintained for the application of pressure, concurrently both on the master pressure gauge and the unit under calibration (UUC), is described. At the end of the working instructions, even a tool kit has been mentioned at 2.6 which should be carried for on-site calibration of pressure gauges.

Technical Capabilities and Scope of Work of the Metrology Laboratory

The calibration work done by an accredited laboratory as per NABL Calibration Protocols and as per DKD-R 6-1 Standard.

Procedure

The Metrology Laboratory is well equipped with the standards to cover its full scope of calibrations at metrology laboratory as well as on site.

1. The Instrument for calibration (unit under calibration) is received by stores. Then, it is sent to the quality assurance department through tracer card and proper identification tag. The Quality Assurance Manager registers the case in Equipment Repair and Calibration File.
2. The Quality Assurance Manager sends all communication to customer, related to instrument's calibration, through designated file.
3. As soon as the technical and commercial terms are cleared from customer end, instrument is given to the Technical Manager for calibration. After calibration, the instrument is sent back to Quality Assurance Manager for further actions.

A few examples have been given herein which explain the procedure/method of carrying out the calibrations:

(a) The calibration of the instrument is performed as per calibration procedures.
(b) The UUC is inspected and checked for:
    - Physical damage for pointer/indicating needle, threads, sealing surface, and pressure channel
    - Cleanliness and readability of indications
    - Zero adjustability/null position
    - Operating instruction (if required)
(c) If the unit under calibration (UUC) is not found in order or deviates from specified accuracy and range, then the person performing the calibrations informs the Technical Manager for necessary actions to be taken. The Technical Manager, after verifications, informs the Quality Assurance Manager who in turn informs the customer for required necessary actions/decision required for further process.
(d) When the calibration of the instrument is done, the instrument is sealed and labeled for its performance. The calibration sticker includes the name of the instrument, sr. no. and type no., date of calibration, due date of calibration, reference no., status of the instrument whether within accuracy, or the status report is given. The calibration sticker is pasted on the instrument.
(e) The results of measurements are reflected in the calibration certificate/status report.
(f) Standard environmental conditions:
    Temperature: (25 + 3) °C
    Humidity: (50 + 20) % Rh
    Light intensity: 250 lux to 500 lux
    Sound level: less than 60 dB

Calibration of Digital/Analog Pressure Gauge/Indicator Reference Standard: DKD-R-6-1, Calibration of Pressure Gauges (ISO 2011)

Method Used: Direct Comparison of the Measurement Values. The comparison between the measurement readings of calibration gauge (UUC) and Master Standard Gauge performed by adjusting pressure according to the indication of Master Standard Gauge:

(a) The instrument, which is to be calibrated, is termed as unit under calibration (UUC).
(b) The environmental conditions, i.e., temperature (25 ± 3) °C and relative humidity (50 ± 20) % of the metrology laboratory, are maintained within specified limits before starting the calibrations.
(c) For site calibration, customer is briefed to maintain the required environmental conditions, i.e., temperature (25 ± 3) °C and relative humidity (50 ± 20) % well in advance.
(d) The Master Standards and UUC are kept under standard environmental conditions before starting the calibrations for temperature equalization.
(e) The pressure points for measurement are decided by evenly dividing the range of the UUC strictly as per our scope of calibration. If uncertainty measurement aimed of UUC is less than 0.6% of FS, then nine points for each cycle are to be considered. But if UUC uncertainty is greater than 0.6% FS, then five points for each cycle is to be considered (refer directive Table 1).
(f) Connect the UUC with the port provided on master pressure pump through nozzle/adaptor and connecting line. All connections are made firm and leak-proof. To check the leakage of the system, increase the pressure of the master & UUC up to the higher range; if the value decreases very fastly, then use Teflon tape, Teflon washers, and oil rings.
(g) Ensure that pressure release valve is fully closed and Master Pressure Gauge is switched "on" along with the UUC (if required).
(h) Rotating handlebars, provided for increasing or decreasing the applied pressure, should be at fully out position.
(i) **Preloading**
   - Firstly close the relief valve of the pressure comparator so that the vacuum is not created in the comparator.
   - Increase the pressure up to highest value by rotating handles in clockwise direction of the pressure comparator.
   - Wait for 2 min and then reduce it to zero value by rotating the handle in anticlockwise direction of the pressure comparator. The number of cycles is to be performed as per while observing the time span as mentioned below.

(Refer Number of Measurements in cycles Table 1)

Table 1 Directive table for calibration

S. no.	Measurement uncertainty aimed in % FS	Number cycles of preloading	Number of measurement points with zero		Number of measurement cycles		Load change + waiting time in seconds	Reference figure
			Up	Down	Up	Down		
A	Less than 0.1	3	9	9	2	2	>30	6
B	0.1–0.6	2	9	9	2	1	>30	7
C	Greater than 0.6	1	5	5	1	1	>30	8

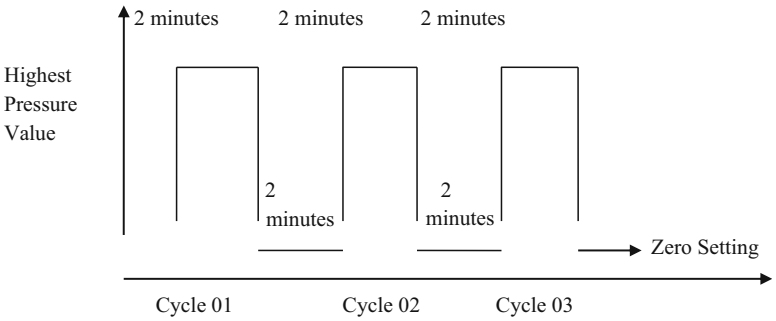

Fig. 4 Preloading sequence

TIME SPAN: The time span for preloading at highest value and time span between two preloadings must be observed at least 2 min (Figs. 4 and 5).

(j) After preloading and after steady state of pressure, indication of UUC is set to zero, and zero reading is noted down for Master Standard Gauge and UUC immediately.
(k) Set the decided pressure (load step) on unit under calibration (in increasing mode) by rotating handlebars clockwise of comparison test pump.
(l) Wait for greater than 30 s and until steady-state/sufficiently stable indication of standard and UUC are reached. As the unit under calibration displayed the set value at same time, note down the Master Standard Gauge (pressure instrument) reading at particular pressure load.
(m) Now set the pressure on unit under calibration for the next decided pressure load by repeating the process from **(Point j) to (Point l)**. This process is followed till the upper limit of the UUC (pressure instrument) is attained.

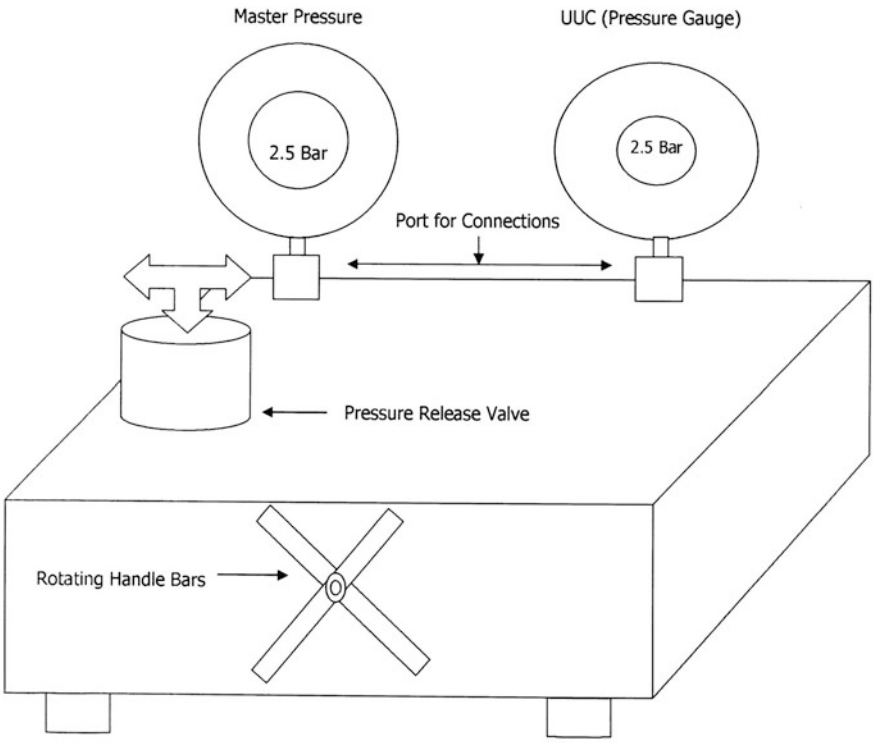

Fig. 5 Comparison test pump for pressure gauge calibration

Note:

(i) The time between two successive pressure load steps should be the same and not less than 30 s. The reading should be made 30 s after the start of the pressure change observed at the earliest.

(ii) While measurement on analog pressure gauge (Bourdon tube type), slightly tap it for minimizing any friction offered to pointer system.

(n) Set the pressure at UUC gauge in nine evenly decided pressure points including zero value **in increasing mode** to the highest range of UUC; at the same time, note down the master pressure gauge value for particular pressure points.

(o) Wait for 2 min at the highest range of UUC; after then repeat the same process in **decreasing mode** (**as per Point m**).

(p) The procedure from **(Point j) to (Point n)** is to be followed for the number of measurement cycles as given in Table 1 for generating data of Master Pressure Gauge and UUC (pressure instrument).

(q) After completion of calibration, switch off the Master Pressure Gauge and UUC (if required), and the accepted/noted down measurement readings are to be transferred in report/certificate format.

Violation of the Sanctity of Calibration and Associated Hazards

An imaginary example of a violation of the sanctity of calibration is reported as follows. The author has no personal intention to malign any entity. Any resemblance to the case of example would only be a coincidence. Suppose a well-known and reputed XYZ Indian company obtained NABL accreditation for the calibration of pressure gauges and temperature gauges to produce precision measuring instruments and calibration standards compliant to ISO 17025:2017.

Necessary human resources and quality infrastructure were created to provide reliable calibrations of the temperature and pressure gauges for on-site calibrations as well. Considering that both temperature and pressure gauges are critical parameters in any industrial applications, more so in oil refineries, oxygen-producing plants, cement, steel, automobile and pharmaceutical industries, hospitals, and other pressure/temperature gauge calibration requirements. Within 6 months of obtaining the accreditation, the XYZ company encountered the following hazardous calibration practices which are rampantly operating in the industrial hubs of Baddi, Paonta Sahib, Faridabad, Ballabgarh, Gurugram, Manesar, and Alwar and the oil refineries, fertilizer plants, and liquefied petroleum gas production plants in Northern India.

1. The host organizations (customers) desired that the calibration certificates be issued against serial numbers of the UUC itself and insisted to place blank calibration certificates along with their company rubber stamps so that they can print the certificates themselves and obtain the signatures of the Technical Manager and Quality Assurance Manager on a specific visit date.
2. Another class of host organizations (customers) refused to remove their pressure and temperature gauges from the pipelines or installations and suggested to just monitor the movement of the indicating needle or digital display and note the serial number of the UUC. It was insisted that the calibration certificates should be issued with serial numbers without carrying any real-time calibrations on the comparison test pump which has to be used to mount the UUC – the Pressure

Gauge and the Master Pressure Gauge of WIKA. Make together and, then, follow the number of cycles of preloading, apply the pressure in ascending mode, and adhere to the procedure specified in DKD-R-6-1 Standard to record the readings against the Master Pressure Gauge and UUC. Such calibrations are "Sham Calibrations." There is, de facto, no calibration of pressure gauges, which are constantly monitoring the pressure and temperature, at various points of the industrial process, inside the oil refineries and other industrial organizations mentioned above.

3. Another class of host organizations insisted to calibrate 100 pressure gauges per day over a period of 8 h with total disregard to the DKD-R-6-1 on a single pressure gauge calibrator machine. By any standards, no metrological processes can calibrate 100 pressure gauges per day with a single pressure calibrator.
4. A large number of accredited laboratories established their branch laboratories are occasionally noticed to issue quick and apparition calibration certificates with "Sham Calibrations."
5. Whenever the gravity of the matter was discussed with the assessors, at the time of recertification audit, they admitted the above-referred rampant malpractices, prevalent in a large number of Indian accredited laboratories toward the calibration of pressure gauges and temperature gauges, but the authority and assessors expressed their deep anguish and helplessness and expressed their inability to undertake any remedial measures.
6. Unable to reconcile and compromise on the sanctity of calibrations, the abovementioned XYZ company decided to surrender the accreditation for the pressure and temperature gauges after maintaining accreditation for 4 years with almost no calibration revenue business simply because the XYZ company did not agree to conduct Sham Calibrations.
7. The responsible authority is not a law enforcement agency in India. They can simply suspend the accreditation of a laboratory based on the report of the assessors during regular audits or surprise audit on such NABL Accredited India Laboratories. Thus, the hazards of poor and apparition calibrations lead to industrial disasters and unfortunate deaths of infant children in the neonatal infant incubators in the hospitals in India and many other underdeveloped and developing countries of the world.
8. The sanctity of calibrations can be maintained if and only if the rigor of calibrations as stipulated in various standards like the ISO 17025:2017 or ISO 376 or Euramet cg-4 or DKD-R-6-1 are adhered to and maintained.
9. In their research, Özdemïrcï et al. (2014) observed serious consequences in terms of mortality of newly born infants in hospitals in Turkey. The researchers observed that 80% of newborn babies in Turkey are put in neonatal incubators because of certain fragile medical complications. The infants born out of premature deliveries are highly sensitive to inside temperature and flow of oxygen inside the incubators. Any erroneous measurements or indicators for temperature and oxygen flowmeter can lead to serious life-threatening consequences. It was revealed in this research study that medical complications among neonatal babies arose because the two incubators in the hospital were

not adhering to the calibration accuracy and standards and thus causing serious hazards to the health of the newborn infants.

10. In their research Rasha M. Abd El-Aziz et al. (2021) observed that care of newborn babies are the essential, most critical, responsible, and integral part of the service in biomedical arena. Neonatal care of infants requires rigorous and committed monitoring of their essential metabolic parameters like oxygen saturation, heart rate, body temperature, and environment of comfort to enable the infant to grow to the normal physical and mental stature. The neonatal infant incubators are meant to nourish the child by providing him the controlled and closed environment as similar as the womb of the mother. But the researchers in this study revealed that the temperature, relative humidity, optimum light, and flow rate of oxygen were not accurately monitored by the measuring instruments mounted outside these incubators babies died in such poorly calibrated incubators. Resultantly the premature delivered babies died either because of overheating, leakage of the gas, or bursting of the incubators.

Sanctity of Calibrations (Case Study – Heavy Metal and Toxic Trace Contents in the Consignment of Basmati Rice Exports)

During the last one decade, the consignments of exports of rice from India to Arab countries, Europe, and the United States have been rejected because there have been traces of heavy metals like lead, chromium, nickel, cadmium, and similar other heavy metals due to improper use of soil irrigation. In a recent study, Tariq et al. (2021) have mentioned in their study and research that in Punjab region of integrated India consisting of existing Pakistan, Punjab, and Haryana in India, rice is the staple food crop that provides a significant amount of nutrition and vitamins. Rice is a staple food for the people of Western Punjab in Pakistan and India and the Northern India and the entire Southern India. It is having high nutritional value. The 100 g of long rice contains 2.2 g of fat (3%), 0.15 g of salt, 130 kcal (27%) of energy, and 2.4 g (20%) of proteins. Rice is characterized by its nature to grow on acidic and alkaline soil. It can also grow in arid areas. The entire West Punjab partially in Pakistan and Sindh province and partially in India known as Punjab and Haryana states are rich centers of rice crops. Most of the people consume rice as their staple food, and the states of Sindh and West Punjab in Pakistan and Punjab and Haryana in India produce bumper harvest of long basmati rice. Both Pakistan and India have been reputed exporters of basmati rice all over the world especially the Arab and the European nations and the United States.

This study revealed that heavy metals with density of 4 g/cm^3 like cadmium (Cd), nickel (Ni), and copper (Cu) are contaminated and aggregated in edible and non-edible parts of plants. In small amounts in the soil, these elements function as micronutrients, but if present, in large amounts they render toxicity to the plant. Now wherever the industrial effluents are discharged in the rivers of Satluj and Beas in the towns of Ludhiana, Jalandhar, and Amritsar in Punjab and on the banks of river Yamuna in Haryana and Delhi, the crops of basmati rice have been

contaminated by the heavy metals. Likewise the environmental pollution due to industrial gases or automobile exhausts and excessive usage of pesticides rendered toxicity and thus found unfit for human consumption.

High metal concentrations can increase the soil's potential to accumulate these elements. Heavy metals have a mobile structure that can be transported from soil to plants. These elements show mobility between root and shoots, and between shoots and grains. Contaminated crops of basmati rice in this belt of Pakistan and India have been found hazardous for human life. Such contaminated crops of basmati rice have been found to cause cancer and kidney, bronchitis, nervous, and orthopedic diseases in people. For example, cadmium leads to kidney and bone density problems. Likewise copper can cause nausea and Wilson's disease.

Contamination of soil by industrial discharge like lead, nickel, cadmium, and stubble burning in India in the states of Punjab and Haryana is rampant and responsible for traces of unacceptable levels of heavy metals and traces of toxic elements in the rice fields of Punjab and Haryana. This has resulted in the rejection of basmati rice from these belts in India.

There are practically no calibration and testing facilities to the farmers and farm fields in this basmati rice bowl of India. Hence, the export of basmati rice from the states of Punjab and Haryana has almost vanished during the last 10 years. There is only one State Food Testing Laboratory in Punjab, and there is hardly any ISO 17025:2017-compliant testing laboratories or NABL-accredited calibrated testing and measuring instruments in the Food Grain Procurement Markets in Northern India.

Conclusion

India has created a well-coordinated quality infrastructure for the production of world-class products that can sell in the international market at affordable and competitive prices. The National Physical Laboratory, New Delhi – the apex National Metrology Institute of India – has mentored an array of institutions like the Quality Council of India, the National Accreditation Board for the Testing and Calibration Laboratories, the Bureau of Indian Standards, the Electronics Test Laboratories, and National Test Houses at the regional and state levels in conjunction with more than 3000 NABL-accredited laboratories which are established within India. It is the solemn responsibility of every NABL-accredited testing and calibration laboratory to generate reliable and usable test and calibration certificates. If the hierarchy of traceability of calibrations is maintained, if the calibration chain is consistent, and if the sanctity of testing and calibration are maintained and adhere to international standards and protocols, India can surely become a trade surplus nation and earn valuable foreign exchange through the export of Indian products.

Abstract

Radiation dosimetry addresses determination of energy deposited in a given medium quantitatively by either calculations or measurements. The objective of radiation dosimetry is to determine absorbed dose in a medium using a detection device, i.e., a radiation detector. Toward this goal, this chapter presents general principles of radiation dosimetry. Interaction coefficients and quantities related to radiation dosimetry of ionizing radiation are included. The chapter also presents various cavity theories in detail that relate absorbed dose measured in one medium to other. Principles of radiation dose measurements involving various dosimeters are also discussed in this chapter.

Introduction

Ionizing radiation is classified as directly ionizing and indirectly ionizing. Directly ionizing radiations are charged particles such as electrons, positrons, protons, negative π mesons (π^-), alpha particles, and heavy ions such as ^{12}C, ^{14}N, ^{16}O, ^{56}Fe, etc. Indirectly ionizing radiations are neutral particles such as photons (X-rays, gamma rays) and neutrons. Directly ionizing radiation interacts with the orbital electrons of atoms in the medium through direct Coulomb interactions and deposits energy in the medium. Energy deposition of indirectly ionizing radiation in matter involves two steps. *Step 1*: A charged particle is produced in the medium. For example, photon interactions with the medium result in production of electrons or positrons, and neutron interactions produce protons, alpha particles, or heavier ions. *Step 2*: The secondary charged particles produced in *Step 1* deposit energy through collisions with the orbital electrons of the atoms in the medium. Radiation dosimetry addresses determination of energy deposited in a given medium quantitatively by either calculations or measurements. The objective of radiation dosimetry is to determine absorbed dose in a medium using a detection device. Dosimetric quantities provide a physical measure of the region of interest which is correlated to the actual or potential effects of ionizing radiation. Dosimetric measurements or calculations require various specifications of the radiation field at the point of interest.

Definitions of the fundamental radiation quantities and their units are the core mission of the International Commission on Radiation Units and Measurement (ICRU). Several reports on the quantities and units in radiation physics, dosimetry, and radiological protection such as Report 10a, Radiation Quantities and Units (1962), Report 51, Quantities and Units in Radiation Protection Dosimetry (1993), Report 60, Fundamental Quantities and Units for Ionizing Radiation (1998), and Report 85, Fundamental Quantities and Units for Ionizing Radiation (Revised) (2011) are made available by the ICRU. ICRU Report 85 (2011) supersedes the previously published reports related to radiation quantities and

units. The definitions of some of the radiometric, dosimetric, and protection quantities of interest are described in the following sections.

Interaction Coefficients and Related Quantities

Cross Section

The cross section, σ, of a target entity, for a particular interaction produced by incident directly or indirectly ionizing radiation (charged or uncharged particles) of a given type and energy, is defined as (ICRU 2011):

$$\sigma = \frac{N}{\Phi} \tag{1}$$

where N is the mean number of interactions per target entity and Φ is fluence of particles. σ is expressed in m^2.

Linear Attenuation Coefficient

Linear attenuation coefficient (ICRU 2011), μ, is defined as the probability of interaction of S-ray and gamma photons per unit path length dl that they travel in an absorber and can be expressed as follows:

$$\mu = \frac{1}{dl}\frac{dN}{N} \tag{2}$$

where N is the number of photons traversing a distance dl in the absorber and dN is number of photons that undergo interactions in the absorber. μ depends upon the incident energy of photons, atomic number, and mass density of the absorber. μ is expressed in unit of cm^{-1}. Inverse of μ is mean free path τ.

μ is a useful parameter to determine the transmitted intensity of X-ray or gamma photons when they traverse an absorber thickness of x. The differential equation for attenuation can be expressed as below:

$$I = I_0 e^{-\mu x} \tag{3}$$

where I is the transmitted intensity for an absorber of thickness x and I_o is the initial intensity of the radiation incident on the absorber. It can be observed that the transmitted intensity can never be equal zero for any thickness of absorber.

Mass Attenuation Coefficient

As μ is directly proportional to the mass density, ρ, of the absorber material, to eliminate this density dependence another coefficient, mass attenuation coefficient,

μ/ρ, is used. μ/ρ of a material, for uncharged particles of a given type and energy, is defined as (ICRU 2011):

$$\frac{\mu}{\rho} = \frac{1}{\rho}\frac{1}{dl}\frac{dN}{N} \tag{4}$$

where dN/N is the mean fraction of the particles that experience interactions in traversing a distance dl in the material of density ρ. The unit of μ/ρ is cm^2/g.

Mass Energy-Transfer Coefficient

Let R be the incident radiant energy of the uncharged ionizing particles (X-rays, gamma rays, and neutrons) incident on a material of density ρ and dR_{tr} the mean energy that is transferred to kinetic energy of charged particles by interactions of the uncharged particles in traversing a distance dl in the material, and then the mass energy-transfer coefficient, μ_{tr}/ρ, is defined as (ICRU 2011):

$$\frac{\mu_{tr}}{\rho} = \frac{1}{\rho}\frac{1}{dl}\frac{dR_{tr}}{R} \tag{5}$$

μ_{tr}/ρ is expressed in cm^2/g.

Let $h\nu$ be the energy of the photon beams traversing in a material having density ρ and $\overline{E}_{tr}$ is the mean fraction of photon energy transferred per unit thickness of the absorber to the charged particles that appears as kinetic energy. Energy-transfer coefficient, μ_{tr}, and mass energy-transfer coefficient, μ_{tr}/ρ, can be written as follows:

$$\frac{\mu_{tr}}{\rho} = \frac{\mu}{\rho}\frac{E_{tr}}{h\upsilon} \tag{6}$$

$$(\mu_{tr}) = \mu\frac{E_{tr}}{h\upsilon}$$

In the case of neutrons,

$$\frac{\mu_{tr}}{\rho} = \frac{\mu}{\rho}\frac{\Delta E_k}{E_k} \tag{7}$$

where $\frac{\Delta E_k}{E_k}$ is the fraction of energy transferred to the charged particles by the incident neutrons of kinetic energy E_k.

Mass Energy Absorption Coefficient

The secondary charged particles generated by the photons may lose their energy through radiative processes such as bremsstrahlung, in-flight annihilation, and

fluorescence radiations while slowing down in the medium (ICRU 2011). Such loss is not part of energy deposition. Hence, a separate quantity mass energy absorption coefficient μ_{en}/ρ is defined as follows:

$$\frac{\mu_{en}}{\rho} = (1-g)\,\frac{\mu_{tr}}{g} \tag{8}$$

where g is the fractional energy loss through abovementioned radiative processes. g depends on the type of material and energy of photons. g is negligible for low-energy photons but significant for high-energy photons and high atomic number materials.

Mass Stopping Power

The quantity stopping power is used in the context of charged particles. The mass stopping power, S/ρ, of a material, for charged particles of a given type and energy, is defined as (ICRU 2011):

$$\frac{S}{\rho} = \frac{1}{\rho}\,\frac{dE}{dl} \tag{9}$$

where dE is the mean energy lost by the charged particles in traversing a distance dl in the material of density ρ (ICRU 2011):

S/ρ is expressed in MeV-cm^2/g or equivalently J-m^2/kg.
The quantity $S = dE/dl$ is linear stopping power (MeV/cm or J/m).

The charged particles lose energy in the absorber through (a) ionization (includes both soft and hard collisions) and excitation with orbital electrons; (b) emission of bremsstrahlung photons in the fields of nucleus or orbital electrons, in-flight annihilation, and fluorescence radiations; and (c) elastic Coulomb interactions in which recoil energy is imparted to atoms. Hence, S/ρ has three components as below:

$$\frac{S}{\rho} = \frac{1}{\rho}\,\frac{dE}{dl} = \frac{1}{\rho}\left(\frac{dE}{dl}\right)_{el} + \frac{1}{\rho}\left(\frac{dE}{dl}\right)_{\text{rad}} + \frac{1}{\rho}\left(\frac{dE}{dl}\right)_{\text{nuc}} \tag{10}$$

where
$\frac{1}{\rho}\left(\frac{dE}{dl}\right)_{el}$ is mass electron or mass collision stopping power
$\frac{1}{\rho}\left(\frac{dE}{dl}\right)_{\text{rad}}$ is mass radiative collision stopping power
$\frac{1}{\rho}\left(\frac{dE}{dl}\right)_{\text{nuc}}$ is mass nuclear stopping power

Linear Energy Transfer

When charged particles propagate in a medium, energy is transferred to orbital electrons through soft and hard collisions. In soft collisions, the energy transfer is

minimum, whereas in hard collisions energy transfer is maximum. The linear energy transfer (LET) or restricted linear electronic stopping power, L_Δ, of a material, for charged particles of a given type and energy, is defined as (ICRU 2011):

$$L_\Delta = \frac{dE_\Delta}{dl} \tag{11}$$

where dE_Δ is the mean energy lost by the charged particles due to electronic interactions in traversing a distance dl. Here, the mean energy lost excludes the mean sum of the kinetic energies in excess of Δ. If there is no threshold or energy cutoff is imposed, it is called unrestricted stopping power. This is denoted as L_∞. Note that L_∞ is always greater than L_Δ.

Radiation Chemical Yield

The radiation chemical yield, $G(x)$, of an entity, x, is defined as (ICRU 2011):

$$G(x) = \frac{n(x)}{\overline{\varepsilon}} \tag{12}$$

where $n(x)$ is the mean amount of substance of that entity produced, destroyed, or changed in a system by the mean energy imparted, $\overline{\varepsilon}$, to the matter of that system. $G(x)$ is expressed in units of mol/J (ICRU 2011). The mole is the amount of substance of a system that contains as many elementary entities as there are atoms in 0.012 kg of ^{12}C (ICRU 2011). Generally, the value of $\overline{\varepsilon}$ is 100 eV, and therefore the G value is expressed in $(100\ \text{eV})^{-1}$. A G value of 1 $(100\ \text{eV})^{-1}$ corresponds to a radiation chemical yield of approximately 0.1036 μmol/J (ICRU 2011).

Ionization Yield in a Gas

The ionization yield in a gas, Y, is defined as (ICRU 2011):

$$Y = \frac{N}{E} \tag{13}$$

where E is the initial kinetic energy of a charged particle of a given type which is completely dissipated in the gas and $N = \overline{q}_\pm/q$. Here, $\overline{q}_\pm$ is the mean total liberated charge of either sign and q is the elementary charge. Y is expressed in J^{-1} and is sometimes expressed in eV^{-1} (ICRU 2011). From the definition of Y, it may be noted that (a) N includes charge produced by bremsstrahlung or other secondary radiations emitted by the initial and secondary charged particles and (b) charge of the initial charged particle is not included in N, as this charge is not liberated in the energy dissipation process.

Mean Energy Expended in a Gas Per Ion Pair Formed

The mean energy expended in a gas per ion pair formed, W, is reciprocal of Y and is defined as (ICRU 2011):

$$W = \frac{E}{N} \tag{14}$$

where E and N have the usual meaning as mentioned above (section "Ionization Yield in a Gas"). W is expressed in J and is sometimes expressed in eV (ICRU 2011).

Dosimetric Quantities

When radiation interacts with matter through different processes, energy is imparted to the medium. Some of the radiation dosimetric quantities are described below (ICRU 2011).

Exposure (X)

Exposure (X) is related to the ability of photons (X-rays and gamma rays) to ionize air medium; thus, it is defined only for photons and air as the medium. When photon is incident on a mass dm of dry air, it produces an ion pair (electron and positive ion) through ionization process. X is defined as (ICRU 2011):

$$X = \frac{dQ}{dm} \tag{15}$$

where dQ is the absolute value of the mean total charge of the ions of one sign produced when all the electrons and positrons liberated or created by photons incident on a mass dm of dry air are completely stopped in dry air. The unit of X is Coulomb per kilogram (C/kg). Roentgen (R) is the commonly used unit of X. The relation between SI unit of X and R is $1\ R = 2.58 \times 10^{-4}$ C/kg.

Kerma

KERMA (*k*inetic *e*nergy *r*eleased per unit *ma*ss), K, is defined for uncharged ionizing radiations such as photons and neutrons for any medium. It is defined as (ICRU 2011):

$$K = \frac{dE_{tr}}{dm} \tag{16}$$

where dE_{tr} is the mean sum of the initial kinetic energies of all the charged particles liberated in a mass dm of a material by the uncharged particle incident on dm (ICRU 2011). KERMA refers to the kinetic energy of the charged particles such as protons, electrons, and positrons generated from indirectly ionizing radiation such as photons or neutrons. The quantity dE_{tr} includes the kinetic energy of the charged particles emitted in the decay of excited atoms/molecules (e.g., Auger, Coster-Kronig, shake-off electrons) or in nuclear de-excitation or disintegration (ICRU 2011). KERMA is a non-stochastic quantity and is applicable only for indirectly ionizing radiations such as photons and neutrons. The special unit of K is Gray (Gy).

Let E be the energy of uncharged particle and Φ be the fluence; then K is related to Φ as follows:

$$K = \Phi E \left(\frac{\mu_{tr}}{\rho}\right) = \Psi \left(\frac{\mu_{tr}}{\rho}\right) \tag{17}$$

where μ_{tr}/ρ has the usual meaning as defined in section "Mass Energy-Transfer Coefficient" and $\Psi = \Phi E$ is the energy fluence of these uncharged particles. In radiation dosimetry, K is generally expressed in terms of fluence of uncharged particles $\Phi(E)$ as below:

$$K = \int \Phi(E) E \left(\mu_{tr}(E)/\rho\right) dE \tag{18}$$

The total kerma, K, is the summation of two components, i.e., collision kerma, K_{col}, and the radiative kerma, K_{col}, and can be expressed as:

$$K = K_{\text{col}} + K_{\text{rad}} \tag{19}$$

K_{col} is due to energy loss through ionization and K_{rad} is due to energy loss through bremsstrahlung photons.

Energy Deposit

The energy deposit, ε_i (a stochastic quantity, expressed in J or eV), is the energy deposited in a single interaction, i, which is defined as (ICRU 2011):

$$\varepsilon_i = \varepsilon_{\text{in}} - \varepsilon_{\text{out}} + Q \tag{20}$$

where ε_{in} is the energy of the incident ionizing particle, ε_{out} is the sum of the energies of all charged and uncharged ionizing particles leaving the interaction, and Q is the change in the rest energies of the nucleus and of all elementary particles involved in the interaction ($Q > 0$, decrease of rest energy; $Q < 0$, increase of rest energy). Note that (a) ε_{in} and ε_{out} do not include the rest energies and (b) interactions with atomic electrons resulting in atomic excitation do not result in a change in rest energies of the nucleus or of elementary particles and thus $Q = 0$, which is due to the fact that there is subsequent de-excitation process.

Energy Imparted

The energy imparted, ε (a stochastic quantity, expressed in J or eV), to the matter in a given volume is sum of all energy deposits in the volume (ICRU 2011):

$$\varepsilon = \sum_i \varepsilon_i \tag{20}$$

where summation is performed over all the energy deposits, ε_i, in that volume. Note that the term energy deposition event denotes the imparting of energy to matter by correlated particles (e.g., a proton and its secondary electrons, an electron-positron pair, or the primary and secondary particles in nuclear reactions).

Mean Energy Imparted

The mean energy imparted, $\overline{\varepsilon}$ (a non-stochastic quantity, expressed in eV or J), to the matter in a given volume is defined as (ICRU 2020):

$$\overline{\varepsilon} = R_{\text{in}} - R_{\text{out}} + \sum Q \tag{21}$$

where R_{in} is the mean radiant energy of all charged and uncharged ionizing particles that enter the volume, R_{out} is the mean radiant energy of all charged and uncharged ionizing particles that leave the volume, and $\sum Q$ is the mean sum of all changes of the rest energy of nuclei and elementary particles that occur in the volume. Note that $Q > 0$, decrease of rest energy, and $Q < 0$, increase of rest energy.

Absorbed Dose

Absorbed dose, D (non-stochastic quantity), applicable to both indirectly and directly ionizing radiations is defined as (ICRU 2011):

$$D = \frac{d\overline{\varepsilon}}{dm} \tag{22}$$

where $d\overline{\varepsilon}$ is the mean energy imparted by ionizing radiation to matter of mass dm. D is expressed in J/kg^{-1}. D is also expressed in Gray (Gy).

Charged Particle Equilibrium (CPE)

When indirectly ionizing radiations such as photons and neutrons propagate in a medium, they transfer their energy to the charged particles (electrons in the case of photons and protons in the case of neutrons). Due to finite range of these charged

particles, energy deposition does not take place at the same location where these charged particles are generated. In the case of photons, the secondary electrons lose energy through ionization and production of bremsstrahlung photons (known as radiative loss). Collision kerma, K_c, does not include radiative loss as the bremsstrahlung photons escape from the point where they are produced. For photons, K_c at a point in the medium depends on the photon fluence at that point. When a parallel beam of photons is incident on the medium, the photon fluence decreases with depth due to exponential attenuation. Hence, K_c also decreases with depth. In the case of absorbed dose, D, secondary electrons generated at earlier depths will deposit their energy at later depths. Hence, D increases with depth initially and decreases after some depth. This decrease is due to the fact that photon fluence decreases due to exponential attenuation in the medium. Hence, there exists a depth, which is equal to the maximum range of secondary electrons, denoted as x_m, at which D is maximum. At this point, charged particle equilibrium exists where both K_c and D are equal, i.e., $D/K_c = 1$. Beyond x_m, at any depth x, D is slightly larger than K_c because D depends on photon fluence at earlier depth, i.e., $x - x'$, whereas K_c depends on photon fluence at depth x; here, x' represents maximum range of the secondary electron. For depths beyond x_m, the ratio $D/K > 1$. The degree of difference between D and K_c depends on photon energy and the type of medium. The depth dose curve of photons therefore shows $D/K < 1$ in the buildup region (0 to x_m), $D/K = 1$ at x_m, and $D/K > 1$ at depths beyond x_m. At the ^{60}Co photon energies, $x_m = 5$ mm in water. At very low-energy photons such as 25 keV, there will not be a buildup region, and therefore both D and K_c will be same at all depths. This is because range of secondary electrons is too small and they deposit energy at the spot where they are generated. At such low-energy photons and since the medium is of low atomic number, there is no radiative loss, and hence K equals K_c.

General Principles of Absorbed Dose Determination

Cavity Theories

In dosimetry of ionizing radiation, one needs a device that has a sensitive medium to measure response in terms of absorbed dose to the incident ionizing radiation. This device is known as radiation dosimeter. Cavity theory is then applied that relates absorbed dose to the cavity to absorbed dose to the medium of interest. Here, cavity implies that a small mass of material which is sensitive to ionizing radiation embedded in the medium whose elemental composition and mass density are generally different from that of the medium. The cavity may be in the form of solid (diode, TLD, OSL etc.) or gaseous form (ionization chamber filled with air; air here is known as cavity).

Bragg Gray Cavity Theory

It was W. H. Bragg who first discussed the relation between absorbed doses of two different media in 1910 (Bragg 1910). Later, L. H. Gray made quantitative

statements on cavity ionization theory (Gray 1929, 1936). Gray went on to prove that when a gas-filled cavity was small enough with respect to the range of the electrons, the presence of cavity did not perturb the electron fluence spectrum.

Let us consider a cavity (medium c) is embedded in the uniform medium m. Assume the medium is irradiated by an ionizing radiation. According to the Bragg-Gray cavity theory, the cavity should necessarily satisfy the following two conditions (Palani Selvam et al. 2021):

(a) The presence of the cavity should not perturb the fluence of charged particles in the medium. For this purpose, the cavity needs to be small as compared with the range of charged. This implies that the charged particle fluence spectra in both m and c are the same (Attix 1986; Palani Selvam et al. 2021).
(b) The energy deposited in the cavity is assumed to be solely by the charged particles produced outside the cavity and they cross the cavity (Attix 1986). This further implies that no secondary electrons are produced inside the cavity and the electrons do not stop within the cavity (Attix 1986, Palani Selvam et al. 2021).

According to the Bragg-Gray cavity theory:

$$\frac{D_m}{D_c} = \left(\frac{\overline{S}}{\rho}\right)_c^m \tag{23}$$

where D_m is dose to m at a point of measurement without the cavity being present, D_c is dose to cavity, and $\left(\overline{S}/\rho\right)_c^m$ is mean mass collision stopping power ratio of m to c.

$$\left(\frac{\overline{S}}{\rho}\right)_c^m = \frac{\int_0^{E_{\max}} \Phi_m(E)(S/\rho)_m dE}{\int_0^{E_{\max}} \Phi_m(E)(S/\rho)_c dE} \tag{24}$$

where $\Phi_m(E)dE$ is the unperturbed primary fluence of charged particles in medium m with energies between E and $E + dE$ and $(S/\rho)_m$ and $(S/\rho)_c$ are the unrestricted mass collision stopping powers of media m and c (in MeVcm^2/g), respectively. The upper limit of the integrals in Eq. (24) is given by the maximum energy, $E_{\max}$, of the electrons in the fluence spectrum, and the lower limit corresponds to the lowest energy in the spectrum, here indicated by a zero.

When a photon beam is incident on m, it generates charged particles such as electrons and positrons. These charged particles are known as primary charged particles and are part of $\Phi_m(E)dE$. These electrons and positron will further generate secondary electrons through collisions with atomic electrons of the medium. However, the δ-rays produced by these charged particles as a result of hard collisions in

the slowing down of the primary electrons are not part of $\Phi_m(E)dE$. In the case of a charged particle beam incident on m, the δ-rays produced by this beam are again not part of $\Phi_m(E)dE$. Note that whatever may be the incident beam (electron, positron or photon), bremsstrahlung photons can always be generated by the charged particles. Here, bremsstrahlung photons can be those generated by both primary charged particles and δ-rays. Note that $\Phi_m(E)dE$ includes charged particles generated by bremsstrahlung photons that are generated by primary charged particles. In general, irrespective of the incident beam, -rays are not part of whichever the ways δ-rays are produced. Hence, Eq. (23) utilizes unrestricted mass collision stopping powers. This means that the δ-rays are assumed to be stopped on the spot where they are generated. However, the energetic δ-rays may leave the cavity resulting in a partial energy deposition in the cavity. Therefore, the Bragg-Gray cavity theory is insensitive to the cavity size. This is in contradiction to the abovementioned two Bragg-Gray conditions. Although large number of knock-on electrons is created, the Bragg-Gray cavity theory still works reasonably well.

Spencer-Attix Cavity Theory

The Spencer-Attix cavity theory also works on two conditions as defined for the Bragg-Gray theory (see section "Bragg Gray Cavity Theory"). However, these conditions are extended to secondary particle fluence in addition to primary particle fluence. Therefore, it can be inferred that the Spencer-Attix cavity theory (Attix et al. 1958; Attix 1986; Spencer and Attix 1955; ICRU 1984) finite range of δ-rays is accounted as opposed to the Bragg-Gray cavity theory. In the Spencer-Attix cavity theory, cavity size is therefore characterized by a parameter Δ that corresponds to approximately the energy of an electron that is just able to cross the cavity (Palani Selvam et al. 2021). Note that Δ is a parameter which defines the limit between transported and absorbed electrons. Thus, the Spencer-Attix cavity theory is based on formulation of a two-group schematization: (a) *fast group*, δ-rays with initial energy greater than a cutoff Δ are assumed to dissipate their energy outside the cavity and therefore are part of fluence spectrum, and (b) *slow group*, δ-rays of energy less than Δ, which are assumed to have zero range, dissipate their energy "locally," i.e., in the cavity. Under these conditions (Attix 1986; Spencer and Attix 1955; ICRU 1984):

$$\frac{D_m}{D_c} = \left(\frac{\overline{L}_\Delta}{\rho}\right)_c^m \tag{25}$$

where

$$\left(\frac{\overline{L}_\Delta}{\rho}\right)_c^m = \frac{\int_\Delta^{E_{\max}} \Phi_m(E)(L_\Delta(E)/\rho)_m dE + \Phi_m(\Delta)(S(\Delta)/\rho)_m \Delta}{\int_\Delta^{E_{\max}} \Phi_m(E)(L_\Delta(E)/\rho)_c dE + \Phi_m(\Delta)(S(\Delta)/\rho)_c \Delta} \tag{26}$$

Here,

$\Phi_m(E)dE$ is the unperturbed primary fluence of charged particles in medium m with energies between E and $E + dE$, including δ-rays.
$(L_\Delta/\rho)_m$ is the restricted mass collision stopping powers (in $MeVcm^2/g$) at electron energy E for the medium m.
$(L_\Delta/\rho)_c$ is the restricted mass collision stopping powers (in $MeVcm^2/g$) at electron energy E for the cavity c.
$(S(\Delta)/\rho)_m$ is the unrestricted stopping powers for the cavity medium c at $E = \Delta$.
$(S(\Delta)/\rho)_c$ is the unrestricted stopping powers for the cavity medium c at $E = \Delta$.

Note that $(L_\Delta/\rho)_m$ and $(L_\Delta/\rho)_c$ are based on restricted collisional energy losses below an energy threshold Δ.

The terms in Eq. (26), i.e., $\Phi_m(\Delta)(S(\Delta)/\rho)_m\Delta$ and $\Phi_m(\Delta)(S(\Delta)/\rho)_c\Delta$, are the track-end terms which account for energy dissipation of electrons with $E \leq \Delta$ through an evaluation of the restricted stopping powers for $\Delta \leq E \leq 2\Delta$ (Nahum 1978).

In ionization chamber-based dosimetry, is traditionally given by the kinetic energy of the electron whose residual CSDA range in air is equal to the mean chord length of electrons crossing the cavity, L. For a convex cavity and an isotropic field, $L = 4\ V = S$ where V is the cavity volume and S the cavity surface area (Attix 1986). Note that L = 4 V/S applies to a convex cavity that is front-back symmetrical, even if the electron field arrives isotropically only from the front and is absent from the back (Attix 1986).

Re-Examination of Spencer-Attix Cavity Theory

As described by Bouchard (2012), for clinical radiotherapy beams (electron and photon beams), Spencer-Attix cavity theory (Attix et al. 1958; Attix 1986; Spencer and Attix 1955; ICRU 1984) further adapted by Nahum (1978) is considered to be the accepted method for converting absorbed dose in a detector (wall-less) to absorbed dose in the medium of interest. This approach is in use for several years and is widely used. Bouchard (2012) re-examined the Spencer-Attix cavity theory from first principles, using a new general cavity theory derived from radiation transport equations. Bouchard (2012) highlighted the drawbacks of the Spencer-Attix theory as below:

In practice, the ideal conditions needed for the Spencer-Attix theory are not generally met. Also, there is a neglect of physical effects such as electron binding energy, positron transport, etc., hence the introduction of fluence perturbation factors (AAPM 1983; IAEA 1987) to correct for departure from the idealistic conditions. For a standard dosimetry, the departure from the Spencer-Attix theory is corrected by applying fluence perturbation correction, K_{fl}. However, for a nonstandard beam dosimetry such as IMRT (intensity modulated radiation therapy) practice, such corrections are easily predictable (Bouchard et al. 2009). K_{fl} is usually calculated using the Monte Carlo techniques. For example, the quantity of interest in radio-therapy is absorbed dose to water D_w, whereas the ion chamber measures dose to air

D_a. K_{fl} is calculated as below to account for deviation from the Spencer-Attix cavity theory:

$$K_{fl} = \frac{[D_w/D_a]}{[L(\Delta)/\rho]_w/[L(\Delta)/\rho]_a} \tag{27}$$

Limitations of the Spencer-Attix theory as put forth by Bouchard (2012) are given below:

(a) The response of a detector is evaluated using the condensed history-based Monte Carlo methods (Kawrakow 2000). Therefore, one can argue that the theoretical ground on which stopping power ratio calculation relies is arbitrary.
(b) The choice of Δ itself is arbitrary that may result in theoretical and practical inconsistencies. For example, the secondary electrons set in motion close to the wall with energy slightly smaller than Δ such that they can exit the volume are ignored considering that Δ is the kinetic energy of the electrons which is just sufficient to cross the cavity.
(c) Δ defined for the cavity volume is assumed to be the same for the cavity filled with the medium of interest which is always a dense material to which the stopping power ratio is calculated.
(d) The electron impact ionization differential cross sections generally increase with decreasing energy loss (Kim and Rudd 1994), and therefore the statement that Δ should be equal to the energy necessary for an electron to cross the cavity is unfounded. This is because the electrons with kinetic energy less than Δ have on average a kinetic energy much lower than Δ.

Despite the abovementioned shortcomings associated with the Spencer-Attix cavity theory, the validity of this theory (Ma and Nahum 1991; Borg et al. 2000) and the choice of Δ (Borg et al. 2000; La Russa and Rogers 2009; Rogers and Kawrakow 2003; Sempau et al. 2004) have been revised over the years. For example, a study by Wang and Rogers (2007) on Monte Carlo-simulated response of a silicon detector shows unrealistic values of Δ for the purpose of matching the calculated response. La Russa and Rogers (2009) discussed that there is still no proper method to determine Δ for ionization chambers to avoid significant corrections in the air kerma formalism for ^{60}Co beams.

The basic approach adapted by Bouchard (2012) is the same as Spencer-Attix cavity theory in terms of categorization of knock-on electrons, i.e., slow and fast electrons. The Nahum formulation (Nahum 1978) of Spencer-Attix theory (applicable for electrons, positrons, and photons in the energy range of radiation therapy) is shown to be a special case of this model. The model can also be adapted to the class II condensed history Monte Carlo technique. The model demonstrates that Δ is only associated with the error on the solution of the transport equation, rather than the electron kinetic energy necessary to cross the cavity. Numerically, it is shown that there is no prescription for the value of Δ yielding either independence of the beam

energy or a fulfillment of Bragg-Gray conditions. The inconsistencies with Spencer-Attix theory recently reported in the literature are explained, and the overall approach is the use of the Monte Carlo approach to calculate detector dose response. Thus, the Monte Carlo-based approach is no longer reflected by Spencer-Attix theory and that an appropriate formalism could be adopted as a standard theory for radiation dosimetry.

Burlin Cavity Theory

Burlin (1966, 1968) proposed a theory that includes all cavity sizes. The Burlin cavity theory for photons that relates dose to medium (D_m) and dose to cavity (D_c) can be written as follows:

$$\frac{D_m}{D_c} = d(S/\rho)_c^m + (1-d)(\mu_{en}/\rho)_c^m \tag{28}$$

where d is a parameter related to cavity size ($d = 1$ for small cavities, $d = 0$ for large cavities), $(S/\rho)_c^m$ is the mean ratio of the restricted mass stopping powers of medium and cavity, and $(\mu_{en}/\rho)_c^m$ is the mean ratio of the mass-energy absorption coefficients for the medium and cavity. Burlin and Snelling (1969) derived the expression for electron beams from the general cavity theory of ionization for photons as below:

$$\frac{D_m}{D_c} = d\left(1/(S/\rho)_c^m\right) \tag{29}$$

where $(S/\rho)_c^m$ is calculated by Spencer-Attix theory and d is a dimensionless weighting factor which accounts for the decrease of the electron spectrum characteristic of the medium inside the cavity. Almond and McCray (1970) extended Burlin's cavity theory by introducing an additional term as below. This is to include the production of delta rays within the cavity:

$$\frac{D_m}{D_c} = d\left(1/(S/\rho)_c^m\right) + (1-d)(Z/A)_c^m \tag{30}$$

where $(Z/A)_c^m$ is ratio of the electron densities of the cavity to the wall medium.

It is interesting to note that for small cavities, Burlin's cavity theory approaches the Spencer-Attix stopping power ratio and (μ_{en}/ρ) ratio for large size cavities. The main drawback of Burlin cavity theory is that it ignores the scattering effects of secondary electrons that result in large discrepancies in experimental measurements in high atomic number media (Horowitz et al. 1983; Kearsley 1984). Janssens (1983) argues that the modifications to Burlin theory proposed by Horowitz and Dubi (1982) were factually incorrect.

Kearsley Cavity Theory

A new general cavity theory was developed by Kearsley (1984) for photon. The model includes the following components:

(a) The model takes into account scattering of secondary electron at the cavity boundaries.
(b) The model treats the wall contribution to the energy deposited in the cavity as a perturbation of the matched wall cavity case.
(c) The model takes into account the secondary electron scattering at the cavity boundaries using the analysis and experimental data of Dutreix and Bernard (1965).
(d) The model reduces to the Burlin theory (i.e., a linear combination of the mass stopping power ratios and the mass energy absorption coefficient ratio).

The advantages of the model are (i) it is easy to use, (ii) it provides a better fit to available experimental data, and (iii) it can provide dose distribution information inside the cavity. The principal disadvantage of the model is the knowledge on the secondary electron backscatter factors produced by photons. Such factors for high-energy X-rays (11, 15, and 20 MV) and ^{6o}Co gamma rays for a variety of materials have been made available by Dutreix and Bernard (1965).

Haider et al. (1997) mentioned that an outstanding feature of Kearsley model (1984) is the ability to calculate dose distributions inside plane parallel cavities surrounded by medium. In the absence of secondary electron backscattering, the Kearsley theory converges to Burlin's theory. However, the Kearsley theory has poor correlation with experimental results in high-Z media. For example, Kearsley theory has numerous parameters and dose to cavity depends on choice of parameters.

Haider Cavity Theory

Haider et al. (1997) addressed shortcomings of Kearsley theory through a new general cavity theory. In their model, the authors chose X-ray photons (500 kV–20 MV) in which the Compton scattering is the dominant interaction. The electron density is proportional to the energy loss cross section of electron stopping power which is mainly determined by the excitation energy of the molecules and the Compton scatter cross section (Haider et al. 1997). According to Janssens (1983), when the Compton is the predominant interaction and the difference of mean excitation energies per electron is small, then the stopping power ratio is equal to the ratio of electron densities, independent of the cavity size. In the approach, the total electron fluence in the cavity of thickness is divided into three groups (Haider et al. 1997). According to this approach, the electron fluence is as follows:

(a) That originated in the cavity including the backscattered electrons generated by it in the cavity travelling in the opposite direction
(b) That originated in the front wall medium including the backscattered electrons generated by it in the cavity travelling in the opposite direction
(c) In the cavity resulting from the difference in the backscattering coefficients of the cavity medium and the back wall medium

In the theory, medium g (known as cavity medium) of thickness t is sandwiched between medium w and medium m (Haider et al. 1997). The final expression, i.e.,

ratio of dose to cavity (g) and the medium (w) surrounding the cavity, is given as (Haider et al. 1997):

$$f = d_1(\mu_{en}/\rho)_w^g + d_2F_w\left(1 + b_g\right)(S/\rho)_w^g + d_3d_4F_g(\mu_{en}/\rho)_w^g + d_5F_w(S/\rho)_w^g\left(b_m - b_g\right) \quad (31)$$

Here, d_1, d_2, d_3, d_4, and d_5 are weighting factors, F_w is the fractional forward electron fluence originating in the medium w, F_g is the fractional forward electron fluence originating in the medium g, b_g is the probability of backscattering of the medium g, b_m is the backscattering coefficient of the medium m, $(\mu_{en}/\rho)_w^g$ is ratio of mean mass energy absorption coefficient of medium g and medium m, and $(S/\rho)_w^g$ is ratio of mean mass collision stopping power of medium g and medium m.

When the cavity size is very large compared with the range of the electrons, Eq. (31) reduces to:

$$f = (\mu_{en}/\rho)_w^g \quad (32)$$

When the cavity size is very small compared to the range of the electrons and when the font wall and back wall are:

(a) Identical medium (i.e., w), hence, f reduces to the Bragg-Gray theory, i.e., $f = (S/\rho)_w^g$.
(b) Not identical, hence, f does not reduce to the Bragg-Gray theory. This is because the contributions from the front wall medium, the cavity medium, and the backscattering from the back wall medium are calculated separately and all three media could be of different atomic composition (Haider et al. 1997).

Detectors Used in Radiation Dosimetry

The general principles of absorbed dose determinations can be applied when different types of dosimeters are to be used in the determination of absorbed dose. In this section, dosimeters such as calorimeters, chemical dosimeters, and ionization chambers that can be used for the absolute absorbed dose measurements and dosimeters such as liquid ionization chambers, solid-state dosimeters, and films that are generally used for relative absorbed dose measurements are discussed.

Ionization Chambers

Air-filled ionization chambers are used for primary air kerma strength standardization of ^{60}Co beam from the charge collected by the chamber free in air. The charge collected in the air is related to absorbed dose to the medium or air kerma (La Russa and Rogers 2009; Rogers 1992):

$$K_{\text{air}} = \frac{Q_{\text{air}}}{m_{\text{air}}(1-\overline{g}_{\text{air}})}\left(\frac{W}{e}\right)_{\text{air}}\left(\frac{L}{\rho}\right)_{\text{air}}^{\text{wall}}\left(\frac{\mu_{en}}{\rho}\right)_{\text{wall}}^{\text{air}} K_h K_{\text{wall}} K_{\text{an}} K_{\text{comp}} K \tag{33}$$

where $Q_{\text{air}}/m_{\text{air}}$ is the charge measured in humid air per unit mass of dry air that would occupy the cavity at standard temperature and pressure, $(W/e)_{\text{air}}$ is the mean energy deposited in dry air per unit charge of one sign released, $\overline{g}_{\text{air}}$ is the fraction of charged particle kinetic energy lost to radiative processes, $(\mu_{en}/\rho)_{\text{wall}}^{\text{air}}$ is the spectrum-averaged ratio of mass energy absorption coefficients, and $(L/\rho)_{\text{air}}^{wall}$ is the Spencer-Attix ratio of restricted mass collision stopping powers. The correction factors due to humidity is K_h, attenuation and scatter by the wall is K_{wall}, axial nonuniformity of the beam is K_{an}, and material inhomogeneity in the chamber is $K_{\text{comp.}}$

Under certain ideal conditions, K_h, K_{an}, and K_{comp} corrections are unity by definition. Furthermore, the correction for additional nonideal conditions, K, reduces to a fluence correction, denoted here as K_{fl}, to correct for a potential perturbation of the wall's charged particle fluence in the cavity gas.

Under the assumption that photon interactions in the cavity is negligible (which is not true for low-energy photons) and that the departure from Spencer-Attix conditions is solely due to the perturbation of the charged particle fluence by the presence of the cavity:

$$K_{\text{air}} = \frac{D_{\text{air}}}{(1-\overline{g}_{\text{air}})}\left(\frac{L}{\rho}\right)_{\text{air}}^{\text{wall}}\left(\frac{\mu_{en}}{\rho}\right)_{\text{wall}}^{\text{air}} K_{\text{wall}} K_{fl} \tag{34}$$

As $(K_c)_{\text{air}} = K_{\text{air}}(1-\overline{g}_{\text{air}})$, the above equation is rewritten as:

$$(K_c)_{\text{air}} = D_{\text{air}}\left(\frac{L}{\rho}\right)_{\text{air}}^{\text{wall}}\left(\frac{\mu_{en}}{\rho}\right)_{\text{wall}}^{\text{air}} K_{\text{wall}} K_{fl} \tag{35}$$

The values of $(L/\rho)_{\text{air}}^{\text{wall}}$, K_{wall}, and K_{fl} are generally calculated using Monte Carlo methods. Note that these values are chamber-specific.

Calorimetry

Calorimetry method can be applied for absorbed dose measurements in a small volume of an irradiated absorber. In this method, the small volume having mass *dm* medium is thermally isolated. The mean absorbed dose D is given by (ICRU 1954):

$$D = \frac{\Delta\overline{\varepsilon}}{\Delta m} = \frac{\Delta E_h}{\Delta m} + \frac{\Delta E_s}{\Delta m} \tag{36}$$

where $\Delta\overline{\varepsilon}$ is the mean energy imparted to the absorber by the incident ionizing radiation, ΔE_h is the energy appearing as heat, and ΔE_s is the chemical defect, which

may be positive or negative. An example of ΔE_s is the energy produced or absorbed in induced radiochemical reactions. When there is no change of state,

$$\frac{\Delta E_h}{\Delta m} = c_p \Delta T \tag{37}$$

where c_p is specific heat capacity at constant pressured and ΔT is the change in temperature.

Chemical Dosimetry

Chemical dosimetry involves determination of dose by the measurement of chemical changes induced in materials by ionizing radiation. The mean absorbed dose to dosimeter solution, D, using a chemical dosimeter can be determined as follows:

$$D = \frac{\Delta A}{\rho \, l \, \varepsilon_m G} \tag{38}$$

where ΔA is increase in absorbance due to irradiation at a temperature "t" during the spectrometric measurement, ρ is the density of dosimeter solution (g/cm^3), l is optical length in the photometer cell (m), ε_m is the molar linear absorption coefficient of the product (m^2/mol) at the wavelength used for spectrophotometric measurements, and G is radiation chemical yield (in mol/J).

G is the fundamental quantitative characteristic of any chemical transformation induced by ionizing radiation. Earlier G values were reported as the number of molecules of product formed (X), as $G(X)$, or of starting material Y changed $G(-Y)$, per 100 eV energy absorbed. Radiation chemical yield has the same symbol $G(X)$ or $G(-Y)$ as the case may be. $G(X)$ is the molar concentration n(X), produced/changed for a known energy E (in J) is imparted to it:

$$G(X) = n(X)/E \tag{39}$$

G-values in terms of number of species per 100 eV can be converted to SI units by multiplying by 1.036×10^{-7} or in other words 1 mol/J $= 9.649 \times 10^6$ mol/100 eV.

The value of the radiation chemical yield may depend on the type of radiation and the chemical reactions involved. When the radiation-induced reaction is a chain reaction, then the G value is high. For nonchain reactions, it is not large. The value of G can be calculated if the absorbed dose and the concentration of the product being formed (or decomposed) are both known.

$$\mathrm{G}\left(\mathrm{mol\,J^{-1}}\right) = \mathrm{n}\left(\mathrm{mol\,kg^{-1}}\right)/\mathrm{Dose}\left(\mathrm{J\,kg^{-1}}\right)$$

In actual practice, the G value is found from kinetic curves, relating product concentration and absorbed dose. If the relationship is linear, the slope of the curve is

the G value. If the experimental points show deviation from linearity, G is calculated by drawing a tangent to the curve from the point of origin.

Film Dosimetry

Radiographic Film

Radiographic film finds applications in diagnostic radiology, radiotherapy, and radiation protection. The film consists of a base of thin plastic with a radiation-sensitive emulsion, usually silver bromide (AgBr) grains suspended in gelatine, coated uniformly on one or both sides of the base.

When ionizing radiation is incident on the film, it forms a latent image in the film. This latent image becomes visible due to film blackening and is permanent after processing. Hence, light transmission is a function of the film opacity which can be measured in terms of optical density (OD) using densitometers. The OD is defined as:

$$\mathrm{OD} = \log_{10}(I_0/I) \tag{40}$$

where I_0 is the initial light intensity and I is the transmitted intensity. Although films provide qualitative information of absorbed dose, using a calibration curve dose vs OD, dose can be determined. Ideally, the relationship between the dose and OD should be linear, but some emulsions exhibit linear response over a limited dose range, and some are nonlinear. The dose vs OD curve should therefore be established for each film before it is used for dosimetry work.

Radiochromic Film

Radiochromic film (RCF) is a planar dosimeter for applications in radiotherapy and food irradiation. RCF film consists of a radiosensitive (7–23 μm thick) colorless leuco dye bonded to a 100- m-thick Mylar base. These films are colorless before irradiation. Upon irradiation, the sensitive material, dye, is polymerized and turns a deep blue color without physical, chemical, or thermal processing. Thus, RCF is self-developing and requires neither developer nor fixer. As RCF is grainless, it has a high spatial resolution of 1200 lines/mm (McLaughlin et al. 1991). The polymer absorbs light, and the transmission of light through the film can be measured with a suitable densitometer. Response of RCF is stable and is reproducible if protected from UV light, unstable temperatures, and humidity. Since the dye is nearly tissue-equivalent, its deviation from tissue-equivalent energy response is much smaller.

There are various types of radiochromic films such as EBT, EBT2, EBT3, HD-V2, B3, etc. It is important that each film is subjected to different doses and the absorbance is determined using suitable system that has range of a light source (different wavelengths). Suitable light source should be identified based on maximum absorbance through the absorbance vs wavelength. The color intensity of the film is proportional to the radiation absorbed dose. For dosimetry applications involving B3 film, optical density of the exposed films can be measured at 552 nm

using Genesys 20 portable spectrophotometer (Thermo Electron Corp, USA). The color formation in the irradiated B3 film is not complete at the end of the irradiation.

An important aspect in dosimetry involving RCF is the generation of calibration curves for the film and the reading system. For example, if HD-V2 film is intended for dose measurements during irradiation of onion, potato, mango, etc. and the reading system to be used is a spectrophotometer at 550-nm wavelength, then a calibration curve for the film and the reading system should be generated. Similarly, if B3 film is used along with Genesys 20 portable spectrophotometer (552 nm) for measuring doses in the range of kGy, it is required to generate a calibration curve for this dosimetry system.

Dosimetry using RCFs has a few advantages over radiographic films, such as elimination of the need for darkroom facilities, film cassettes or film processing, dose rate independence, better energy response characteristics, and insensitivity to ambient conditions. RCFs are generally less sensitive than radiographic films and are generally useful at higher doses, and nonlinearity should be corrected for in the very high-dose region.

Solid-Sate Detectors

Usage of gas-filled detectors (e.g., ionization chamber) is somewhat limited due to a number of factors. For example, the small number of electron-ion pairs is generated in a gas, and the number of target atoms per unit volume in the gas that the incident radiation encounters is smaller. Solid-state detectors such as semiconductors, scintillation, and thermoluminescent dosimeters have some advantages over gas-filled detectors.

Semiconductor Detector

Semiconductors are most commonly used when best energy resolution is desired. They are called semiconductors because their electrical conduction properties lie between those of insulators and conductors. In semiconductors, the fundamental information carriers are electron-hole pairs, which are collected. Germanium (Ge) and silicon (Si) are two of the most commonly used semiconductor materials. The choice of semiconductor depends on many factors:

(a) Resistivity
(b) Mobility of charges
(c) Drift velocity
(d) Purity
(e) Operating temperature
(f) Cost

Scintillation Detectors

As opposed to gas-filled detectors, the scintillation detector works on a different principle. When ionizing radiation is incident on scintillation material, energy is

transferred to the atoms of the material, which takes the atoms into short-lived excited states. When these excited atoms return to their ground states, they result in emission light photons. These photons are known as scintillation photons. The basic steps involved in detection of these scintillation photons are:

- Transfer of energy to the bound states of the material
- Relaxation of the excited state to the ground state, resulting in the emission of light photons
- Collection of photons by a suitable photodetector
- Detection of the photodetector signal by associated electronics system

The amount of light produced in the scintillator is small. It must be amplified before it can be recorded as a pulse or in any other way. The amplification or multiplication of the scintillator's light is achieved with a device known as the photomultiplier tube (PMT). Its name denotes its function: it accepts a small amount of light, amplifies it many times, and delivers a strong pulse at its output. Amplifications of the order of $l0^6$ are common for many commercial PMTs.

Alpha, beta, gamma, and neutron radiations can be detected using scintillation detectors. Scintillator detectors, which can be solid, liquid, and gas, are generally made of plastic, organics, or inorganic materials. They can be made in any shape and size. NaI(*Tl*) detector is commonly used for gamma detection and gamma spectrometry. The detector is generally shielded to reduce background radiation level before use as it gives high background radiation levels due its high sensitivity.

Thermoluminescent Dosimeters

When ionizing radiation is incident on certain solids doped with appropriate impurities, it creates an electron-hole pair in the crystalline structure. The liberated electron migrates to the conduction band where it further migrates to an electron trap, while the hole left migrates to a hole trap. The charge carriers are maintained for a time that depends on the potential energy of the trap (the trap depth). If the traps are deep, upon heating, the electrons and holes in the shallowest traps are released first. The released charge carriers recombine with their counterparts at a luminescence center or at a trap that is closely coupled to such a luminescence center. As a result of this recombination, there is the release of visible light, which is characteristic of the impurity recombination center. The light emitted is quantified and is related to absorbed dose in the material. The material can be reused after annealing. Annealing is application of appropriate heating to the material. As the methodology involves application of thermal energy to stimulate emission of luminescence, it is known as "thermoluminescence," and the associate dosimetry is called thermoluminescence dosimetry (TLD). Note that pure TL crystal does not exhibit considerable luminescence and therefore is not quantifiable. Addition of trace amounts of impurities (about ppm level) in the crystal lattice enhances its TL properties. Several TL materials with dopants such as LiF:Mg,Ti,, LiF:Mg,Cu,P, $CaF_{2:}$Mn, and $CaSO_4$: Dy are being used in radiation dosimetry.

Properties of Dosimeters

The dosimeters must be characterized before they are used for the intended purposes. The properties of a dosimeter should be characterized by accuracy and precision, linearity, dose or dose rate dependence, absorbed dose and intrinsic energy response, directional dependence, spatial resolution, etc.

Accuracy and Precision

The dosimetric quantity measured through a dosimeter will have an uncertainty. Uncertainty is a parameter that describes the dispersion of the measured values of a quantity. Uncertainty is expressed in terms of accuracy and precision. Precision of dosimetry measurements specifies the reproducibility of the measurements under similar conditions. Therefore, precision can be estimated through repeated measurements. High precision means the standard deviation associated with the measured value is small. The accuracy of dosimetry measurements is the proximity of their expectation value to the "true value" of the measured quantity. Note that measured values are not absolutely accurate and the inaccuracy of a measurement result is characterized as uncertainty.

Linearity

Linearity is a parameter that describes the relationship between the dosimeter response and the dose delivered as a function of dose. Generally, the dosimeter reading is reliable in certain range of doses as beyond a certain dose range a nonlinearity may set in. The dosimeters may also exhibit saturation after certain dose. The linearity range, the nonlinearity behavior, and the saturation behavior depend on the type of dosimeter and its physical characteristics. Hence, it is important to know whether the response of the detector is directly proportional to the dose being measured. In general, one can write:

$$D_{\mathrm{det}}(D) = \alpha k_l \left[M_{\mathrm{det}}(D)\right] M_{\mathrm{det}}(D) \tag{41}$$

where $k_l\,[M_{\mathrm{det}}(D)]$ is the intrinsic linearity whose value is unity for some reference dose D_0 and α is a quantity that relates $M_{\mathrm{det}}(D_0)$ to $D_{\mathrm{det}}(D_0)$ (Rogers 2009). If k_l is independent of D and $M_{\mathrm{det}}(D)$, then the detector's response is said to be linear (Rogers 2009). This means that if the dose is doubled, the response of the detector doubles. However, some detectors may not exhibit this behavior which should be taken into account.

Dose Rate Dependence

The integrating systems that measure the dosimeric quantity should be independent of the dose rate which means that the response of a dosimetry system at two different

dose rates should be constant. However, in practical applications, the dose rate may influence the dosimeter readings. Hence, appropriate corrections must be incorporated.

Let $M_{\mathrm{det}}^{\mathrm{raw}}\left(\dot{D}\right)$ be the raw response of the detector measured at dose rate $\dot{D}$ and then dose rate corrected response of the detector $M'_{\mathrm{det}}\left(\dot{D}\right)$ is:

$$M'_{\mathrm{det}}\left(\dot{D}\right) = k_{dr}\left[M_{\mathrm{det}}^{\mathrm{raw}}\left(\dot{D}\right)\right] M_{\mathrm{det}}^{\mathrm{raw}}\left(\dot{D}\right) \tag{42}$$

where $k_{dr}\left[M_{\mathrm{det}}^{\mathrm{raw}}\left(\dot{D}\right)\right]$ corrects for the dose rate dependence.

Energy Dependence

Energy dependence of radiation detectors is an important property for determination of absorbed dose as the detectors are exposed to a beam quality Q which is often different from the calibration beam. Hence, it is important that such a dependency is corrected for. The overall energy dependence of a detector is composed of two parts, namely, intrinsic energy dependence and absorbed dose energy dependence (DeWerd et al. 2009; Rogers 2009), which are explained below.

Intrinsic Energy Dependence

The intrinsic energy dependence, $k_{bq}(Q)$, relates the reading of the detector to the dose to the sensitive volume of the detector (Rogers 2009). It is defined as:

$$k_{bq}(Q) = D_{\mathrm{det}}(Q)/M_{\mathrm{set}}(Q) \tag{43}$$

where $D_{\mathrm{det}}(Q)$ is the absorbed dose to the sensitive volume of the detector at a given beam quality, Q, and $M_{\mathrm{det}}(Q)$ is the meter reading of the detector at the same Q.

In principle, the intrinsic energy dependence could also be dependent on other factors such as dose, dose rate, temperature and pressure, direction, etc. General-purpose Monte Carlo codes that model radiation transport can be used to calculate the absorbed dose energy dependence. However, such codes cannot be used to calculate the intrinsic energy dependence as the thermoluminescence mechanism is not modeled. Hence, intrinsic energy dependence can be determined only through measurements.

Absorbed Dose Energy Dependence

The absorbed dose energy dependence relates the dose to the detector material to the dose to the medium at the point of measurement of the detector (Rogers 2009). The absorbed dose energy dependence at the beam quality Q, $f(Q)$, is also known as extrinsic energy dependence. It is defined as:

$$D_{\mathrm{med}}(Q) = f(Q) D_{\mathrm{det}}(Q) \tag{44}$$

where $D_{med}(Q)$ is the absorbed dose to the medium at the point of measurement of the detector in the absence of the detector at the beam quality Q and $D_{med}(Q)$ is the absorbed dose to the sensitive material of the detector at the same Q. The factor $f(Q)$ encompasses the component-specific and replacement perturbation effects as well as the absorbed dose energy dependence of the detection material. It is a function of beam quality Q but can also be a function of dose, dose rate, geometry of source and detector location, etc.

Abstract

Radiation level and activity concentration of radioisotopes present in the earth's environment can be detected and measured by specific instruments based on several detection techniques. The environmental radioactivity monitoring and measurement instruments commonly use gaseous ionization chamber (GM Tube), liquid or solid scintillation medium [LSC, NaI(Tl), ZnS(Ag)], semi-conductor (HPGe, PIPS), or their combination as detection methods. These instruments should be capable of measuring trace levels of radionuclides present in the environmental matrices with utmost accuracy. In the last few decades, organizations like ISO, IAEA, and BIPM have taken several measures to bring conformity in measurement through proper certification and QC mechanisms which are recognized worldwide. It is safely assumed (and often demonstrated) by an instrument manufacturer that a new instrument is calibrated as per established norms. It initially behaves according to the specifications; however, its capabilities gradually vary with time due to mechanical deterioration, dust, moisture, chemicals, etc. present in the operating environment. These deviations from standard specifications depend upon the frequency of usage and the severity of the operating conditions and are expected and acceptable within documented limits. A recalibration of the instrument becomes necessary when these limits are breached and the results are no more acceptable. Calibration of environmental radioactivity detection and measurement instruments, using certified standard radioactive sources or certified reference materials, is of paramount importance, as it has a direct impact on the health of humans, environment, and non-human biota. In addition, these sources must be traceable with an unbroken chain of measurements to the SI (BIPM) via international bodies like NIST, ILAC-MRA, or National Metrological Institutes/Laboratories.

Introduction

Our environment is immersed in radiation from space and from within, and it has been so before the existence of human beings or any life form. Radiation, in form of radioactive isotopes and cosmic and associated emissions (particulate and electromagnetic), is present everywhere around us (USNRC 1999). Electromagnetic rays (EMRs), covering the entire EMR spectra from extremely high-frequency cosmic rays to low-frequency microwaves, can technically be called radiation. Nevertheless, the word "radiation," especially in the field of nuclear energy, is used for ionizing radiations such as particulate nuclear emissions (alpha, beta, protons, and neutrons), X-rays, and gamma-rays (WHO 2020). Radioactivity and radioactive emissions cannot be detected by human sensory organs; however, it can be efficiently detected using instruments. Monitoring of the radiation level and the radionuclide concentration in the environment, primarily in air, drinking water, agricultural products, and food, provides a measure of trends in activity levels (Hegde et al. 2009). This permits the evaluation of radioactivity relevant to human exposure as well as in identifying bio-indicators that concentrate radionuclides (ICRP 2012). Table 1 shows some common radionuclides found in the environmental matrices.

The environmental monitoring is of routine and special types. Special type of monitoring includes drills for emergency preparedness and monitoring during nuclear or radiological emergency. Routine environmental monitoring around nuclear power plants is a strict compliance requisite sought by the nuclear regulatory authority of respective country (IAEA 2015). The regulatory bodies through environmental survey laboratories ensure that no harm is caused to the member of public

Table 1 Typical radionuclides in the environment from natural and anthropogenic sources

Samples	Radionuclides
Air	^{131}I, ^{134}Cs, ^{137}Cs
Water	^{3}H, ^{89}Sr, ^{90}Sr, ^{131}I, ^{134}Cs, ^{137}Cs
Milk	^{89}Sr, ^{90}Sr, ^{131}I, ^{134}Cs, ^{137}Cs
Meat	^{134}Cs, ^{137}Cs, ^{90}Sr
Other foodstuffs	^{89}Sr, ^{90}Sr, ^{134}Cs, ^{137}Cs
Vegetation	^{89}Sr, ^{90}Sr, ^{95}Zr, ^{95}Nb, ^{103}Ru, ^{106}Ru, ^{131}I, ^{134}Cs, ^{137}Cs, ^{144}Ce
Soil	^{89}Sr, ^{90}Sr, ^{134}Cs, ^{137}Cs, ^{238}Pu, $^{(239+240)}$ Pu, ^{241}Am, ^{242}Cm

IAEA (1996)

or to the environment. Apart from compliance, these regular monitoring are also carried out to instill confidence in public towards safe use of nuclear energy.

Nuclear installations along with their front- and back-end facilities, fuel reprocessing plants, etc. release radionuclides into the environment in amounts strictly regulated by the national regulatory agencies of respective countries under strict adherence to ALARA (*as low as reasonably achievable*) principle. Some of the radionuclides which are regularly monitored for environmental assessment are tabulated in Table 1 (IAEA 1989a, 1989b; 1996). After Chernobyl and then Fukushima incidents, the regulatory bodies have become more sensitive towards demonstration of capability by the radio-analytical laboratories to effectively measure trace level of radioactivity in the environmental matrices (Beresford et al. 2016; Callen and Homma 2017). Every radionuclide releases a single or a cascade of emissions (alpha, beta, gamma, positron, and sometimes proton and neutron) from its nucleus to transform into a stable element form. These emissions bear specific energies which are signatures of a particular radioisotope. This property is utilized for measurement and quantification purposes by using multitude of equipment. Environmental laboratories monitor the level of radiation and radioactivity concentrations of radioisotopes by using specific detector materials and instruments such as gas-ionization chambers, Geiger-Mueller counter, scintillators, and semiconductor detectors. Since the concentration of radionuclides gets diluted once it enters an environmental matrix, the equipment for their activity measurement should be quite sensitive (on both precision and accuracy parameters) and need to be calibrated regularly within a stipulated time interval to ensure confidence in accuracy and precision.

Environmental Monitoring of Terrestrial, Aquatic, and Atmospheric Radionuclides

The terrestrial, aquatic, and atmospheric matrices of the environment, e.g., soil, surface-water, and air, contain natural as well as anthropogenic radionuclides. Due to atmospheric nuclear tests, carried out in the past, radionuclides like cesium and strontium are now found distributed worldwide (Yoshitome et al. 2003). The naturally occurring radionuclides present like uranium, thorium, and their daughter products are the major contributors of the terrestrial radiation. Natural background radiation (NBR), e.g., cosmic and terrestrial, is a major contributor to the annual absorbed dose to the human beings. International Commission of Radiological Protection (ICRP), through various calculations, has arrived at an annual dose of 1 mSv (1 milli Sievert) which may not lead to a statistically significant rise in excess cancer risk to the people living around nuclear installations (ICRP 2012).

Areas near nuclear power plants (NPPs), nuclear facilities, and uranium mining sites require regular monitoring of background radiation levels as well as radionuclides activity concentration in environmental samples for calculation of annual absorbed dose to the member of the public. It is for demonstration and for regulatory compliance to establish that the effective absorbed dose (from all the pathways) to

the members of public remains minimum and never exceeds the allowed limits of 1 mSv per annum (ICRP 1991, 2012). It is emphasized here that this dose of 1 mSv is over and above the dose received from natural background radiation, i.e., any exposure from cosmic radiation at the surface of the earth, from unmodified concentrations of radionuclides in most raw material, and from ^{40}K in the body (IAEA 1996).

Equipment for Environmental Monitoring of Radiation and Radionuclides

There is no single equipment or detection methodology which can detect all types of ionizing radiations with the same effectiveness. Various types of detection systems are thus available, catering for the type of radiation and measurement requirement specific. Radiation monitoring instruments which are used in environmental radiation monitoring can be broadly classified into four categories (Hegde and Verma 2004; Lawrence Berkeley Laboratory 1980):

1. Portable radiation survey meters (dose rate and nuclide identification).
2. Gas-filled proportional counter (beta and alpha quantification).
3. Scintillation (inorganic, organic and plastic) detectors.
4. Semi-conductor detectors (alpha and gamma spectrometry).

In case of radionuclides having a short half-life (minutes to days), it may be necessary to evaluate the concentrations or the radiation exposure by making measurements in the field or at the place of origin itself, e.g., by use of thermoluminescent dosimeters (TLDs), pressurized ion chambers, or in situ gamma spectrometers (IAEA 1996). However, in cases where a radionuclide with an intermediate half-life (weeks to months) is released continuously or intermittently, sampling and analysis of environmental media in the associated pathway is carried out at intervals not greater than two or three half-lives of the nuclide. In radionuclides which have a relatively long half-life (i.e., years), measurements are to be made at least once per year. In NPP sites where seasonal or other temporal variations are evident, the frequency of sampling should be planned to allow resolution of any important effects caused due to changing seasons. In some cases, sampling on a continuous basis may be necessary (e.g., air sampling and continuous measurement of cumulative external radiation exposure). Composites of some selected sample types such as air-filters may be appropriate for measurement of long-lived radionuclides.

Essentials of Calibration and Metrological Traceability

The primary goal of calibration is to minimize the uncertainty of a specific measurement by ensuring the accuracy of equipment under test. It quantifies and controls errors or uncertainties in the measurement processes to an acceptable level.

Concisely, *calibration of an instrument is a process of determining its accuracy* (BiPM 2012). All kinds of radiation detectors require calibration, especially those which involve some kind of measurement, e.g., survey meters and spectrometry systems. A detector is calibrated to allow the radiation to be interpreted in terms of energy, rather than channel number, or voltage, and amount of radionuclide, rather than number of pulses. Moreover, if computer analysis of the spectrum is examined, it may be necessary to provide information about the peak width variation with energy or channel number. All the instruments available in the market provided by certified suppliers need to go through the full characterization which is different from the routine calibration requirements of the user (NCRP. 1990). All the calibration process mentioned in this chapter fall into category of routine calibration to fulfill specific needs of regulatory compliance, doses measurement, and surveillance.

Considering the kinds of calibration requirements, it can be divided into performance of three calibration tasks (Gilmore 2008):

1. *Efficiency calibration* – the relationship between number of counts and disintegration rate.
2. *Energy calibration* – the relationship between channels and energy.
3. *Peak width calibration* – the variation of peak width with energy (Full width at Half-maximum, FWHM)

However, in some gamma-ray spectrometric systems, the software itself performs energy calibration simultaneously with the FWHM calibration, which means that not only the centroid but also the width of the peak (in terms of the FWHM) is required. This quantity is calculated by a complex formula using the counts in several channel intervals (Isaksson and Raaf 2017).

Instruments which measure counts, count rate, or dose rate (irrespective of individual radionuclide, such as survey meters) require count rate (cpm) and efficiency calibration, while those which involve spectrometric measurement or identification of radionuclides need all the three calibrations.

It is important to emphasize here that a "calibration" is incomplete until it fulfils the essential requirement of establishing the metrological (measurement) traceability of the standard (radiation) sources used in the process of calibration. Metrological traceability is defined as the "property of a measurement result whereby the result can be related to a reference through a *documented* unbroken chain of *calibrations*, each contributing to the *measurement uncertainty*." (BiPM 2012). For traceability to be successfully achieved, we need to look for three important aspects: the documentation (generally in terms of available and verifiable reports), calibrations (certifications of measurements against physical standards), and measurement uncertainty (all the possible sources of uncertainty both statistical and otherwise, significantly affecting the results). While measurement traceability alone cannot guarantee valid results, but without it, system calibrations are uncertain and results can often be unreliable (Karam 2014). The extent of globalization of markets and availability of online databases for instant verification of a certificate has led to more consumer awareness with regards to results which should be acceptable worldwide. The

measurement traceability, nowadays, is not only required for regulatory compliance, but it also provides a foundation to support the national and international market place.

During the recent Covid pandemic, we have seen the evolution of international acceptance of Covid (+/−) results through molecular tests (e.g., reverse transcriptase-polymerase chain reaction, RT-PCR) or antigen tests at airports as a mandatory requirement for entry to a country or to a state. Such internationally acceptable results can only be provided by the laboratories which are accredited by a national or international body through mutual recognition arrangement (MRAs) by participating countries. The International Laboratory Accreditation Cooperation (ILAC) is one such body which has recognized a consistent policy on measurement traceability as crucial for confidence in calibration, testing, and inspection by accredited laboratories and others covered by the ILAC mutual recognition arrangement, called ILAC MRA (ILAC 2022a). The role of ILAC has been discussed in the last section of the chapter.

National Metrology Institutions (NMIs), such a NIST (National Institute of Standards and Technology, under US Department of Commerce) of United States of America, around the world provide necessary fundamental metrological infrastructure supporting measurement traceability for a variety of applications including those of radiological instruments. NMIs are generally nonregulatory and are established to facilitate the development of various national standards for traceability from research through development to implementation. Through participation in international measurement comparisons with each other, NMIs, along with the International Bureau of Weights and Measures (BIPM), make possible worldwide uniformity of measurements and their traceability within stated uncertainties (which are derived from the measurement uncertainties of all the participants). Estimation and proper accounting uncertainties are absolutely essential for the determination of confidence in a measurement. The Guide to the Expression of Uncertainty in Measurement (commonly known as GUM) is used by laboratories, manufacturers, factories, and NMIs to demonstrate quality control, develop and maintain physical reference standards and materials, and calibrate those standards and associated instrumentation (ISO/IEC 2010).

Radiation Survey Meters for Background Radiation and Contamination Detection

Portable radiation survey meters are the most commonly used instruments for the measurement of background radiation levels, area survey or for detection of radioactive contamination. It comes in several shapes and sizes as per the requirement. Survey meters can be used to detect particulate emissions like alpha, beta, and neutron as well as gamma radiation. These instruments provide readings in form of counts per second (cps) and dose rate (nSv/h, mSv/h, μSv/h). Advance survey meters use inorganic crystals like sodium iodide (NaI), lanthanum bromide (LaBr), cadmium zinc telluride (CZT), etc., which are also capable of spectroscopy to

distinguish radionuclides based on their gamma-ray energies. It not only fulfills the basic need of a radiation survey meter but also serves as a portable gamma spectrometry system to track and identify radionuclides. For calibration of the survey instruments, ^{137}Cs and ^{60}Co are used.

Calibration of GM Tube-Based Radiation Survey Meters

Geiger-Mueller tube (GM Tube)-based radiation survey meters mostly come factory calibrated and must be regularly calibrated, at least annually, to an accuracy of ±20%, which is acceptable for general survey purposes. Before calibration, the operational checks such as battery check, radiation response, and zero check must be performed. Routine calibration measurements should be made using either a radioactive check source with known count rate (or dose-rate) or a calibrated radiation field. It is done to ensure that the reproducibility of the reference instrument is within ±2% of the certificated value. In case of standard sources, due corrections should be applied for the radioactive decay and for changes in air density from the reference conditions, if applicable.

Low-cost analogue or digital survey meters which do not have provision for spectrometric identification of radionuclides are calibrated for count rate, dose rate, and/or efficiency only. Regular (non-spectroscopic) survey meters can be calibrated by using the following:

1. A standard source with known counts (cps) or dose rate.
2. A radiation survey meter which has been previously calibrated.
3. Using both in conjunction, i.e., a source with known cps and a calibrated survey meter (IAEA 2000)

The most common way is to use a fixed source-to-detector distance variable-dose rate method. Dose rate from a point source can be calculated by using inverse square law:

$$\text{Dose rate} \propto \frac{1}{(distance)^2}$$

The percent efficiency of an instrument which expresses its results in terms of count rates can be calculated from the following formula:

$$Efficiency\ (in\%) = \frac{Observed\ count\ rate - Background}{Disintegration\ Rate\ (Standard\ Source)} \times 100$$

For example, if a ^{14}C standard source has a disintegration rate (decay corrected) of 90,000, disintegration per minute (dpm), say the GM counter under test, gives a value of 50 counts per minute (cpm) for the background and 6000 cpm when the source is placed. The efficiency of the counter can be calculated as

$$Efficiency\ (\%) = \frac{6000\ cpm - 50\ cpm}{90000\ dpm} \times 100$$

$$= 6.6\%$$

The same procedure can be repeated for instruments which provide reading in dose-rate (μSv/h or nSv/h) format. The survey meter is then exposed at computed distances, and actual dose-rate reading is recorded. From the reading, the calibration factor (CF) is calculated.

$$CF = \frac{Theoretical\ Reading}{Observed\ Value}$$

The above process is repeated several times (10–15 times) choosing different distances and with different dose rates, and an average CF is taken. A CF of 0.8–1.2 is considered satisfactory (Nadeera Hemamali et al. 2015).

Calibration of Advance Radiation Survey Meters

Advance radiation survey meters with spectroscopy features (radionuclide identification) are usually calibrated automatically, every time it is switched "ON," with a securely sealed source (internal: ^{137}Cs and, external: ^{40}K, intrinsic: ^{138}La) provided with the instrument or with one of the methods given in the respective section depending upon the type of detector used. In most cases, these advance survey meters are not user serviceable, and if the inbuilt calibration file is lost or reset, it must be sent to a certified calibration laboratory or to the supplier for re-calibration.

Gas Flow Beta Counter Having Anti-Coincidence Technique

It is a modification of gas proportional counter where two GM counters of either planar or spherical shape, viz., main counter or guard counter, are used. In a continuous gas-flow counting system, any air contamination from previous samples is swept out of the detector by continuously flowing the fill gas through the active volume. The counters have an aluminum-coated mylar foil window of about 1.0 mg/cm^2 through which the beta particles traverse and reach the gas chamber (argon with isopropyl alcohol vapors) and ionize the medium. The signals from both counters are collected through the anode wire. By using anticoincidence technique and proper shielding, the background of such systems can be reduced to about 1–2 cpm.

Calibration of Gas Flow Beta Counter Having Anti-Coincidence Technique

The efficiency of the counter is independent of incident beta particle once the particle enters the chamber. However, due to absorption of energy of incident particle by the window material, the efficiencies get affected for different energies. Nuclides that decay directly to the ground state by emitting (one or more) betas are called pure beta-emitters, and these can be effectively used for calibrating a gas flow beta counter. Strontium-90 along with daughter product yittrium-90 (^{90}Sr/^{90}Y) is such a source, which emits a continuous spectrum of betas from 0.546 to 2.27 MeV. The half-life of ^{90}Sr is 27.7 y and that of ^{90}Y is 64 hours (about 2 and a half days). The efficiency for ^{90}Y is about 45% and approximately 40% for ^{40}K, and for ^{137}Cs and ^{90}Sr, it is about 35%. The efficiency is also influenced by the thickness of sample. The MDL (3σ) of low background beta counting system is 0.023 Bq for 3600 s (about 1 hour) counting duration.

Geiger-Mueller Counter

A Geiger-Mueller detector is a gaseous ionization detection system used for the detection and measurement of alpha, beta, and gamma radiation. It is sometimes called as Geiger counter or simply a GM counter. It consists of a cylindrical gas-filled tube (usually helium or argon) with electrodes, across which a high-voltage (~900–1500 V) is applied, with no flowing current. When ionizing radiation passes through the chamber causing the ionization of the gas, it leads to an intense electrical pulse which is measured or counted. At higher voltages multiple pulsing can happen which can be reduced by addition of some quench gas (halogens, Cl_2 or Br_2) in the tube. The number of pulses per second is the measure of the intensity (flux) of the radiation.

Some of the advantages of Geiger-Mueller counters are the following:

1. Relatively inexpensive.
2. Durable and portable.
3. It can detect all types of radiation with suitable modifications.

GM Counter for Measurement of Beta Activity

Beta counting systems utilize a medium-sized sealed normal type or low background type of end window Geiger-Muller tube as detector. Argon as counting gas and halogens or organic gas as quenching gases is used in these tubes. Beta counting system can be assembled by utilizing nuclear instrumentation modules like EHT (extra high tension or high voltage power supply) unit, paralysis unit, timer/scalar, and the power supply bin. Standalone systems are also available which contain electronic circuitry to provide required functions of the above units.

Calibration of Geiger Mueller Counter for Beta Activity

These detectors are most widely used in the field of radiation detection, survey, and monitoring. Certified sources from SSDLs or other recognized commercial supplier can be used for calibration purpose. A sufficiently reliable calibration source can be prepared in the laboratory by the following procedure. Analytical grade potassium chloride crystals (KCl) are powdered after drying at 110 °C for 1 hour and uniformly spread and fixed with gelatin or collodion over an aluminum planchet. The size of the planchet is carefully chosen to match the detector and window size. Activity of around 2 Bq of ^{40}K is sufficient to give significant count rate. Natural potassium contains about 0.012% of radioactive ^{40}K. Higher strengths will increase the thickness of standard source causing self-absorption. The efficiency of the detector is mostly independent of energy in GM mode of operation, but attenuation due to sample thickness needs to be corrected. Gas-filled GM counters normally give 15–20% efficiency and about 0.4 cps (counts per second) background. The specific activity of KCl (potassium chloride) is 16 Bq/g.

Liquid Scintillation Detector

Liquid scintillation counting (LSC) or liquid scintillation analysis (LSA) system is a standard laboratory method to quantify the activity concentration of low-energy radioisotopes, mostly beta-emitting and alpha-emitting isotopes in liquid media (Kleinschmidt 2004). The sensitive LSC detection method requires specific cocktails, supplied with different trade names, to absorb the energy and convert it into detectable light pulses (L'Annunziata 2020). Liquid scintillators are widely applied to count radioactive material that can be dissolved as part of the scintillator solution. It is used for detection of low-energy beta-emitters like ^{3}H and ^{14}C, ^{35}S, ^{32}P, and ^{125}I (Table 2). It is predominantly important for regular and critical evaluation of tritium (^{3}H) and ^{14}C in the environment.

Liquid scintillation (LS) solutions, called as cocktails, consist of four components, where the fourth is an optional component used in specific conditions:

1. Solvent: The large part of the solution is an alkylated aromatic organic solvent xylene, toluene, etc.

Table 2 Some common radionuclides which are detected by liquid scintillation counting (LSC)

Isotope	Emission Type	Energy (MeV)	Half-life ($t_{1/2}$)
Tritium (^{3}H)	β	0.019	12.3 y
Carbon (^{14}C)	β	0.156	5730 y
Sulfur (^{35}S)	β	0.167	87.2 d
Phosphorus (^{32}P)	β	1.710	14.3 d
Phosphorus (^{33}P)	β	0.249	25.3 d
Iodine (^{125}I)	γ	0.178	60 d

2. Primary scintillator: It absorbs energy from the solvent and emits light. PPO (2,5-diphenyloxazole) is most commonly used scintillator.
3. Secondary scintillator: It is added to absorb emissions of the primary solute and to re-emit photons of longer wavelength [e.g., POPOP (1,4-di-(2–5-phenyloxazole) benzene), Bis-MSB (p-bis-(omethylstyryl) benzene)].
4. Other Additives used in specific cases: LS solutions frequently contain additives, like surfactants, to improve counting efficiency.

Orbital electrons of the scintillators absorb the incoming energy and become excited and by transitioning to the ground state produce a light pulse which is characteristic for specific radionuclides and the scintillator. The light is then detected by the photomultiplier tube (PMT) attached to the liquid scintillation counter. As high as 100% efficiency could be obtained for ^{14}C using this scintillator medium. Organic scintillator solutions are routinely used for beta counting and beta spectrometry of low-energy beta-emitters.

Calibration of Liquid Scintillation Counter/Analyzer (LSC/LSA)

Proper assessment of tritium (^{3}H), ^{14}C, and other beta-emitters in various environmental samples requires accurate and traceable calibration of the LSC. LSCs can be calibrated by secondary standards which are commercially available and are traceable to NIST, NPL (UK), or any other National Metrology laboratory. The standard sources come in sets of quenched or unquenched LSC standards.

The optimum counting conditions for an LSC system can be done by establishing different counting windows by adjusting the gain and discriminator setting. Based on statistics, an optimum window setting is given by the term "Figure of Merit," the larger the figure of merit, the more significant the sample measurement:

$$Figure\ of\ Merit = \frac{S^2}{S + 2B}$$

where S = sample counts and B = background counts.

A major part of calibration of LSC systems involves the Quench correction, which is one of the key issues in LSC systems. It occurs when the energy transmitted by the radioisotope is not caught by the PMT entirely. We encounter three types of quenching in LSC systems which are physical, chemical and color based. The color of the sample and the cocktail have a huge effect on the quenching process, and it varies as the combination varies.

Calibration of an LSC system also involves the optimization of the quenching process. The quench correction methods commonly used are as follows:

1. Internal standardization.
2. Sample channels ratio (SCR).
3. External standard ratio (ESR).

Quenching effects can be reduced by optimizing sample preparation, choosing the correct energy window, and optimizing the counting windows. Some LSCs are equipped with radioactive sources (external standards) such as ^{137}Cs, ^{133}Ba, and ^{152}Eu for quench corrections. ^{152}Eu is a mixed gamma source of broad spectrum of energies falling between 1 keV to 1.4 MeV (Adelman 1998).

Gamma Spectrometry System

Most of the radionuclides in the environment produce gamma-rays of various energies and intensities. A detailed analysis of this spectrum is used to determine the identity and quantity of gamma-emitters present in the sample. Gamma spectrometry systems are one of the essential instruments for quantitative analysis of naturally occurring radioactive materials (like ^{210}Pb, ^{228,226}Ra, ^{238}U, ^{234,228}Th, ^{40}K, etc.) and anthropogenic radionuclides (like ^{137}Cs, ^{134}Cs, ^{131}I). The gamma spectrum is characteristic of the gamma-emitting nuclides contained in the source. The equipment used in gamma spectrometry contains an energy-sensitive radiation detector, a pulse sorter (multichannel analyzer), associated amplifiers, and data readout devices backed by suitable software.

Environmental laboratories commonly use thallium-doped sodium iodide (NaI) scintillation detector and high purity germanium detectors (HPGe) for estimation of radionuclides present in extremely low concentrations. Gamma-ray (γ-ray) spectrometry is a rapid and nondestructive analytical (NDA) technique that can be used to detect various radioactive isotopes in a sample with minimal efforts. In a gamma-ray spectrometry system, the energy of incident gamma-rays from the sample is measured by a detector. The energy range for a typical gamma spectrometry system lies usually in 10 keV to 3 MeV.

Prerequisites for Calibration of Gamma Spectrometry Systems

Apart from the type of detector, both scintillator and semi-conductor-based gamma spectrometry systems share almost common calibration methods. However, for the sake of clarity, both kind of systems have been discussed separately with regards to their calibration procedures.

The γ-ray spectrum in both the system can be modeled assuming the following:

1. A point-like gamma-source is measured, i.e., gamma-ray self-attenuation is negligibly small.
2. The detector pulse pile-up effect due to both true and random coincidence summing is negligible.
3. The losses of counts due to the spectrometer dead time are negligible.
4. A multi-channel analyzer with absolute linearity is used.

Table 3 Typical standard sources of choice and gamma-ray energy peaks used in energy calibration of gamma spectrometry systems

Source	Energy (keV)	Source	Energy (keV)
^{210}Pb	46.5	^{192}Ir	468.1
^{241}Am	59.5	^{22}Na	511.0
^{109}Cd	88.0	Annihilation	511.0
^{182}Ta	100.1	^{207}Bi	569.7
^{57}Co	122.04	^{208}Tl	583.1
^{144}Ce	133.5	^{192}Ir	604.4
^{57}Co	136.5	^{192}Ir	612.4
^{141}Ce	145.4	^{137}Cs	661.6
^{182}Ta	152.4	^{54}Mn	834.8
^{139}Ce	165.8	^{88}Y	898.0
^{182}Ta	179.4	^{207}Bi	1063.7
^{182}Ta	222.1	^{60}Co	1173.2
^{212}Pb	238.6	^{22}Na	1274.5
^{203}Hg	279.2	^{60}Co	1332.5
^{192}Ir	295.9	^{140}La	1596.2
^{192}Ir	308.4	^{124}Sb	1691.0
^{192}Ir	316.5	^{88}Y	1836.1
^{131}I	364.5	^{208}Tl	2614.7
^{198}Au	411.8	^{24}Na	2754.1

(Knoll 2010) with permission from © 2010, John Wiley and Sons)

As stated earlier, the efficiency calibration must be performed with sources that are traceable to a national standards laboratory, such as NIST, NPL, PTB, or any of the recognized NMLs. A mixed gamma-ray standard for both energy and efficiency calibration containing ^{57}Co, ^{60}Co, ^{137}Cs, ^{109}Cd, ^{85}Sr, ^{139}Ce, ^{203}Hg, ^{113}Sn, ^{88}Y, and ^{241}Am is available from many commercial companies which provide NIST traceable sources. The gamma-ray energies of this mixed standard as well as some other commercially available NIST traceable radionuclides that are suitable for efficiency calibration (and energy and shape calibration) are shown in Table 3. An example list of standard sources from authorized suppliers for an environmental survey laboratory is provided in Table 4.

Energy Resolution of Gamma-Ray Spectrometry Systems

FWHM (full width at half-maximum) denotes the resolution capability of an instrument. It is important to perform resolution calibration, also called FWHM calibration, which establishes a function to describe the peak width at a specific spectral energy. The lower the width at half-maxima of the energy peak, the finer the resolution of the instruments. It is an important parameter which signifies an instrument's ability to resolve different photon emissions in a narrow energy range. Majority of environmental laboratories worldwide use ^{137}Cs and ^{60}Co as standard sources for energy and FWHM calibration.

Table 4 An example list of standard sources from an environmental survey laboratory in BARC, India, for calibration of instruments used for detection and measurement of radionuclides and their traceability to certified laboratories

Radionuclide	Issuing agency	Strength	Unit	Standard traceable to
H-3	PERKIN ELMER	450	Bq/ml	NIST (SRM4947C)
Eu-152	Amersham	3.7	kBq	Primary standard supplied by Amersham PLC.UK and traceable to NIST (ANSIN42.22.1995)

For an ideal detector and supporting pulse processing electronics, the spectrum of 662-keV gamma-rays from a ^{137}Cs radioactive source would exhibit a peak in the spectrum whose width is determined only by the natural variation in the gamma-ray energy. The major source of this peak broadening is the number of photo-electrons emanated from the photocathode for a 662-keV gamma-ray. Hence, FWHM for a specific photopeak is defined as

$$\%Resolution\ (FWHM) = \frac{\partial E}{E} \times 100 \approx \frac{k \times 100\%}{\sqrt{\mathrm{E}}}$$

or, alternatively,

$$\%Resolution\ (FWHM) = \frac{\partial C}{E} \times Fe \times 100$$

where:

E = Energy of the peak (keV) of standard source (^{137}Cs or ^{60}Co).
∂E = FWHM of the peak in energy units.
k = Proportionality constant characteristic of the particular detector.
∂C = Width in channels at the half height of the maximum peak counts.
Fe = Energy calibration factor (keV/ch).

Efficiency Calibration of Gamma-Ray Spectrometry Systems

It is important to emphasize here that efficiency cited by the manufacturer of a Ge detector following the IEEE standards (ANSI/IEEE Standard 325–1986) is known as *relative efficiency* and it is not the *absolute efficiency* of the detector. It only represents the ratio of the absolute detector efficiency (of HPGe system) to that of a 3 × 3 inch NaI (Tl) scintillation detector, the point source being placed at 25 cm (about 9.84 in) on the axis of the endcap (measured from the center of the source to the front of the endcap) at 1332.5 keV (^{60}Co). The absolute efficiency at 1.3 MeV of 3 × 3 inch NaI (Tl) scintillation detector is measured at the same distance of 25 cm is 1.2×10^{-3} (L'Annunziata 2020).

Precise calibration of efficiency is essential for quantitative estimation of radionuclides in the environmental samples. It is important to check certain things before calibration:

1. Sample to detector geometry.
2. Calibration sources: As far as possible, certified standard sources of the radionuclide to be estimated should be used for geometries typically used.
3. Efficiency is expressed as radionuclide counting efficiency considering total disintegration rate or gamma energy efficiency by applying the gamma abundance factor (number of gammas per disintegration) of the source used.

It is common to perform a monthly calibration for determining counting efficiencies by measuring a known quantity of radionuclide(s) of interest within a similar matrix and with the same source-detector configuration as the sources requiring analysis. This is done to eliminate any effect that might be caused by differences in standard and sample characteristics, e.g., density, moisture content, shape, and size. Modern software allows saving multiple efficiency calibration curves for different matrices and source-detector configurations for later use.

Gamma Spectrometry System with NaI (Tl) Detector

Sodium iodide (thallium) is the most commonly used detector for routine analysis due to several advantages which include a high light yield, high density, reasonable cost, and availability of detector crystal (NaI) in large sizes. A sodium-iodide scintillation detector is composed of a sodium-iodide (NaI) crystal doped with thallium as scintillator, a photomultiplier tube (PMT), and a data acquisition system. The PMT, which amplifies low level light input from the detector, is attached with a multichannel analyzer (MCA) that converts the overall pulse into a digital signal, corresponding to a given acquisition channel. Sodium iodide detectors have an edge over HPGe in terms of efficiency. The best resolution achievable ranges from 7.5% to 8.5% for the 662 keV gamma ray from ^{137}Cs for a 3" × 3" optimized crystal and is slightly worse for smaller and larger sizes. NaI (TI), just like common salt NaCl, is hygroscopic, and its crystal will deteriorate if exposed to the atmosphere for a brief

time. The NaI (Tl) crystals must therefore be "canned" in an airtight container for use as detector (Knoll 2010).

NaI (Tl) typically converts about 11% of the incident gamma energy into photons with an average energy of 3.0 eV. A 1000 keV gamma will produce, on average, 4.3×10^4 photons.

Energy Calibration of Sodium Iodide Gamma Spectrometry Systems

Energy calibration of NaI (Tl) detector is performed by using sources like ^{137}Cs (662 keV gamma) and ^{60}Co (two gammas of 1.173 and 1.332 MeV). For lower energies, ^{192}Ir and ^{108m}Ag can be used (Hegde and Verma 2004). Sources should be chosen in such a way that they have long half-lives and are monoenergetic or have multiple energies with wide separation. Initially, after setting up of the spectrometer, a standard ^{137}Cs source is placed, and spectrum is acquired. The peak position due to ^{137}Cs source is noted. Gain of the linear amplifier is either increased or decreased obtaining the peak at desired position. For example, if a 10 keV/channel calibration is required, the peak should be positioned at 66th channel for 662 keV gamma line of ^{137}Cs. In an equivalent way, a different standard source (e.g., ^{60}Co) of known energies is taken for calibration.

A linear equation of $y = mx + c$ *or* $E = m(ch) + c$ can be easily fitted for energy versus channel. The equation can later be used to find the energy of unknown peak channel. The energy calibration is performed manually (by picking energy peaks manually) or automatically by the software, by measuring one (^{152}Eu) or several radioactive standard sources with a minimum of three different energy peaks usually covering a wide spectral range between 50 keV and 2500 keV.

Efficiency Calibration of NaI (Tl) Detectors

It is to be noted that efficiency calibration is always done for a specific geometry in which the samples will be counted. Efficiency calibration should be carried out monthly or quarterly, at least. Long lived, certified, and traceable standard gamma sources like ^{137}Cs, ^{60}Co, ^{192}Ir, ^{108m}Ag, and ^{54}Mn can be used to calibrate the system for various gamma energies. A plot of energy versus efficiency is to be drawn for a particular geometry which can be used for other energies for which a standard source may not be available. Certified reference standards are available from IAEA, NPL (UK), CMI, NIST, and other recognized suppliers. The efficiency in percentage can be determined by the following equation presented in its simplest form:

$$Efficiency\ (Ef)\% = N \times \frac{100}{dps} \times \frac{100}{A}$$

where:

Ef = Efficiency of the system for particular gamma energy for a specific geometry.

N = Net cps under the photopeak area after subtracting the background in cps.

dps = Disintegration per second, activity of the standard (Bq).

A = Percent abundance of that particular energy out of total disintegration.

High Purity Germanium (HPGe) Gamma Spectrometry Systems

HPGe gamma-ray spectrometry systems are used to quantify trace levels of gamma emitting radionuclides in the environmental samples. It employs minimal sample preparation and is non-destructive in nature. High Purity Germanium (HPGe) has a relatively high resolution as compared to Sodium Iodide systems. HPGe systems are also widely used for identification of radionuclides formed in Neutron Activation Analysis (NAA).

The most common type of germanium gamma-ray spectrometer consists of a high-purity (mildly *p*-type) crystal fitted with electrodes in a coaxial configuration. The depletion region in germanium can be made several centimeters thick which increases the *resolution*. Due to smaller band gap in germanium (as compared to silicon), thermally generated charge carriers, even at extremely low temperatures, is a potential problem. As a result, virtually all germanium detectors are cooled to liquid-nitrogen temperature (77 Kelvin) during their use.

Apart from factory calibration which involves calibration of all the functional parts of HPGe system including the detector, regular routine calibrations are done with mixed gamma-ray sources in a similar matrix and with the same geometric form as the sample to be analyzed. This requires the purchase of several calibration sources of different energies and geometries. It is now possible to order commercial calibration sources of single or mixed gamma-ray emitters in a matrix of known chemical composition and density in user-supplied containers. Calibrations based upon these sources can then be adjusted to correct for any differences in composition and density between the calibration source and the test source (EPA and FDA 2004).

Energy Calibration of HPGe Type Gamma Spectrometry Systems

Energy calibration of High Purity Germanium (semiconductor) detectors is carried out using a solid or sealed liquid source of mixed radionuclides kept at a standardized distance from detector. The sources commonly used are ^{133}Ba, ^{137}Cs and ^{60}Co. However, mixed standard sources with nearby gamma energies, and sometimes multiple gamma-emitting standard source like ^{152}Eu can also be used. The gain of spectroscopy amplifier or built-in amplifier of analyzer is adjusted to get required energy calibration of 0.2 keV/channel to 2 keV/channel. For example, 662 keV gamma peak of ^{137}Cs should fall on 662nd channel if calibration of 1 keV/ch is required. The peak position can be seen by moving the cursor along the spectrum. Linearity of the system must be checked by plotting a graph of energy against corresponding channel number with respective peaks of ^{133}Ba, ^{137}Cs and ^{60}Co (Fig. 1).

Compared to NaI (Tl), there is a factor of 30 enhancement in the full width at half-maximum (FWHM) resolution. Thus, many nuclear energy peaks which cannot be resolved separately with NaI (Tl) detectors are easily resolved using HPGe detectors. By convention, HPGe detectors are usually characterized by the FWHM in keV at 1332 keV gamma of ^{60}Co. As a rule of thumb, two gamma energies separated by less than 2 resolution widths (FWHM) are usually not resolved fully. FWHM in keV can be calculated by:

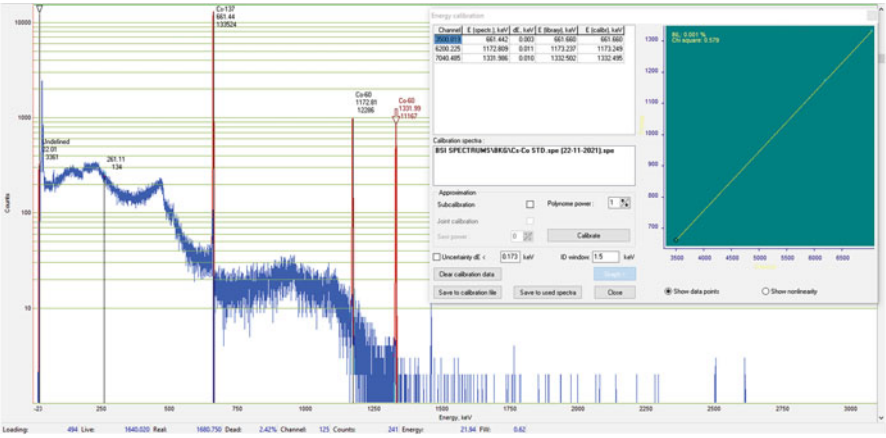

Fig. 1 Energy Calibration of a typical coaxial p-type HPGe system with a relative efficiency of 50%

$$FWHM(keV) = \frac{Nr \times 159}{X_2 - X_1}$$

Nr = Width at half maximum in no. of channels.
X_2 = Position of 1332 peak channel.
X_1 = Position of 1173 peak channel.
159 keV is the difference between 1173 and 1332 keV gamma peaks of ^{60}Co.

Efficiency Calibration of HPGe Systems

The efficiency of HPGe system for a particular geometry and container used is determined. For example, if 20 ml bottle of cylindrical geometry is used for sample counting, standard also must be taken in 20 ml bottle of the same geometry. It is important to keep the sample in the same configuration with respect to detector. Counts are acquired for a minimum of 300 s (i.e., 5 minutes) for efficiency calculation at a particular energy.

$$Efficiency\ (Ef)\% = N \times \frac{100}{dps} \times \frac{100}{A}$$

Ef = Efficiency of the system for particular gamma energy.
N = Net cps under the photopeak area after subtracting the background in cps.
dps = Disintegration per second, activity of the standard (Bq).
A = Percent abundance of that particular energy out of total disintegration.

For efficiency calibration purpose of the detector Standard (Certified) source of ^{137}Cs or ^{60}Co source typically 1 μCi, with reference date (e.g., 22.12.2010) is used. Let us take an example of ^{60}Co which is traceable to NIST (Fig. 2). The absolute efficiency of the germanium detector for 1332.5 keV photons is measured with

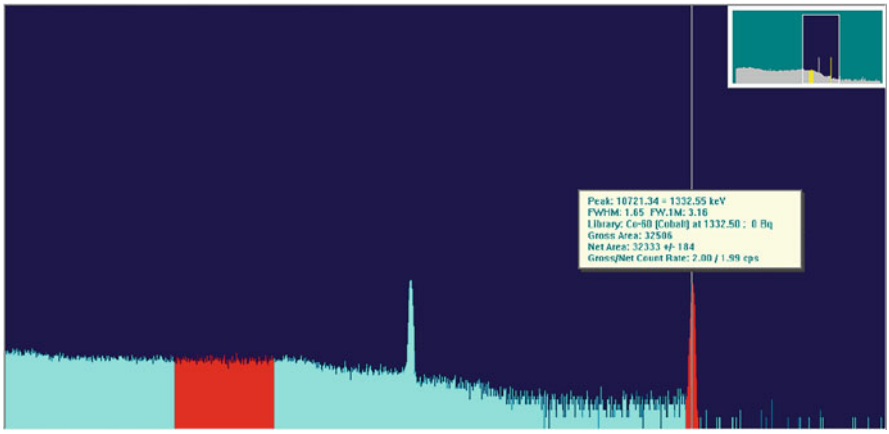

Fig. 2 Efficiency calibration of a HPGe Gamma spectrometry system

appropriate dead time corrections. It is given as the ratio of the total counts in the 1332.5 keV peak to the total number of disintegrations during the elapsed live time.

The half-life ($t_{1/2}$) of ^{60}Co can be taken from international nuclide databases like IAEA Live Chart, DDEP, LBNL etc. (Chu et al. 2022; IAEA and DDEP 2022; LBNL 2022) which is 5.271 years. The activity of ^{60}Co on the counting date (e.g., 22.04.2022) can be found by using the equation:

$$A_t = A_0 \times e^{-\lambda t}$$

$$A_0 = 1\mu Ci = 37000\ Bq$$

$$(Decay\ Constant)\lambda = \frac{0.693}{Half\ \ life}$$

$$= {}^{0.693}\!/_{5.271\ y}$$

$$= 0.1314\ y^{-1}$$

t = elapsed time = 4139 days = 4139/365.25 = 11.33 y.

The above inputs can now be put into the equation

$$A_t = A_0 \times e^{-\lambda t}$$

$$= 37000 \times e^{-0.1314 \times 11.33}$$

$$A_t \approx 8348\ \ \text{Bq}$$

Peak area at 1332.5 keV = 32,506 counts.
Acquisition Time = 16226.60 seconds (Live Time).
Total counts from the source in t seconds = $t \times 8348 \Rightarrow 16226.6 \times 8348$

$$\Rightarrow Absolute\ Efficiency = \frac{Total\ counts\ recorded\ in\ the\ detector}{Total\ counts\ from\ standard\ source}$$

$$\Rightarrow \frac{32506}{16226.6 \times 8348}$$

$$\Rightarrow 2.39 \times 10^{-4}$$

We can get the relative efficiency of the HPGe detector with that of NaI (Tl) which has an absolute efficiency of 1.2×10^{-3} by simple calculation. For example, in above case it will be ~20%.

Similarly, efficiencies can be calculated for different gamma energies and geometries using sources of ^{133}Ba, ^{60}Co, ^{134}Cs, ^{54}Mn, etc. A graph is drawn taking logarithm of energy (keV) in X-axis and logarithm of efficiency in Y-axis.

Calibration of Gamma-ray Spectrometry Systems for Environmental Samples (Geometry)

For environmental or low-activity samples (0.01 to 1 Bq/g), typically, 300 to 500 g of prepared solid samples are used. If a fixed volume is used, the mass will vary according to the density. High-density samples may cause significant self-absorption of low-energy gamma-rays and degrade the higher energy gammas. Therefore, it is important to calibrate the detector with standards of the same geometry, composition, and density, or use appropriate attenuation and geometry correction algorithms. The photopeak efficiency calibration for solid materials, like soil and sediments, is done by using certified reference materials (CRMs) released by the IAEA, coded as RGU-1, RGTh-1, and RGK-1 for uranium, thorium (and their daughter products), and potassium (Fig. 3). The specific activities of the CRMs are certified at 95% confidence level and are equal to 4940 ± 30 Bq/kg for ^{238}U (RGU-1), 3250 ± 90 Bq/kg for ^{232}Th (RGTh-1) (both in secular equilibrium), and 14,000 ± 400 Bq/kg for ^{40}K (RGK-1).

Measurement of Alpha-Emitting Radionuclides and Standard Sources for Calibration

Alpha (α) particles are positively charged and highly massive compared to other nuclear emissions (beta, positron, and neutron). As a result of high coulombic interaction with nearby atoms, alpha particles lose all their energy over a noticeably short distance and typically traverse only to few centimeters in air and have extremely limited penetration into matter. Alpha particles tend to lose all their energy

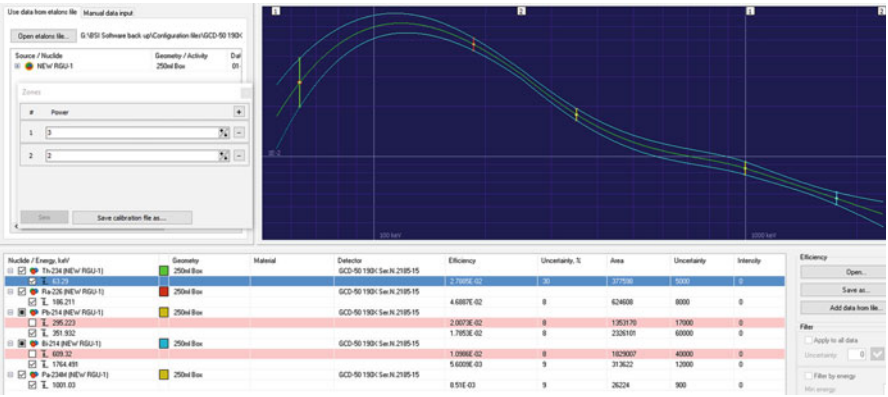

Fig. 3 Efficiency calibration of HPGe gamma spectrometry system for a 250 g cylindrical box containing certified reference material (CRM) from IAEA

characterized by an intense high rate of energy loss while passing through matter. Most energetic alphas seldom penetrate below the dead layer of human skin.

The alpha detection systems, most widely used, are ionization chambers, gaseous proportional counters, solid-state (silicon) semiconductor detectors/spectrometers, and scintillation counters (plastic, ZnS phosphor-PMT combination, or LSC). The associated electronic components in almost all the cases comprise of high-voltage power supplies, preamplifiers, amplifiers, pulse discriminators, scalers, and output devices. ADC (analogue to digital converter) and MCA are additional components when alpha spectroscopy is done. Alpha counters usually have exceptionally low background and high efficiency (10 to 100%).

Alpha calibration standards are available from NIST, NPL, or a commercial vendor (complying with national standards bodies) that supplies NIST or NPL traceable sources. Among the radionuclides available are ^{230}Th, ^{241}Am, ^{235}U, ^{239}Pu, ^{228}Th, ^{238}U, and ^{226}Ra. Other radionuclides are also available.

Alpha Scintillation Counting by ZnS (Ag) System

Most of the inorganic scintillators comprise of translucent single crystals. Some, such as silver-activated zinc sulfide, are efficient scintillators, but growing it in the form of optical-quality large crystals is not yet possible. Silver-doped zinc-sulfide [ZnS (Ag)] systems are commonly used for gross-alpha counting on a thin base, *viz.,* a metal planchet or filter paper. It does not differentiate between alpha energies; hence a gross count of all alpha emitters present is delivered. It is most commonly used for surface contamination detection and gross alpha count of radionuclides present in water samples on a planchet (dried under IR lamps).

Alpha probe consists of a scintillator detector made up of a thin layer of silver-activated zinc sulfide [ZnS (Ag)] crystal and a high-performance PMT. The density

of the crystal is about 10 mg/cm^2. The PMT and crystal are placed in a light tight steel casing to have extremely low background of the order of about 1.0×10^{-3} cps at an efficiency of about 30%. The operating voltage is usually less than 1500 V enabling the use of simple scalers.

Calibration of ZnS (Ag) Counting System

An electroplated thin alpha-emitting source with known cps (counts per second), usually ^{239}Pu, is used for calibration. The background is taken for a sufficient time (in general the background counts come around 0.002 cps). A ZnS (Ag) alpha detection system can have an efficiency of 45 to 50 percent for an electrodeposited calibration source. The efficiency, to a significant extent, is influenced by the thickness of sample. MDA (3) for unit volume of sample is 0.0075 Bq for a counting time of 5000 s (about 1 and a half hours).

Counter Efficiency:

$$S\%(\text{Efficiency}\%) = N \times \frac{100}{dps}$$

where:

S% = Efficiency of the counter in percentage.

N = Net cps after subtracting the background in cps.

dps = Disintegration per second, activity of the standard (Bq).

Alpha Spectrometry System

Alpha spectrometry is used to identify and determine the concentration of various alpha-emitting radionuclides in environmental samples such as ^{238}Pu, $^{239\,+\,240}$Pu, ^{241}Am, ^{242}Cm, and ^{237}Np. Samples from various matrices are subjected to radiochemical separation of respective radionuclides, and the separated sample is electrodeposited on a stainless steel planchet to count in alpha spectrometer.

An alpha spectrometry system consists of either SSB (silicon surface barrier) detector or PIPS (passivated implanted planar silicon) detector of suitable size (generally 300–450 mm^2 area) in a vacuum system (0.01 mm of Hg). SSB detectors are found in old systems, while modern age systems contain PIPS detector which has more advanced feature than the former (Table 5). The system is calibrated with ^{239}Pu, ^{242}Pu, and ^{241}Am standard sources in the detector chamber at a standard distance.

The range of alpha particles is only a few centimeters (cm) in air and much less in solids. It is, therefore, necessary to have a thin source and to keep the source and detector in vacuum to obtain maximum energy resolution and high efficiency. The background of the detector amplifier system should not be more than 1 count per 10^4 seconds in the energy range of 2 to 10 MeV. Environmental samples are normally counted for 50,000 − 80,000 seconds or longer depending upon the activity levels.

Table 5 Some operating parameters of alpha spectrometry systems available worldwide

Active area (mm^2)	300	450	600	900	1200
Thickness (mm min/max)	150/315	150/315	150/315	150/315	150/315
Recommended bias (V)	+20/80	+20/80	+20/80	+20/80	+20/80
Si resistivity (min U-cm)	2000	2000	2000	2000	2000
Operating temperature (min/max)	−20/+40	−20/+40	−20/+40	−20/+40	−20/+40
Leakage current (at 25 °C) (typical/max in nA)	15/70	25/100	30/120	40/200	60/300
Alpha resolution (keV)	17/19	18/20	23/25	25/30	30/37
Absolute efficiency (%)					
At 2 mm spacing	36.8	40.2	41.0	43.6	44.5
At 5 mm spacing	23.5	28.3	31.2	34.8	36.9
At 15 mm spacing	7.3	10.1	12.4	16.1	18.9

L'Annunziata (2003)

Energy Calibration of Alpha Spectrometry System

The energy resolution obtained from an alpha spectrometric system is dependent on the detector, uniform thickness of source, amplifier, and the analyzer. Though the detectors are quoted to have a resolution of about 20 keV, (FWHM), a resolution of about 50 keV or less is acceptable in the analysis of alpha emitters for the environmental samples.

Electroplated sources of about 50 Bq concentration each of ^{239}Pu (5.155 MeV), ^{242}Pu (4.90 MeV), and ^{241}Am (5.486 MeV) either as single or mixed sources are used to carry out energy calibration. Amplifier gain and the conversion gain of multichannel analyzer are adjusted such that an energy calibration of about 10 keV/channel is arrived. Linearity of the system is verified by counting the other sources under the same setup. A linear equation of energy versus channel number is established by using the three discrete alpha energies and the respective channel numbers.

Resolution of Alpha Spectrometry Systems

Energy resolution of a detector amplifier system is expressed as energy at full width half maximum (FWHM). An electroplated ^{241}Am source (5.49 MeV and 5.44 MeV alphas with 85% and 13% abundance, respectively, and a half-life of 433 y) can be easily prepared in a radiochemical laboratory and is best suitable for energy resolution. A 50 Bq ^{241}Am source can be positioned in detector chamber, usually at a 2 mm distance from the detector. While FWHM and MDA increase with increasing distance, efficiency decreases due to attenuation. Calculation of the energy resolution is identical to gamma-ray spectrometry system.

$$\mathrm{FWHM}\% = \frac{\partial E}{E} \times 100 \approx \frac{k \times 100\%}{\sqrt{\mathrm{E}}}$$

or, alternatively,

$$\text{FWHM}\% = \frac{\partial C}{E} \times Fe \times 100$$

where:

E = Energy of the peak (keV) of the standard source (^{241}Am).
∂E = FWHM of the peak in energy units.
k = Proportionality constant characteristic of a particular detector.
∂C = Width in channels at the half height of the maximum peak counts.
Fe = Energy calibration factor (keV/ch).

Efficiency Calibration of Alpha Spectrometry Systems

Electroplated sources of about 50 Bq concentrations each of ^{239}Pu, ^{242}Pu, and ^{241}Am are prepared. Each of them is counted for about 300 seconds (about 5 minutes) in a well-evacuated chamber. Vacuum for each standard should be the same and must be less than 0.01 mm Hg. The distance between the source and the detector is usually fixed at about 2 mm. The efficiency of the spectrometer decreases rapidly with the increase in the distance between detector and source (Table 5).

$$\textit{Efficiency}\ (Ef)\% = N \times \frac{100}{dps} \times \frac{100}{A}$$

where:

Ef = Efficiency of the system for particular alpha energy.
N = Net cps under the photopeak area after subtracting the background in cps.
dps = Disintegration per second, activity of the standard (Bq).
A = Percent abundance of that particular energy out of total disintegration.

Similar set-up conditions must be used for the counting of electrodeposited sample of environmental matrices.

Traceability of Standard Sources Used in Calibration of Environmental Monitoring Equipment

In the 11th General Conference of Weights and Measures (CGPM), an International System of Units (SI System) was adopted as an extended version of metric system. SI system provided internationally accepted definitions and prototypes for 7 fundamental or base units and 22 derived units and has authority to work together with member states on the matters related to measurement science and measurement standards. The world has moved from local measurement units, which varied from one country to the other, to a truly global system of measurement accepted worldwide. The SI units nowadays hold an official status in majority of the countries worldwide. The BIPM located at Sevres, France, is the official home of SI units and international reference time scale (UTC) (Hanisch et al. 2022).

Reliable and consistent measurement is an essential requirement for virtually all conformity assessment processes, including those which support health, safety, and

environmental objectives. It is also important for the international recognition of those measurements, which is an essential aspect within the world trading system (BiPM 2012). For flawless trade, research publications, safety regulations (e.g., dosimetry), and acceptance of test results across the world require that respective commercial, non-governmental, or governmental bodies providing such certifications must in turn get their measurement methods accredited according to some international norms acceptable to all the participating economies.

Role of International Laboratory Accreditation Cooperation (ILAC)

ILAC, a trans-governmental network headquartered at Utrecht (Netherlands), has played a pivotal role in providing such services (calibration, testing, medical testing, inspection, reference material producers, and proficiency testing providers accreditation) to the participating countries through mutual recognition arrangement (MRAs) (ILAC IAF 2014).

ILAC is the international organization along with NMIs and other national accreditation bodies (commercial, non-governmental, or governmental), which operate according to the guidelines, jointly issued by International Organization for Standardization (ISO) and International Electrotechnical Commission (IEC), i.e., ISO/IEC 17011. ISO and IEC themselves do not provide any certification or accreditation; however, they provide comprehensive guidelines for such process through documentation. ILAC is involved in the accreditation of laboratories worldwide including calibration laboratories (using ISO/IEC 17025), testing laboratories (using ISO/IEC 17025), medical testing laboratories (using ISO 15189), inspection bodies (using ISO/IEC 17020), proficiency testing providers (using ISO/IEC 17043), and reference material producers (using ISO 17034) (ILAC 2022a).

The ILAC MRA links the existing regional MRAs of the Recognized Regional Cooperation Bodies and delegates authority for the evaluation, surveillance, re-evaluation, and associated decision-making relating to the signatory status of the accreditation bodies that are ILAC MRA signatories. The signatories agree to accept the results of each other's accredited bodies. Hence, the results from the laboratories accredited by the ILAC MRA signatories are able to be recognized internationally. Usually, an online directory of accredited facilities is provided on ILAC webpage to perform a signatory search (ILAC 2022b).

Accreditation is the independent evaluation of conformity assessment bodies (CABs, the term CAB has now been replaced with "laboratory" in recent ISO/IEC 17025 document) or laboratories against recognized standards to carry out specific activities to ensure their impartiality and competence. Through the application of national and international standards, government, procurers, and consumers can have confidence in the calibration and test results, inspection reports, and certifications provided.

The regional arrangements are managed by the recognized regional cooperation bodies that work in harmony with ILAC and IAF (International Accreditation Forum). The recognized regional cooperation is also represented on the ILAC and

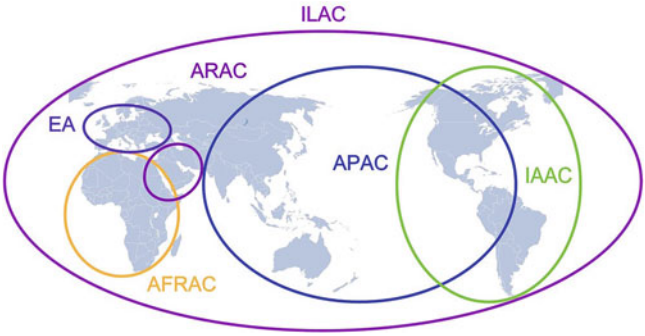

Fig. 4 Five recognized regional (European, Asia-Pacific, Arab, Africa and Inter American) cooperation bodies under the ILAC MRA

IAF Executive Committees. As depicted in Fig. 4, ILAC works closely with five (but not limited to) regional cooperation bodies involved in accreditation, notably EA in Europe, APAC in the Asia-Pacific, IAAC in the Americas, AFRAC in Africa, and ARAC in the Arab region (ILAC MRA 2022).

Traceability to SI

The laboratory or a third party performing the calibration shall ensure that the measurement results are traceable to International System of Units (SI). It can be ensured when a) calibration is provided by a competent laboratory (conforming to the guideline of ISO/IEC 17025), b) it is performed using certified values of certified reference material producer (RMP), or c) direct realization of SI through NMIs or any international body. There are instances when metrological traceability to SI units is not possible; in such cases, it can be demonstrated through comparison with an appropriate reference, e.g., by using certified values of a CRM.

The instruments used of radiation detection and measurement are regularly calibrated with standard sources which are traceable NIST, NPL (UK), and National Metrology Laboratories/Institutes (NMLs/NMIs) or to IAEA which in turn is traceable to BIPM (International Bureau of Weights and Measures, *Bureau international des poids et mesures*), which is an internationally recognized body for SI Systems by General Conference on Weights and Measures (Conférence générale des poids et mesures, CGPM) (Fig. 5). As per CGPM, the International System of Units (SI) plays a pivotal role in providing confidence in the accuracy and global comparability of measurements needed for international trade, manufacturing, human health and safety, protection of the environment, global climate studies, and scientific research.

All the instruments used for environmental monitoring and surveillance must be calibrated with internationally traceable standard sources for authenticity of the results and for regulatory compliance.

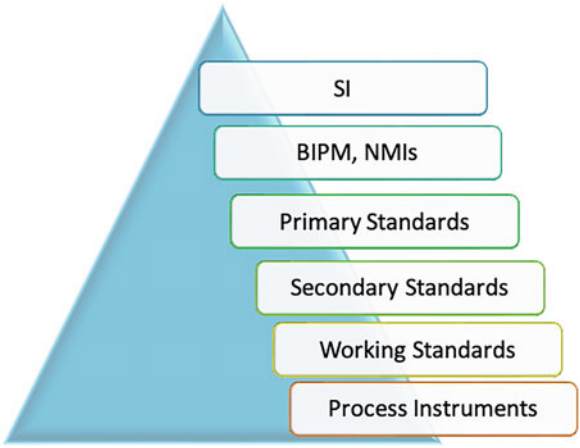

Fig. 5 Traceability pyramid in which SI is the absolute international standard with least uncertainty

Instrument calibration should be performed at certain intervals, documented in manual or as per requirement of certification agency, and that too only with certified standard sources traceable to a national standards body (Foster 2009) recognized by BIPM (International Bureau of Weights and Measures, *Bureau international des poids et mesures*) such as the National Institute of Science and Technology (NIST), NPL (UK), IAEA, and other NMLs/NMIs. Some of the radionuclides which are commonly available as standard sources for calibration from laboratories or commercial suppliers certified by an NMI (some international certifying agency recognized by CGPM) are given in Tables 6 and 7.

Routine calibrations of environmental instruments (for efficiency calibrations) should be done using certified reference materials of known and documented value and stated uncertainty. These certified or standard reference materials (CRMs) may be supplied by the following:

1. NIST, along with other national standards bodies such as the National Physics Laboratory (NPL, UK), Physikalisch-Technische Bundesanstalt (PTB) of Germany, Czech Metrology Institute (CMI) of Czech Republic

   A list of NMLs is provided by NIST at their website for easy reference (Foster 2009).
2. A calibration-source supplier whose measurement capabilities or manufacturing processes are tested periodically by NIST or national standards bodies.
3. IAEA, International Atomic Energy Agency (Vienna, Austria).
4. A calibration-source supplier who documents derived materials with stated uncertainty, and whose values has been verified with analytical and measurement systems that have been tested periodically through an unbroken chain of comparisons to the national standards (Table 7)

Table 6 Standard sources used for calibration of equipment used in environmental monitoring

Type of radiation detection	Equipment	Important standard sources for calibration	Standard source form
Alpha	ZnS (Ag), alpha spectrometry system	^{232}U, ^{238}Pu, ^{241}Am, ^{242}Pu	Alpha sources
Beta	Liquid scintillation counting (LSC/LSA)	^{3}H, ^{14}C, ^{90}Sr, ^{36}Cl	Beta liquid sources
Gamma	Gamma spectrometry systems NaI (Tl), HPGe	^{137}Cs, ^{133}Ba, ^{60}Co, ^{152}Eu	Gamma source kits, resin sources

Establishing Metrological Traceability

A laboratory or an organization as a whole, given that all the laboratories in that organization use the same standard sources or reference materials kept at a centralized location, can establish metrological traceability as per clause 6.5 of ISO/IEC 17025:2017 document (ISO/IEC 2017). It has been further elaborated in the Annex A of the same document. It states that a metrological traceability can be established by considering and then ensuring the following:

1. The specification of the measurand, i.e., the quantity to be measured.
2. A documented unbroken chain of calibrations going back to an appropriate national, international, or intrinsic standard.
3. Measurement uncertainty for all the steps in the traceability chain has been evaluated.
4. Each step of the chain is carried out with appropriate methods, and the results are stated with associated uncertainties.
5. The laboratories performing (other than the one under consideration) one or more steps in the chain shall also supply evidence for their technical competence.

The above five steps have been reproduced *verbatim* from the ISO/IEC 17025: 2017 document. It is the responsibility of the laboratory to ensure and demonstrate metrological traceability. Certified values of certified reference materials (CRMs) supplied from reference material producers (RMPs) which conform to the ISO 17034,provide metrological traceability (ISO 2016). A laboratory can demonstrate metrological traceability through various methods conforming to ISO/IEC 17025 which include third party recognition, e.g., from an accreditation body, and external assessment by the end-users (second party recognition) or by self-assessment (first party). Additionally, internationally accepted paths include calibration and measurement capabilities provided by an NMI, a designated institute, or an accreditation body which themselves have been subjected to suitable peer-review processes conducted under CIPM MRA (International Committee for Weights and Measure Mutual Recognition Arrangement) or under ILAC. The BIPM KCDB (Key Comparison Database) provides details about the range and measurement uncertainty for each listed service (BIPM KCDB 2022; 2022).

Table 7 A list of essential instruments for measurement of environmental radionuclides and standard sources of calibration [example taken from Environmental Survey Laboratory of BARC, India]

Instruments	Detector	Calibration	Certificate/ manufacturer	Traceability
Gamma spectrometry	HPGe	Standards of ^{241}Am,^{133}Ba,^{137}Cs, and ^{60}Co or ^{152}Eu standard	UKAS/Amersham plc Buckinghamshire/GE health care ltd., Buckinghamshire Czech metrology institute Czech Republic, etc.) CRM from IAEA	NPL (UK) Czech national standard IAEA
	NaI (Tl)	Standards of ^{133}Ba,^{137}Cs, and ^{60}Co	UKAS/Amersham plc Buckinghamshire/GE health care ltd., Buckinghamshire Czech metrology institute Czech Republic, etc.) CRM from IAEA	NPL (UK) Czech national standard IAEA
Beta counting systems	Liquid scintillation analyzer	^{3}H, ^{14}C standard solutions	UKAS/Amersham plc Buckinghamshire/GE health care ltd., Buckinghamshire Czech metrology institute Czech Republic, etc.) CRM from IAEA	NPL (UK) Czech national standard IAEA
	Low background GM/plastic scintillator	^{40}K standard ^{137}Cs standard ^{90}Sr standard	Prepared in-house using standards from UKAS/Amersham plc and KCl- AR grade	IAEA

	ZnS (Ag) alpha counter	$^{239+240}$Pu standard ^{241}Am standard	Prepared in-house using tracer (^{236}Pu) from Czech metrology institute Czech Republic	
Radiation survey meters	Low range survey meters	^{137}Cs point source	Amersham	NIST
	High range survey meters	^{137}Cs point source		
	NaI(Tl) survey meters	^{137}Cs point source		

Certified Reference Materials (CRM)

A reference material (RM) is defined as a material which is sufficiently homogenous and stable with respect to one or more specified properties, i.e., quantitative or qualitative, and which has been established to be fit for its intended use in a measurement process (e.g., identity of substances or species) (Elordui-Zapatarietxe et al. 2016; ISO 2017; NIST 2022). A certified reference material (CRM) is different than a reference material in that it is accompanied by a certificate and has metrological traceability, and each property value has an uncertainty value assigned to it (IAEA 2009). These values are stored by the CRM and then transferred along with the CRM itself when transported from one location to another. A CRM producer's method must meet the requirements of ISO's general requirements of homogeneity and stability (ISO 2017). A standard reference material (SRM) is a patented name for reference materials from NIST (NIST 2022).

ISO 17025: 2017 (ISO/IEC 2017) discusses about demonstration of metrological traceability which clearly states that *Laboratories are responsible for establishing metrological traceability. Certified values (with associated uncertainty) of certified reference materials from CRM producers conforming to ISO 17034 provide a verifiable metrological traceability.*

An unbroken metrological traceability and known uncertainty for the property values of the material is provided by the CRMs. The traceability is provided via a paper trail or through a digital certificate that clearly documents the property values, the uncertainty, and the authoritative issuing body. CRMs can be used for method validation, method verification, monitoring process and control, calibration, and training.

For environmental radioactivity measurements, IAEA provides CRMs (Table 8) for efficiency calibration of instruments for specific radionuclides which can be ordered through IAEA nucleus website (IAEA 2003; 2022).

IAEA ALMERA Network for Proficiency Tests and Interlaboratory Comparison Exercises

The ALMERA network (Analytical Laboratories for the Measurement of Environmental Radioactivity) was established by the IAEA in 1995 and is a cooperative effort to harmonize and improve the analytical capabilities of environmental laboratories worldwide in the member countries (Almera 2020). IAEA member states can nominate laboratories which are expected to provide reliable and timely analysis of environmental samples in the event of an accidental or intentional release of radioactivity.

ALMERA consists of 194 laboratories representing 90 countries. The IAEA helps the ALMERA network of laboratories to maintain their readiness by coordination activities which includes organizing meetings, developing standardized

Table 8 A list of certified reference materials supplied by IAEA

methods for sample collection and analysis, and organizing interlaboratory comparison (ILC) exercises and proficiency tests (PTs) as a tool for external quality control.

As per the "The ALMERA Network – Nucleus" resource, participation of laboratories in these activities results in the following:

1. Demonstration of technical competence of ALMERA laboratories through participation in proficiency tests.
2. Wider application of recommended validated methods and methodological harmonization, leading to enhanced worldwide comparability of environmental radioactivity measurement results.
3. Shared information on available analytical capabilities and expertise, which facilitates the identification of laboratories with competence in specific areas of interest, particularly in emergency situations.

The IAEA Terrestrial Environmental Radiochemical Laboratory (TERL) organizes annual proficiency tests (PT) and interlaboratory comparison (ILC) exercises for member states and ALMERA laboratories which are designed to monitor and demonstrate their performance and analytical capabilities and to identify gaps and problem areas where further development is required (Almera 2020).

Acknowledgments Authors would like to thank Dr. D. K. Aswal, Director, Health, Safety, and Environment Group (HS&EG), BARC for taking keen interest on the subject and providing constant help and guidance throughout the preparation of this chapter. We would also like to thank our colleagues from Bhabha Atomic Research Centre (BARC) who provided insight into several topics through discussion and review.

Abstract

The Bhabha Atomic Research Centre (BARC) is the designated institute in ionizing radiation metrology for the country. The BARC designs, develops, establishes, maintains, and disseminates various national standards for physical quantities of ionizing radiation in India. The IAEA/WHO has recognized the BARC as a Secondary Standard Dosimetry Laboratory (SSDL) for disseminating radiological standards to users in the country. SSDL-BARC provides traceable calibration to the users in the field of teletherapy, brachytherapy, radiation protection, and diagnostic radiology. The pace of the advances in radiation therapy with the expected improvement in patient treatment has brought out the need for greater accuracy in the treatment process. SSDL-BARC participates in international intercomparison programs to establish its equivalence with international standards, thereby validating the calibration procedure followed in the laboratory. Radioisotope targeted therapy has been employed in the treatment of wide variety of cancers. The activity of these radiopharmaceuticals at the nuclear medicine centers is measured using the radionuclide calibrators. BARC as the national metrological laboratory for radioactivity has been conducting the audit program for activity measurements with RC for more than four decades. Neutron sources/fields not only are critical for operating and regulating nuclear reactors but also are important for various other research, industrial, and radiation protection applications. Therefore, precise value of neutron source strength and resultant field is highly essential which is provided by the BARC using several neutron standards developed for the purpose.

Radiation processing technologies are very widely used in different industrial applications like sterilization of healthcare products, processing of food and agriculture products, material modification and emerging fields like environmental remediation, synthesis of advanced materials and products, medical applications such as irradiation of blood, etc. Proper dosimetry is the backbone of success of these applications. Conventional radiation measuring techniques like ionization chambers, calorimeters, etc. are unable to measure absorbed doses for most of these applications. Chemical dosimetry techniques provide a cost-effective alternative for radiation processing dosimetry.

Radiation monitoring instruments are backbone to all the radiological and nuclear installations for the safety of occupational radiation workers. Performance of these monitors depends on calibration and measurement traceability to the national standards. Protection-level radiation monitors cover a wide range of radiation field (gamma ray, X-ray, and beta ray) intensity and energy; therefore, measurement standards of various types and sizes are established. The BARC has also established various radiological facilities for gamma rays, X-rays, and beta

rays which are used for calibration and testing of all kinds of protection-level radiation monitors.

Introduction

The National Physical Laboratory of India (NPL-India) is the national metrology institute (NMI) for the country, and the Bhabha Atomic Research Centre (BARC) is the designated institute in ionizing radiation metrology. As the designated institute of ionizing radiation metrology, the BARC designs, develops, establishes, maintains, and disseminates various national standards for physical quantities of ionizing radiation in India. Primary standards, secondary standards, and field standards for all types of ionizing radiation like alpha, beta, and gamma rays, X-rays, and neutron are developed, established, and maintained at the BARC. The BARC participates in various international intercomparison exercises to establish the equivalence with other NMIs in the world.

The BARC is an active member of the Asia Pacific Metrology Programme (APMP), consisting of a group of NMIs from the Asia-Pacific region, and is engaged in improving regional metrological capability through sharing of expertise and exchange of technical information. APMP is a regional metrology organization recognized by the International Committee for Weights and Measures.

As a designated institute, the BARC is a member of Consultative Committee for Ionizing Radiation (CCRI) as follows:

1. CCRI Section I (Dosimetry): X-Ray and Gamma Rays and Charged Particles
2. CCRI Section II (Radioactivity Measurement): Measurement of Radionuclides
3. CCRI Section III (Neutron): Neutron Measurements

Radiation Metrology and Radiotherapy

Radiotherapy is a key treatment modality for cancer patients. Approximately one in three people will develop cancer during their lifetimes. Depending on the region of the world they live in, up to 65% of all cancer patients could benefit from radiotherapy as part of their treatment management.

Advances in radiation therapy technology have allowed the treatment to evolve from a conventional 2D therapy to more complex treatment modalities like conformal radiotherapy, intensity-modulated radiotherapy, image-guided radiotherapy, etc. The pace of the advances in radiation therapy with the expected improvement in

patient treatment has brought out the need for greater accuracy in the treatment process. In order to ensure sustained accuracy in radiation therapy, all the steps involved in the radiation treatment have to be covered in the quality assurance program of the institution. It is well recognized that there is a need to evaluate the influence of different factors affecting the accuracy of radiation dose delivery and to define the actions necessary to maintain treatment uncertainties at acceptable levels.

All countries which use ionizing radiation for treatment purpose should maintain a national standard for the relevant quantity to establish metrological traceability to international standard. Standards should be traceable to the International System of Units (SI) and may either be a primary standard maintained at a primary standards dosimetry laboratory (PSDL) or a secondary standard that is traceable to a primary standard and maintained at a secondary standards dosimetry laboratory (SSDL).

An SSDL can be traceable to the SI and international measurement system in different ways. Some SSDLs are traceable to a PSDL or directly to the BIPM if there is no national primary standard and the country is a member of the Metre Convention. Many SSDL Network members are traceable to primary standards through the International Atomic Energy Agency (IAEA). In Fig. 1 (reproduced from IAEA TRS 398 (IAEA 2000)), the highlighted box shows the traceability route for user or radiotherapy centers in India.

The IAEA/WHO has recognized the BARC as a Secondary Standard Dosimetry Laboratory (SSDL) for disseminating radiological standards to users in the country.

SSDL-BARC provides traceable calibration to the users in the field of teletherapy, brachytherapy, radiation protection, and diagnostic radiology. SSDL-BARC participates in international intercomparison programs to establish its equivalence with international standards, thereby validating the calibration procedure followed in the laboratory. The BARC also participates in quality audit conducted by the IAEA in the field of radiotherapy.

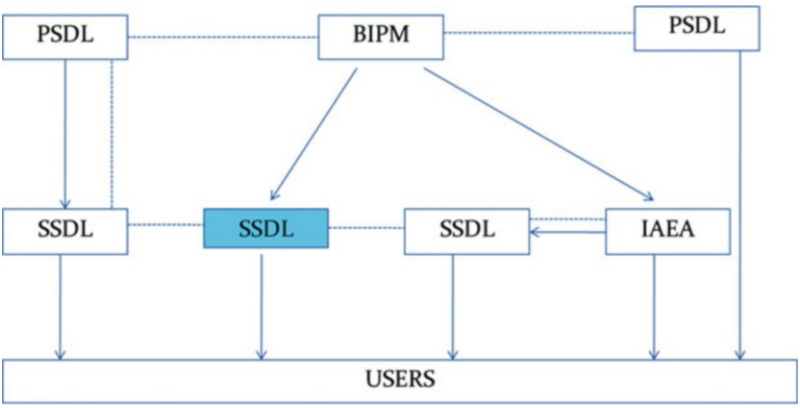

Fig. 1 Simplified representation of the international measurement system for radiation dosimetry. (Reproduced from IAEA TRS 398)

Traceability of Dosimeters Used in External Beam Therapy

Cylindrical ionization chambers and parallel plate ionization chambers of nominal volume up to 0.6 cc are used in dosimetry of teletherapy. Calibration of dosimeters is carried out by following IAEA protocol TRS-398. It is based on the determination of a calibration coefficient in terms of absorbed dose to water in ^{60}Co. Users of dosimeter use this calibration coefficient to perform dosimetry at user's radiation beam. Annually, around 350 SSDs are calibrated at SSDL-BARC.

The level of accuracy achievable in a clinical setup is primarily based on the accuracy achievable in the calibration laboratory.

SSDL-BARC maintains reference standards calibrated at BIPM with a relative standard uncertainty of 0.3% ($k = 1$). The chambers were calibrated in terms of absorbed dose to water and air kerma at ^{60}Co energy.

The laboratory has established international equivalence by participating in various intercomparison programs. Some of the recent comparison programs at ^{60}Co energy are:

- IAEA comparison of absorbed dose to water and air kerma for SSDLs at ^{60}Co energy (2015)
- Asia Pacific Metrology Programme (APMP) key comparison of absorbed dose to water for ^{60}Co (APMP.RI(I)-K4) (2010)
- Asia Pacific Metrology Programme (APMP)/TCRI key comparison of measurement of air kerma for ^{60}Co gamma rays (APMP.RI(I)-K1), 2006

Reference Air Kerma Rate Calibration at ^{192}Ir and ^{60}Co Beams (Brachytherapy)

Brachytherapy is the use of encapsulated radioactive source to deliver a high dose to tissue with the source placed very close to the tumor volume. Source strength determination is an important part of the QA program for brachytherapy. In dosimetry of brachytherapy, well-type ionization chambers of nominal volume of 200 cc are used. Calibrations of these dosimeters are carried out in terms of reference air kerma rate (RAKR) in ^{192}Ir and ^{60}Co energy. IAEA-TECDOC 1274 (IAEA 2002) is used for this calibration. Yearly around 100 well-type ion chambers are calibrated at ^{192}Ir energy at SSDL-BARC. Onsite well-type chamber calibration is carried out for ^{60}Co HDR brachytherapy sources based on the request from institutions.

The reference standard developed at SSDL-BARC for RAKR measurement is graphite-walled ionization chamber having a nominal volume of 1000 cc. Figure 2 shows the reference standard and the ^{192}Ir HDR calibration facility maintained in the laboratory.

TLD-Based Quality Audit Program

SSDL-BARC conducts dosimetry quality audit for radiotherapy centers in India. Participating in quality audit program gives confidence to the participating

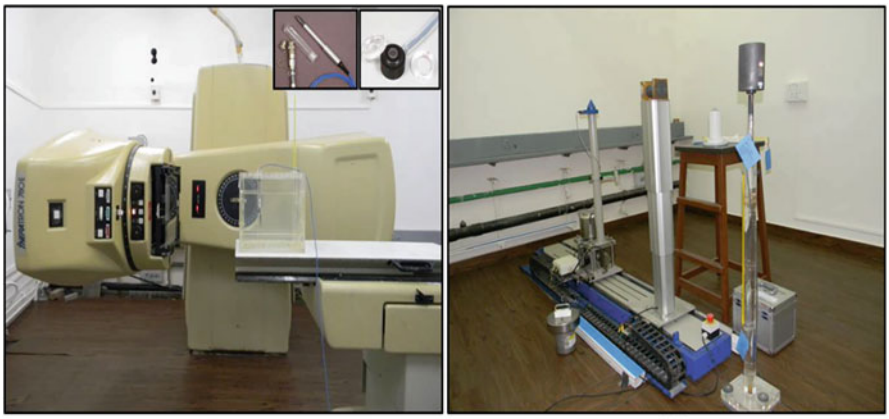

Fig. 2 (**a**) Telecobalt calibration facility, [inset] typical cylindrical ionization chamber and plane parallel chamber calibrated at SSDL-BARC. (**b**) Calibration facility for well-type ionization chamber

radiotherapy centers about the quality of treatment given to the patients. The quality audit program has evolved from the basic reference audit to more complex treatment techniques like intensity-modulated radiation therapy.

An independent verification of the quality of the dosimetry practices in radiotherapy centers is a part of the quality assurance (QA) guidelines. Postal dose quality audit provides a cost-effective methodology to verify dosimetry practices covering a large number of institutions and machines. Audits are useful to identify incorrect dosimetry practices followed at institution level and to correct them. Technical support is provided to the medical physicists to improve the dosimetry status at the radiotherapy centers. Workshops, training programs, and lectures on dosimetry are delivered to update the knowledge of the medical physicist community.

Since 1976, SSDL-BARC has been conducting TLD postal dose quality audit programs for radiotherapy centers in India. By participating in the external quality audit program, the radiotherapy center's QA program gets validated. Figure 3 shows improvement in the accuracy of the dose delivery capability at radiotherapy centers.

Calibration of Diagnostic Radiology Instruments at 20–150-kV X-Ray Diagnostic Beam Qualities

With the increased use of medical diagnostic procedures in clinical fields, there is a growing concern for the small increase in radiation-associated cancer risk to the general public which can become a public health concern if large number of the population undergoes such procedures. With the advent of new and specialized diagnostic tools, concern has been raised regarding the radiation dose received by patients and the healthcare providers involved in these procedures. In view of the importance of patient dose in radiology procedures, patient dose is controlled by the

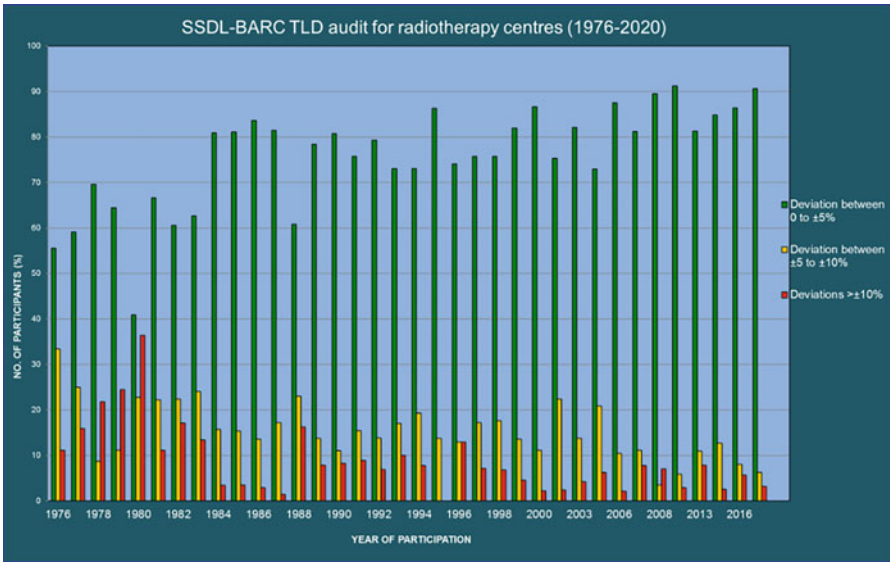

Fig. 3 Dosimetric quality audit program conducted by SSDL-BARC

principle of optimization along with regulatory control. Dosimetry in diagnostic radiology is a challenge as the instruments should be designed to cater to the varied clinical applications. The use of these instruments and the interpretation of the results obtained may require specialized techniques and knowledge. It is imperative that a standardized procedure be followed for dose measurements in clinical setup.

For the calibration of such instruments and their clinical measurements, the IAEA has a protocol, i.e., IAEA TRS-457–Dosimetry in Diagnostic Radiology: An International Code of Practice (IAEA 2007). SSDL-BARC has implemented IEC 61267 (IEC 2005) recommendations and the IAEA protocol TRS-457 by establishing diagnostic beam qualities and disseminating it to the users in the field of diagnostic radiology.

Nineteen diagnostic range X-ray beam qualities have been established and standardized at SSDL-BARC in the YXLON X-ray system available in the laboratory using the primary standard free air ionization chamber (FAIC) and the diagnostic range free air ionization chamber (Fig. 4).

SSDL-BARC has started providing traceable calibration to users in the field of diagnostic radiology. The primary standard for X-rays is the FAIC, and the chamber was used to participate in international intercomparison for narrow series and CCRI X-ray beam qualities, and its international equivalence was established. The following is a couple of recent intercomparison participated by SSDL-BARC under the aegis of APMP:

- APMP supplementary comparison of air kerma in ISO 4037 wide and narrow series X-ray beams: APMP.RI(I)-S3
- APMP key comparison of air kerma standards for the CCRI reference qualities in the medium-energy X-ray region (APMP.RI(I)-K3)

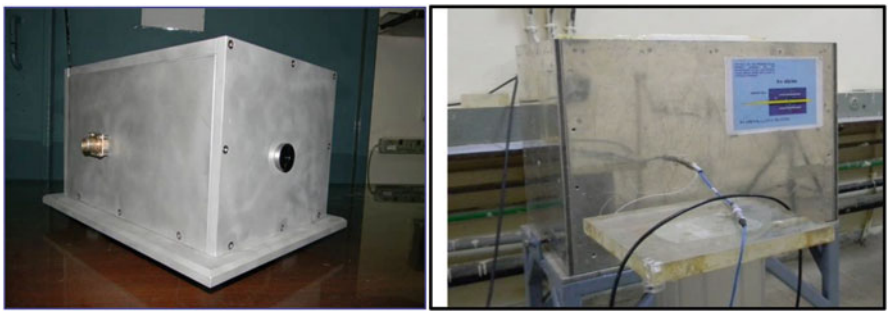

Fig. 4 Free air ionization chambers as X-ray measurement standards

Radiation Metrology and Nuclear Medicine

With the advancement and development in science and technology, a tremendous surge of usage of radioisotopes in a wide spectrum of medical applications especially in the field of nuclear medicine and industrial applications was observed over the decades. Additionally, with the discovery of artificial radionuclides and its industrial-scale production, a wide range of artificial radionuclides became available for applications. One such application is radioisotope therapy. It is a targeted therapy where the liquid form of radioisotope is administered orally or intravenously to the patients to specifically target the diseased tissue while sparing the surrounding healthy tissue.

Radiopharmaceuticals (RPs) contains a radioisotope and a tracer which are coupled with the pharmaceutical. RPs carry these radioisotopes to specific organs to deliver localized dose to tumor reducing radiation-induced side effects. As the disintegration of radioisotope begins, it targets tumor/cancerous cells since cancerous cells absorb a greater fraction of radioisotope than healthy cells. This ensures higher dose of radioactivity to tumor ultimately destroying the tumor. As the radiation destroys the cancerous cells, the body naturally eliminates them simultaneously repairing the normal tissues, if affected. Before administering RPs to patients, quantity of RP is carefully determined depending on the type of tumor, location, age of the patient, gender of the patient, etc.

Radioisotope targeted therapy has been employed in the treatment of wide variety of cancers, such as brain cancer, thyroid cancer, bone metastases, bile duct cancer, liver cancer, etc. A number of radionuclides, such as ^{131}I, ^{32}P, ^{90}Sr, ^{90}Y, ^{117m}Sn, ^{153}Sm, ^{169}Er, ^{177}Lu, ^{186}Re, ^{188}Re, and ^{223}Ra, have been used successfully for the treatment of many benign and malignant disorders. For example, ^{131}I is mainly used to treat some types of thyroid cancer. Once it is ingested, it gets concentrated in the thyroid cells, killing the cancer cells. ^{153}Sm can be used to treat some types of metastatic bone cancer.^{177}Lu is used for prostate cancer, while ^{188}Re is used in therapeutic applications like radionuclide synovectomy, bone pain palliation, intravascular radiation therapy, and other applications in nuclear medicine. ^{223}Ra is used to treat prostate cancer that has spread to the bones.

Traceability of Radioactivity Measurements in Nuclear Medicine

The safety and efficacy of these drugs depend on various factors and on the ability of the clinic to accurately determine the amount of radioactivity which determines the dose to the patient. The activity of these radiopharmaceuticals at nuclear medicine centers is measured using the radionuclide calibrators (RC) as shown in Fig. 5 and must be determined as accurately as possible for the optimized diagnosis or treatment.

The BARC, as the national metrological laboratory for radioactivity, has been conducting the audit program for activity measurements with RC for more than four decades (since 1979), to establish traceability of measurements with radionuclide calibrators in nuclear medicine centers (NMC) to national standards and to ensure calibration of RC. In order to investigate the quality performance of routine measurements at NMCs, audit programs of Iodine-131 activity measurements are conducted biannually. Quality audit programs (QAPs) help to ensure that the RCs are working satisfactorily so that the activity of the radiopharmaceutical measured before administering to patients is within the acceptable limits of $\pm 10\%$ from the prescribed dose. If the radioactivity administered is higher than that prescribed, the patient is unnecessarily exposed to radiation. On the other hand, if lower than the prescribed dose is administered, the image quality will be poor leading to poor diagnosis or, in the case of therapy, leads to inefficient treatment. Nineteenth audit of ^{131}I activity measurements with RC was conducted in 2021, and the results of all the audits conducted are shown in Fig. 6.

The continuous improvement is an important aspect of any quality assurance/audit program, and this is being achieved as demonstrated by the results of the ^{131}I audit. The results of the audit are very encouraging, as the number of participants whose deviation greater than $\pm 10\%$ has declined tremendously over the years. Thus, these programs ensure that patients receive maximum benefit with minimum

Fig. 5 Radionuclide calibrator (RC) used in nuclear medicine centers

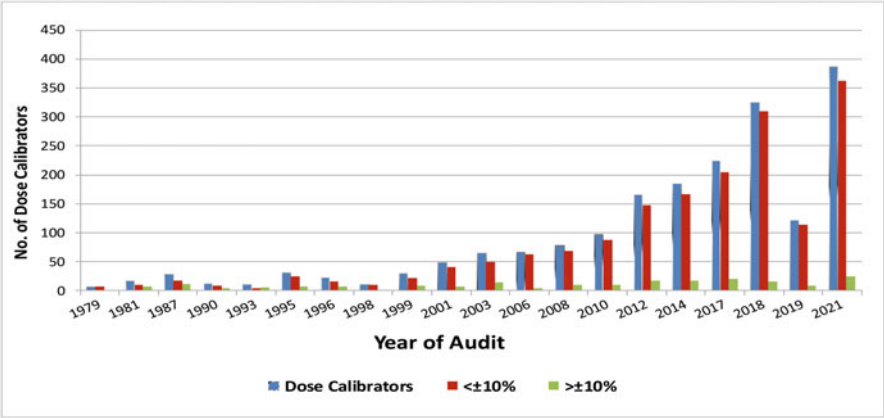

Fig. 6 Summary of results of national audits conducted from 1979 to 2021

exposure and establish traceability of radioactivity measurements to national and international standards.

Primary Standards of Radioactivity Measurements in Metrology Lab

Coincidence technique is an absolute method for the measurement of activity of radionuclides and has been in use over several decades. The technique, with its variants, enables the direct measurement of activity of most of the radionuclides, without any specific value being assumed for branching ratios or other decay scheme parameters, for source and detector efficiencies. It is directly applicable to all radionuclides decaying by the simultaneous emission of two or more radiations in prompt succession, such as β-γ, α- γ, electron capture- γ, γ -γ, γ-x, etc.

Various primary standards for radioactivity as shown in Fig. 7 based on coincidence technique are developed and established at the BARC:

1. Proportional counter-based 4πβ(PC)-γ coincidence counting system for activity measurements
2. Liquid scintillation-based 4πβ(LS)-γ coincidence counting system for activity measurements
3. Plastic scintillation-based 4πβ(PS)-γ coincidence counting system for activity measurements

Secondary Standards for Radionuclides

Standardization of radionuclides using primary methods is complex, tedious, time-consuming, and destructive (sample cannot be retrieved); hence, secondary standards were developed which are faster and rugged and are used to disseminate

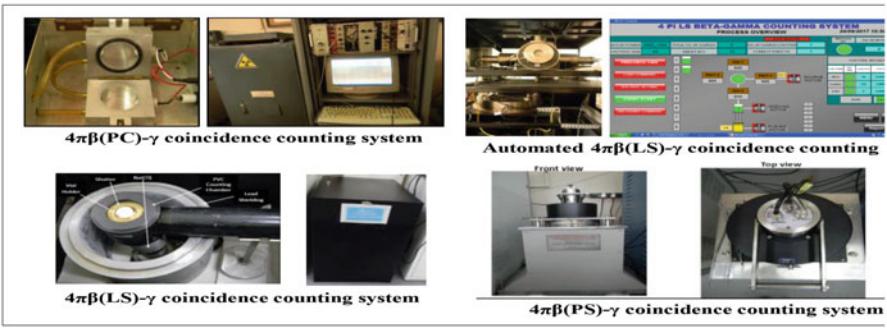

Fig. 7 Coincidence counting system-based primary standards for activity measurements

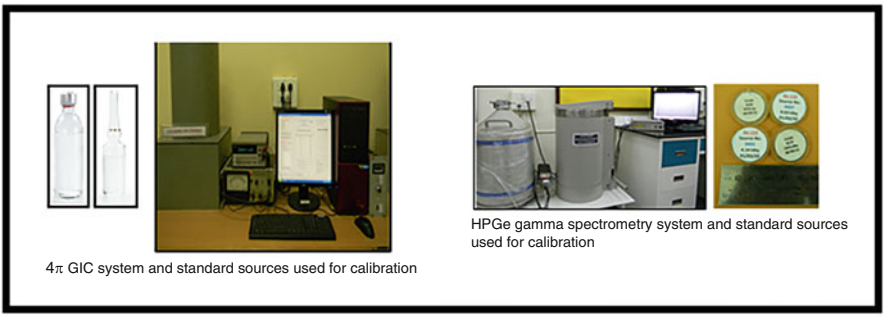

Fig. 8 Secondary standards for activity measurement

radioactivity standards to end users in the country. Secondary standard available at the BARC are as follows:

4π-γ Ion Chamber (4π GIC) for Activity Measurements of Gamma-Emitting Radionuclides

It is used for the standardization of liquid sources of gamma-emitting radionuclides. It uses the reentrant-type 4π-γ ion chamber and electrometer for current measurements. The radioactive source is placed in the GIC, and current produced by ion chamber is measured using electrometer. The system is calibrated against the primary standards using primary standardized standard sources of radionuclides.

HPGe Gamma Spectrometer for Activity Measurements of Gamma-Emitting Radionuclides

High-purity germanium (HPGe) gamma spectrometer was established as a secondary standard for standardizing solid sources of gamma-emitting radionuclides. It consists of HPGe detector, multichannel analyzer (MCA), and spectrum acquiring software. The system is calibrated against the primary standards using primary standardized solid standard sources of various radionuclides. Photograph of 4π-γ ion chamber and HPGe gamma spectrometry system is shown in Fig. 8.

Equivalence of Primary Standards with Other International National Metrology Institutes (NMIs)

Accurate radioactivity measurements of the source are important and play a pivotal role in all medical and industrial applications, due to the growing concerns of health risks and contamination associated with radioactivity. The quality of the results of measurements depends directly on the accuracy of the standards. Thus, with the proliferation in the use of radioactive materials, it became essential to establish traceability of measurements with national and international standards of radioactivity. As a result, the systems used for the measurements of radioactivity must be calibrated using accurate and traceable standards.

To establish international equivalence of activity standards maintained at the BARC with other national metrology institutes (NMIs) around the world, the BARC participates in international intercomparison organized by BIPM, France, and APMP, Japan.

International Intercomparison of ^{59}Fe (APMP.RI (II)-K2.Fe-59)

The international comparison of activity measurements of ^{59}Fe, APMP.RI (II)-K2.Fe-59, was carried out within the framework of the Asia-Pacific Metrology Programme (APMP). A graphical presentation of the activity concentration results of the participants in the intercomparison is shown in Fig. 9. From the figure, it is

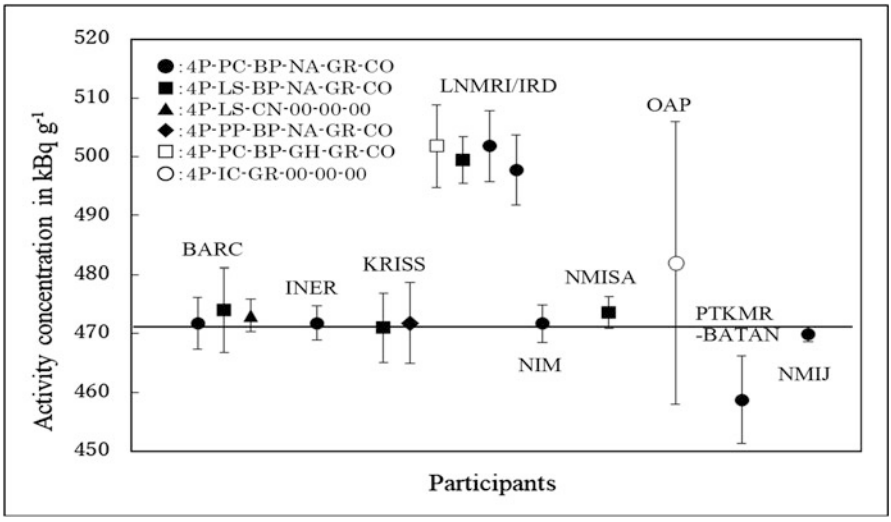

Fig. 9 Activity concentration of ^{59}Fe of various national metrology institutes participated in APMP.RI (II)-K2.Fe-59. The uncertainty bars correspond to the combined standard uncertainty on each respondent's value. The solid line represents the proposed comparison reference value (CRV) of 470.8 kBq g^{-1}, and the dashed lines represent the combined standard uncertainty of 1.7 kBq g^{-1} on the CRV

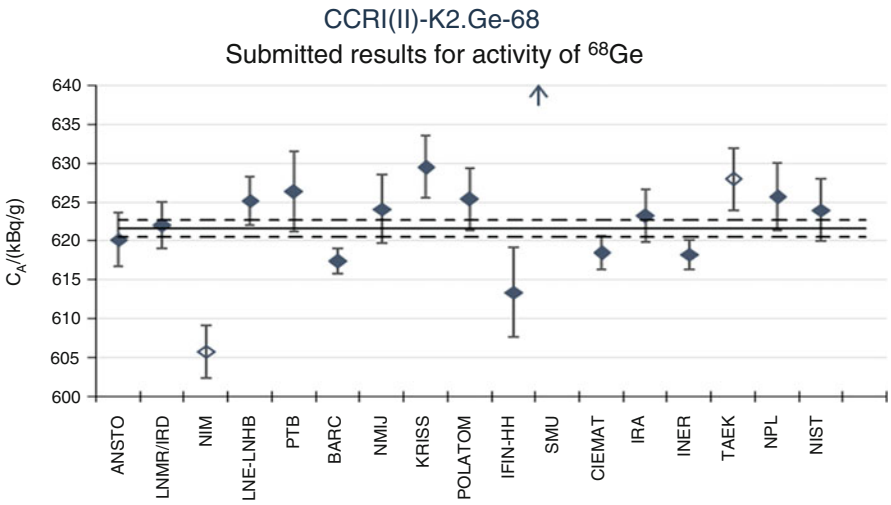

Fig. 10 Activity concentration of ^{68}Ge of various national metrology institutes participated in CCRI(II)-k2.Ge-68. The uncertainty bars correspond to the combined standard uncertainty on each respondent's value. The solid line represents the proposed comparison reference value (CRV) of 621.7 kBq g^{-1}, and the dashed lines represent the combined standard uncertainty of 1.1 kBq g^{-1} on the CRV

observed an excellent agreement of BARC results with that of other international laboratories.

International Intercomparison of ^{68}Ge (CCRI(II)-k2.Ge-68

An international key comparison, identifier CCRI(II)-K2.Ge-68, was carried out in 2014. The National Institute of Standards and Technology (NIST) served as the pilot laboratory, distributing aliquots of a ^{68}Ge/^{68}Ga solution. Results for the activity concentration of ^{68}Ge at a reference date of 12 h00 UTC 14 November 2014 were submitted by 17 laboratories, encompassing many variants of coincidence methods and liquid scintillation counting methods. A graphical presentation of the degrees of equivalence with the comparison reference value (CRV) is shown in Fig. 10.

Role of Radiation Metrology in Reactors and Accelerators

Radiation technology is successfully being used in several fields including basic research, industrial, medical (diagnostic and therapeutic), food irradiation, space, etc. In order to meet the increasing demand of energy, several nuclear reactors are being set up in the country, whereas in the field of medical applications, the use of accelerators all over the world has increased significantly. However, the legal functioning of these nuclear installations requires a reliable radiation protection services for radiation workers in order to keep the personnel exposure of different types of radiations within the prescribed limits, as set by the regulatory body Atomic

Energy Regulatory Board (AERB). This brings the role of radiation metrology in these fields. Neutron sources/fields not only are critical for operating and regulating nuclear reactors but also are important for various other research, industrial, and radiation protection applications. Therefore, precise value of neutron source strength and resultant field is highly essential. Several neutron standards to provide traceability to various users are available as discussed subsequently.

Radiation Instruments Used

Manganese Sulfate Bath System

$MnSO_4$ bath facility is the primary standard for the measurement of neutron source yield of laboratory neutron sources and is shown in Fig. 11a. It consists of a spherical tank containing aqueous saturated solution of $MnSO_4$ and a NaI(Tl) detector in specific geometry. The fast neutrons emitted by source are thermalized by water and activate ^{55}Mn to generate radioactive ^{56}Mn which subsequently decays by gamma

Fig. 11 (**a**) MnSO4 bath facility, (**b**) STAG facility, (**c**) recoil proton telescope, (**d**) PLC

radiation. The measured radioactivity is then correlated to the neutron yield. The uncertainty associated with the measurement is within ±1%.

Standard Thermal Assembly in Graphite (STAG)

It is a primary standard for the thermal neutron fluence rate as shown in Fig. 11b. The system is consisting of six ^{241}Am-Be neutron sources inside a graphite cubical assembly. Thermal neutrons are produced by the slowing down of the emitted fast neutrons by graphite moderator. The arrangements of the sources are in staggered positions in order to get the better uniformity of neutron fluence. A central channel [4 cm × 4 cm × 15 cm] inside the cubical pile is kept for irradiation of different detectors and dosimeters. There are three different locations where thermal neutron fluence rate has been standardized based on the ^{197}Au and ^{55}Mn foil activation techniques. The system is highly useful for the calibration of different thermal neutron detectors used in research as well as power reactors and irradiation of solid-state detectors for neutron dosimetry applications.

Proton Recoil Neutron Telescope

It is an absolute standard for the measurement of neutron yield of monoenergetic fast neutrons (Fig. 11c). The system consists of a polyethylene radiator $(C_2H_4)_n$ and a CsI (Tl) detector in a specific arrangement which are placed inside a vacuum chamber. The basic working principle of the system is that fast neutrons create recoil protons in the thin radiator which are detected using the CsI (Tl) detector placed at a specific solid angle. Based on the n-p scattering cross-section data from ENDF-VII, the efficiency of the system was analytically calculated for 14.57-MeV monoenergetic neutrons which were found to be $(54.5 \pm 2.09) \times 10^{-7}$ counts/neutron/steradian (Ghodke et al. 2020). The system is utilized for the standardization of neutron yield of Purnima D-T neutron generator.

Precision Long Counter (PLC)

PLC is the secondary standard for the neutron source yield measurement, which is traceable to the manganese sulfate bath system (Fig. 11d). The working principle is based on the detection of fast neutrons by slowing it down to thermal region by using suitable moderating medium. It consists of a BF_3 proportional counter which is kept inside two concentric high-density polythene cylindrical moderators separated by an annular thermal neutron shield made up of 5% boron-loaded polythene. The position of different moderators and their thickness and length are adjusted to make its response independent of neutron energy. It has constant efficiency (4.0 ± 0.2 cps/n/cm^2/s) within the energy range of 24 keV to 5 MeV. The system is highly capable of standardizing the commonly available laboratory neutron sources, viz., ^{241}Am-Be, ^{241}Am-B, ^{252}Cf, etc., within short time as compared to $MnSO_4$ bath facility.

Portable Transfer Standard

It is an indigenously developed secondary standard for the measurement of neutron yield. The system works based on the basic principle of precision long

counter (PLC). The system has constant efficiency [(2.85 ± 0.2) counts/n.cm^2] for the neutron energy range from few keV to 10 MeV and also for the commonly available laboratory neutron sources. The weight of the system is about 22 kg. Considering both the demand for onsite neutron source standardization and difficulties to use in-house existing heavy and bulky standards, viz., $MnSO_4$ bath facility and PLC, in the field, this system is highly useful for the said purpose.

Role of RSS in Reactor Criticality and Onsite Testing and Calibration of Reactor Instruments in Protection and Regulatory Channels

The responsibility for safe installation of nuclear power plant in India is vested in Safety Review Committee for Operating Plants (SARCOP). It is essential that procedures leading to criticality be conducted according to documented technical specifications that are approved by SARCOP. Based on the reviews of the Unit Safety Committee and on its own assessment, SARCOP makes recommendations for its implementation. Different types of neutron detectors, viz., ^{10}B-lined proportional counter, fission counters, BF_3 detectors (delayed neutron monitoring), etc., are used in a nuclear power reactor to monitor a neutron fluence rate of about 14 decades starting from 10^0 to 10^{14} n/cm^2/s. According to documented commissioning procedure, these neutron counters designated for the central thimble (in-core) and the vault (out-of-core) as well as the ion chambers used in the "Regulatory, Primary Shut-down System and Secondary Shut-down System" have to be source checked prior to heavy water flushing of moderator and auxiliary systems. These counters are divided into source range monitors (10^0 to 10^5 n/cm^2/s), intermediate range monitors (10^4 to 10^9 n/cm^2/s), and power range monitors (10^8 to 10^{14} n/cm^2/s). For proper functioning of the detector system, the detectors have to be properly tested before and after installing in the reactor (Sathian et al. 2008). In order to evaluate different operating characteristics and the thermal neutron sensitivity of these detectors, several systems are used which are described below:

Thermal Neutron Howitzer

It consists of a polythene (block 41 cm × 37 cm × 37 cm with a 15 cm deep, 16 cm cavity on the front surface) assembly and a 5-Ci Am-Be neutron source. Neutrons after multiple scattering in the moderating assembly emitted in the forward direction provide a wide beam of thermal neutrons, thus acting as a howitzer. The distribution of thermal neutron fluence rate at different distances was measured with a standard BF_3 counter which is used for detector calibration purposes.

Portable Thermal Neutron Water Jig

It is a portable thermal neutron assembly used for the performance evaluation studies of neutron detectors. It consists of a cuboid tank [32 cm × 32 cm × 35 cm] filled with water to a fixed level. There is a stainless steel cover at the top with two empty

tubes for keeping neutron source and the ion chamber, respectively. A 5 Ci ^{241}Am-Be neutron source is placed at the source tube. The thermal neutron fluence rate over the length of the tube where ion chamber is placed and also at three different preset distances, viz., 6 cm, 12 cm, and 18 cm from the surface of the tank (source side), is measured using ^{197}Au foil activation technique. The system is regularly used for the onsite testing and calibration of startup counters and DNM detectors used in power reactors. Various neutron detectors calibrated at different reactor sites are given in Table 1.

Metrology and Radiation Processing Industries

Radiation processing technologies are now very widely used in different industrial applications like sterilization of healthcare products including pharmaceuticals; processing of food and agriculture products for various end objectives, such as disinfestation, shelf life extension, sprout inhibition, pest control, sterilization, etc.; and material modification such as polymer cross-linking, chain scission, gemstone colorization, etc. Besides these well-established uses, new radiation processing applications are emerging for environmental remediation like flue gas treatment for SOx and NOx removal, wastewater purification, sludge hygienization, etc.; synthesis of advanced materials and products and medical applications such as irradiation of blood and different biological samples; etc.

Proper dosimetry is the backbone of success of these applications. Conventional radiation measuring techniques like ionization chambers, calorimeters, etc. are unable to measure absorbed doses for most of these applications. Chemical dosimetry techniques provide a cost-effective alternative for radiation processing dosimetry.

Standards for high dose are established and maintained in laboratories belonging to the BARC for calibration and standardization of high-dose radiation processing applications. Fricke dosimeter is maintained as a reference standard according to ISO/ASTM 51026 (ISO 2015a) for standardization of other dosimeters. Gamma chambers used for irradiation are calibrated using the Fricke dosimetric system; according to ISO/ASTM 52116 (ISO 2013a) as well as to ISO/ASTM 51607 (ISO 2013b), alanine ESR is the internationally accepted reference/transfer standard dosimeter, and glutamine is the indigenously developed transfer standard dosimetry systems, which are currently being used for dosimetry in radiation processing. These standards provide results with uncertainty $<3\%$ at coverage factor $k = 1$ according to ISO/ASTM 51707 (ISO 2015b).

Radiation Processing Applications Involving Chemical Dosimetry

Food Irradiation

Radiation processing of food is done using gamma rays, accelerated electrons, and X-rays. Radiation processing of food can achieve different objectives in varied foods.

In India, the Atomic Energy (Radiation Processing of Food and Allied Products) Rules (2012) are used as guideline by food irradiation facilities.

Medical Sterilization

Radiation sterilization using ionizing radiation is a well-established industrial process in India. It is extremely an efficient and convenient technique for achieving a high level of sterility in medical supplies. Hermetically sealed medical products in cardboard cartons or aluminum tote boxes are generally exposed to a minimum dose of 25 kGy. Exposure of medical products, manufactured under Good Manufacturing Practices (GMP), to a minimum radiation dose of 25 kGy ensures sterility assurance level (SAL) of the order of 10^{-6}. This dose provides an extremely high safety factor.

Sludge Hygienization

Pilot and industrial-scale installations have demonstrated that radiation processing-based technologies for flue gas treatment for Sox and NOx removal, wastewater purification, and sludge treatment can help to mitigate environmental pollution.

Ionizing radiation interacts with the critical molecules like DNA, proteins, and water present in the cell and results in the inactivation of microorganisms. Based on microbiological inactivation, dry- and wet-type sludge hygienization facilities are already operational in India. The by-products from these are used in fertilizer industry.

Blood Irradiation

Irradiation of blood with low dose of ionizing radiation is a very widely used popular technique to inhibit T-lymphocyte proliferation to help prevent transfusion-induced graft-versus-host disease (GVHD) in certain immunocompromised patients and those receiving related donor products.

Treating of the blood with ionizing radiation is considered a sure way to prevent such complications.

Material Modifications

The most widely used application of this technology is the cross-linking of polymer chains: for producing cross-linking in wire and cable insulations, car tires, or vulcanization of natural rubber latex for medical items. The method produces cross-linking in polymers at room temperature and produces superior material properties without toxic chemical residues.

The exact opposite effect of cross-linking is the controlled degradation of polymers also can be achieved through radiation, also called chain scission, and is used to improve the properties as well as the compatibility and processing parameters of both natural and synthetic polymers. The largest commercial application of this technology is the degradation of polytetrafluoroethylene (PTFE) by irradiation, which results in a lower molecular-weight micro-powder with improved compatibility with other materials that then can be used as an additive to inks and coatings.

Facilities and Dosimeters for High-Dose Measurement

Gamma Chambers

Gamma chamber is a compact self-shielded cobalt-60 gamma irradiator providing an irradiation volume of approximately 1000 cc as shown in Fig. 12. The material for irradiation is placed in an irradiation chamber located in the vertical drawer inside the lead flask. This drawer can be moved up and down with the help of a system of motorized drive which enables precise positioning of the irradiation chamber at the center of the radiation field. Radiation field is provided by a set of stationary cobalt-60 sources placed in a cylindrical cage. The center position of the irradiation volume is calibrated by using Fricke reference standard dosimeter and used as a standard source for irradiation of other chemical dosimeters.

Fig. 12 Gamma chamber 1200

UV-Visible-NIR Spectrophotometer

It has high-sensitivity, high-resolution, ultralow stray light, and wide wavelength range. This UV-visible-NIR spectrophotometer as shown in Fig. 13 is used for absorbance, transmission, and reflectance measurement of dosimeters and other samples. It is also used for dose verification exercises and carried out for radiation processing facilities in India using indigenous and imported dosimeters. This spectrophotometer is calibrated regularly as per Indian Pharmacopoeia (Pharmacopoeia 2018).

Fricke Dosimeter

Fricke dosimeter is the best known and most broadly applied chemical dosimeter. It has been accurately standardized by calorimetry and other physical methods. It is used as a reference standard according to ISO/ASTM 51026 for absolute absorbed dose measurements with an uncertainty of 1–2% (2σ).

The principle is based on a process of oxidation of ferrous ions to ferric ions in acidic aqueous solution by ionizing radiation. Irradiation temperature range should be within 10–60 °C. It has useful dose response from 20 to 400 Gy.

FBX Dosimeter

This low-level dosimeter developed in RSSD, BARC, consists of ferrous ammonium sulfate benzoic acid xylenol orange (FBX) in dilute solution of sulfuric acid in aerated water, a chain reaction with benzoic acid (BA) whereby a large number of

Fig. 13 Shimadzu UV 3600 plus UV-visible-NIR spectrophotometer

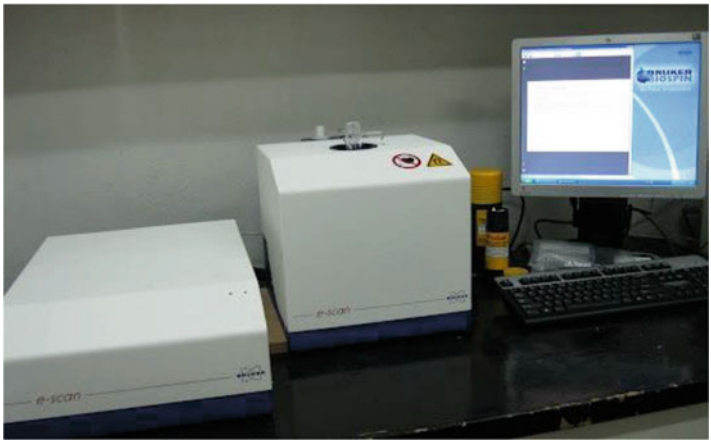

Fig. 14 ESR spectrometer

ferrous ions are oxidized to ferric ions. Xylenol orange (XO) is a dye, which forms a colored complex specifically with ferric ions. This helps in measuring lower concentrations of ferric ions using a spectrophotometer. The presence of BA and XO sensitizes the response and enables this dosimeter measure doses in the therapy level. This dosimeter is capable of measuring doses in the range 0.2 to 50 Gy, with an uncertainty of $\pm 1\%$ (2σ).

Alanine ESR Dosimeters

Amino acids on irradiation form free radicals. Concentration of these free radicals can be related to absorbed dose by electron spin resonance (ESR) analysis. The use of α-L-alanine has shown especially good characteristics for medium- and high-dose measurements. The commercially available alanine ESR dosimetry system as shown in Fig. 14 is used in the range of 10(International Atomic Energy Agency 2000)–10^5 Gy with a precision of 1% (2σ).

Glutamine Dosimeter

The glutamine powder can be used for measurement of absorbed dose in the range of 0.1–100 kGy by using spectrophotometric readout method. Free radicals are formed

on irradiation of glutamine powder. The radiation-induced free radicals indirectly oxidize ferrous ions to ferric ions in ferrous xylenol orange solution. Absorbance of the resulted complex is related to absorbed dose.

Regulatory Role of RSS in Food Irradiation Facilities

Licensed radiation processing facilities have to comply with conditions of approval, operation, and process control prescribed under the Atomic Energy (Radiation Processing of Food and Allied Products) Rules, 2012.

The Department of Atomic Energy (DAE) provides operating license to the irradiator after performing dosimetry exercises through the BARC:

(i) Dose intercomparison and verification exercises for all food irradiation facilities.
(ii) After qualifying the tests, the BARC issues dosimetry certificates; based on these certificates and recommendations of the Dose Verification Committee, license is issued by the DAE to the radiation processing facility.

Protection-Level Radiation Instruments for Measurement and Their Traceability

Radiation monitoring instruments are backbone to all radiological and nuclear installations for the safety of occupational radiation workers. Performance of these monitors depends on calibration and measurement traceability to the national standards. The Bhabha Atomic Research Centre, being the designated institute for ionizing radiation metrology in India, develops and maintains various standards related to radiation protection (gamma rays and X-rays) covering air kerma and ambient dose equivalent measurements for X-ray and gamma dosimetry. Protection-level radiation monitors cover a wide range of radiation field (gamma ray, X-ray, and beta ray) intensity and energy; therefore, measurement standards of various types and sizes are established. The BARC has also established various radiological facilities for gamma rays, X-rays, and beta rays which are used for calibration and testing of all kinds of protection-level radiation monitors. The calibration and testing (for prototype monitors) are carried out as per recommendations of relevant international standards like the IEC, ISO, ANSI, etc.

Periodic calibration of all kinds of protection-level radiation monitors is required to ensure that it is working properly and is suitable for its intended purpose. The BARC provides calibration, response testing, type testing, gamma ray/X-ray irradiations, and onsite standardization of reference radiation field used for protection-level radiation monitors for field ranging from 10^{-6} to 10^{2} Gy/h. These monitors are frequently used by health physicists and radiological safety officers for smooth functioning of power plants and other radiological laboratories/facilities. The BARC also provides traceability to national standards through onsite standardization

of reference radiation field for TLD units of various DAE organizations, BARC/AERB accredited TLD Laboratories, and Calibration Laboratories for radiation monitoring instruments (RMIs). It also provides technical support and guidance for establishment of calibration laboratory for protection-level RMIs. Further, it is also actively involved in the activities related to the regulatory aspects of defense and space organizations. Calibration facilities are also used by various institutes in developmental studies for radiation monitors, dosimeters, shielding materials, and algorithms for personal dosimetry.

The BARC also establishes degree of equivalence in measurement standards through participation in various international intercomparisons with other National Metrology Institutes.

Standards for Radiation Protection

Ionization chambers, the simplest of all gas-filled detectors, are widely used as measurement standard for ionizing radiation dosimetry (energy deposited per unit mass). Protection-level radiation monitors cover a wide range of radiation field intensity and energy; therefore, standards of various types and sizes are established. These standards include the following:

100.9-cc graphite ionization chamber (air kerma-based reference standard): It is an air kerma-based cavity ionization chamber (Fig. 15) which was designed and established by the BARC as a reference standard for protection-level applications/calibrations. It is having adequate sensitivity with a near flat energy response in the energy range 30–2000 keV.

Free air ionization chamber (X-ray dosimetry): Free air ionization chamber (FAIC) (Fig. 15), a primary standard for air kerma/exposure, is a parallel plate-type ionization chamber. For radiation protection applications, the BARC has established various ISO 4037-1 (ISO 2019) specified narrow series and wide series X-ray beam qualities, with an average energy ranging from 12 to 210 keV, using this FAIC. These beams are widely used for calibration and type testing of various protection-level dosimeters/radiation monitors.

Fig. 15 Standards for radiation protection

Air kerma-based secondary standard (PTW 0.3 cc, 30 cc, and 1000 cc IC's): The BARC has also procured and is maintaining PTW; Germany make three secondary standard ionization chambers (Fig. 15) having nominal sensitive volumes of 0.3 cc, 30 cc, and 1000 cc. These standards are frequently used for in-house as well as onsite standardization of gamma reference radiation fields.

Calibration of Radiation Monitoring Instruments (RMIs)

Radiation monitoring instruments are used both for area monitoring and for individual monitoring. For area monitoring, radiation monitors like area gamma monitors (AGM) and radiation survey meters (RSM) area used. For personal monitoring, instruments recording the personal dose equivalents are used and are referred to as personal dosimeters (or individual dosimeters). Periodic calibration of these area and personal monitors (Fig. 16) is required to ensure that they are working properly and are suitable for their intended purpose. Periodic calibration is also a regulatory requirement for all the facilities handling ionizing radiation. The BARC carries out periodic calibration of all kinds of protection-level radiation monitors (installed in almost all the facilities of the BARC) for dose rate range 1 μGy/h (~1 μSv/h) to 100 Gy/h (~100 Sv/h). Annually, ~300 radiation monitors are calibrated at the gamma protection-level calibration facility of the BARC. Periodic calibration of portable radiation monitors and TLD reader system of other DAE units, private institutions, and defense establishments like SSS, Visakhapatnam, INS Chakra, etc. are also carried out.

Establishment of Calibration Laboratories: Role of the BARC

Periodic calibration of radiation monitors is also carried out by other government and private laboratories. Presently, there are ten calibration laboratories which are accredited by the National Accreditation Board for Testing and Calibration Laboratories (NABL) or recognized by AERB. Out of these, three are DAE institutes, namely, Indira Gandhi Centre for Atomic Research (IGCAR), Kalpakkam; Electronics Corporation of India Limited (ECIL), Hyderabad; and Board of Radiation and Isotope Technology (BRIT), Vashi. One institute is in defense sector, i.e., Defence Laboratory, Jodhpur. The remaining laboratories are in the private sector spread across the nation (Fig. 17). These laboratories have either ^{137}Cs or ^{60}Co

Fig. 16 Various types of radiation monitors calibrated at BARC calibration facility

Fig. 17 Private (red), government (yellow), and defense (blue) laboratories recognized by AERB and accredited/under accreditation by NABL, India

sources of various activities (mCi – kCi) for use during periodic calibration of radiation monitors, TLD badge readers, and irradiation of dosimeters. The BARC provides measurement traceability to all these laboratories via onsite standardization of reference radiation field. During source output standardization, radiation field intensity at multiple distances, validation of inverse square law, repeatability of dose rate at a position, and attenuation ratio of lead attenuators are carried out using appropriate measurement standard. Technical help in terms of requirements of establishing a calibration lab and training of staff for calibration, etc. is also provided to these calibration laboratories.

Traceability to Calibration Laboratories

Calibration of secondary standard ionization chambers (along with electrometer), maintained by calibration laboratories, is carried out for ^{137}Cs, ^{60}Co, and ^{241}Am energies to provide measurement traceability to RMI calibration laboratories. These calibrated ionization chambers are used for radiation field verification/standardization by RMI calibration laboratories.

Radiological-Type Testing of Radiation Monitors

Newly developed radiation monitors are required to undergo type testing in accordance with national/international standard to verify the manufacturers' claim (specification) before introducing them in the market. The testing parameters vary around the world for a given product and are dependent on the applicable national/international standard. Type approval means that the equipment or product is certified to meet certain requirements for its type, whatever that may be, as described in the relevant standard. The BARC is the only institution which performs radiological-type testing on prototype or newly developed protection-level radiation monitors (Fig. 18) submitted by any private/government organizations in the country, and a test report is granted to a product meeting technical criteria specified by the applicable standard.

The BARC also provides technical help and assistance in the development of new radiation monitor/dosimeter (Fig. 19), in terms of establishing linearity in response, filter optimization studies for achieving flat energy response, and measurement of detector sensitivity, to various users (government and private labs).

IAEA Postal Dose Quality Audit for ^{137}Cs

Aiming to check quality of radiation protection calibrations provided by the SSDLs and assure proper dissemination of dosimetry standards to radiation protection institutions, the IAEA carries out TLD-based postal quality audit to its member states. The IAEA supplies TLDs to the laboratories and asked them to irradiate it to 5-mGy air kerma. The laboratory sends back the irradiated dosimeters to the IAEA for evaluation. The BARC periodically participates in the IAEA postal dose quality audit for ^{137}Cs beam. In the latest TLD-based quality audit (Table 2), the IAEA

evaluated dose was within ±1% of the BARC irradiated dose (IAEA acceptance criteria: ±7%).

Conclusion

Bhabha Atomic Research Centre (BARC) is the designated institute in ionizing radiation metrology for the country. BARC designs, develops, establishes, maintains, and disseminates various national standards for physical quantities of ionizing radiation in India. IAEA/WHO has recognized BARC as a Secondary Standard Dosimetry Laboratory (SSDL) for disseminating radiological standards to users in the country. SSDL-BARC provides traceable calibration to the users in the field of teletherapy, brachytherapy, radiation protection, and diagnostic radiology. The pace of the advances in radiation therapy with the expected improvement in patient treatment has brought out the need for greater accuracy in the treatment process. SSDL-BARC participates in international intercomparison programs to establish its equivalence with international standards, thereby validating the calibration procedure followed in the laboratory. BARC conducts the postal quality audit of output of therapy centers to ensure the accuracy of measurement. Radioisotope targeted therapy has been employed in the treatment of wide variety of cancers. The activity of these radiopharmaceuticals at the nuclear medicine centers is measured using the radionuclide calibrators (RC). BARC as the national metrological laboratory for radioactivity has been conducting the audit program for activity measurements with RC for more than four decades. BARC has established several systems for the activity measurements. Neutron sources/fields not only are critical for operating and regulating nuclear reactors but also are important for various other research, industrial, and radiation protection applications. Therefore, precise value of neutron source strength and resultant field is highly essential which is provided by the BARC using several neutron standards developed for the purpose. Radiation processing technologies are very widely used in different industrial applications like sterilization of healthcare products, processing of food and agriculture products, material

modification and emerging fields like environmental remediation, synthesis of advanced materials and products, and medical applications such as irradiation of blood. Proper dosimetry is the backbone of success of these applications. Conventional radiation measuring techniques like ionization chambers, calorimeters, etc. are unable to measure absorbed doses for most of these applications. Chemical dosimetry techniques provide a cost-effective alternative for radiation processing dosimetry. Radiation monitoring instruments are backbone to all the radiological and nuclear installations for the safety of occupational radiation workers. Performance of these monitors depends on calibration and measurement traceability to the national standards. Protection-level radiation monitors cover a wide range of radiation field (gamma ray, X-ray, and beta ray) intensity and energy; therefore, measurement standards of various types and sizes are established. The BARC has also established various radiological facilities for gamma rays, X-rays, and beta rays, which are used for calibration and testing of all kinds of protection-level radiation monitors. Development of various radiation standards has helped in improving the accuracy in application of radiation.

Abstract

Radiation monitoring for safety of occupational worker involves measurement of various radiation quantities in field and on person. This chapter unravels various measurement techniques and procedures applied for measurement of radiation quantities for occupational safety in Indian nuclear fuel cycle facilities. How far the radiation metrology principles are embedded in these measurements is explained. The country is engaged in all aspects of nuclear fuel cycle – from uranium mining to spent fuel reprocessing and nuclear waste management. Hence, diverse and complex radiation monitoring practices are evolved for

protection of occupational workers employed in these facilities. Occupational radiation monitoring has different requirements such as workplace monitoring, individual monitoring, and quality assurance for monitoring methods and practices. All the methods used in the country for occupational radiation monitoring conform to the national regulations and international guidelines. However, many of the techniques in radiation monitoring used in the country are indigenously developed and sometimes differ from the most common practices applied elsewhere. Monitoring for external exposure from photons and β-particles is being carried out using the indigenously developed $CaSO_4$:Dy thermoluminescent dosimeter (TLD) badge, and this technique is more sensitive than many other similar dosimeter available in the market. Measurement of exposure to neutron is being carried out using the solid-state nuclear track detector (SSNTD) method employing poly-allyl-di-glycol carbonate (PADC) polymeric film as the detector. Extensive laboratory set-up along with technical expertise has been developed for detection of intake of radionuclide into human body and estimation of dose resulting from such intake. Both in vivo and in vitro methods are extensively used for this purpose. The procedures and equipment adopted in workplace monitoring are well-designed to promptly detect and warn the radiation workers on hazardous radiological status, if any, developing in working areas. The effectiveness of the radiation monitoring program is evident in the gradual reduction of collective dose and average individual dose received by the workers in nuclear fuel cycle facilities operational in the country.

Introduction

Our understanding of harmful health effects of ionizing radiation progressed parallel to the development of nuclear energy and uses of radio isotopes and radiation (UNSEAR 2019). Analysis of the large quantum of epidemiological data on harmful effects of ionizing radiation on exposed population has resulted in setting up limits on dose resulting from exposure to radiation. The dose limits for occupational radiation worker practiced in the system of radiation protection is intended to minimize the stochastic effect (cancer and genetic effects) and prevent all tissue reactions (deterministic effects) to those who get exposed to ionizing radiation. Based on the consensus that exposure to any quantity of radiation may have adverse health effects (UNSEAR 2021), estimation of radiation dose to occupational workers is mandatory in all practices employing radioactivity and radiation. Measurement of relevant radiological quantities by various techniques is the key to estimate the dose received by workers while handling radiation and radioactive materials. The robust system of radiological protection based on radiation measurement at workplace and

on person is a most vital component for safe and continued use of nuclear technology.

It is mandatory to follow the principles of metrology for ensuring accuracy in measurement of a quantity to the desired level. However, radiation measurements done for occupational radiation protection is often too complex to directly apply the principles of radiation metrology. However, the basic intention of these measurements is protection of human health, and as a result, highest level of accuracy and reliability is expected in results obtained from these measurements. This practical difficulty is resolved by continuous improvements in measurements of radiation quantities intended for radiological protection through a multipronged approach. Application of relevant codes and standards in measurement procedures makes many measurements closer to metrology requirements. Also, continuous research and development in radiation detection and measurement techniques often result in improving the accuracy in measurements. This chapter on occupational radiation monitoring explains the radiation measurement practices for radiation protection followed in nuclear fuel cycle facilities in the country and also its relationship to the radiation metrology fundamentals.

Overview of Indian Nuclear Fuel Cycle Activities

Nuclear energy program in India is more than seven decades old. The country has developed expertise in almost all stages of nuclear fuel cycle. All nuclear fuel cycle activities in the country are under the ambit of the Department of Atomic Energy (DAE), the central government department dedicated to the development of nuclear energy and allied technologies in the country. Each activity such as uranium mining and processing, nuclear fuel fabrication, nuclear power reactor design and operations, etc. is under separate organizations within the DAE. Uranium Corporation of India Limited (UCIL), responsible for uranium mining and processing, operates six underground mines (Bagjata, Jaduguda, Bhatin, Narwapahar, Turamdih, and Mohuldih) and one open pit mine (Banduhurang) in the State of Jharkhand. Ore produced from these mines are processed in two process plants located in Jaduguda and Turamdih. UCIL also operates an underground mine and a processing plant in Tummalapalle in Andhra Pradesh. Fuel fabrication activities for commercial nuclear power plants (NPPs) are performed at Nuclear Fuel Complex, Hyderabad. At present, there are 22 NPPs (2 boiling water reactors (BWR), 18 pressurized heavy water reactors (PHWRs), and 2 Russian design water-water energetic reactors (VVER)) operating in the country with a total installed capacity of 6780 MW. Nuclear Power Corporation of India Ltd. (NPCIL) is the utility organization responsible for all commercial nuclear power production and related activities. DAE operates three large nuclear fuel cycle facilities, two located in the state of Maharashtra (Trombay and Tarapur) and one in Kalpakkam in Tamil Nadu. Facilities at these sites are engaged in front end research in nuclear science and technology, operation of research reactors, reprocessing of spent fuel, nuclear waste management, and fabrication of MOX fuel for Fast Breeder Test Reactor (FBTR) and the

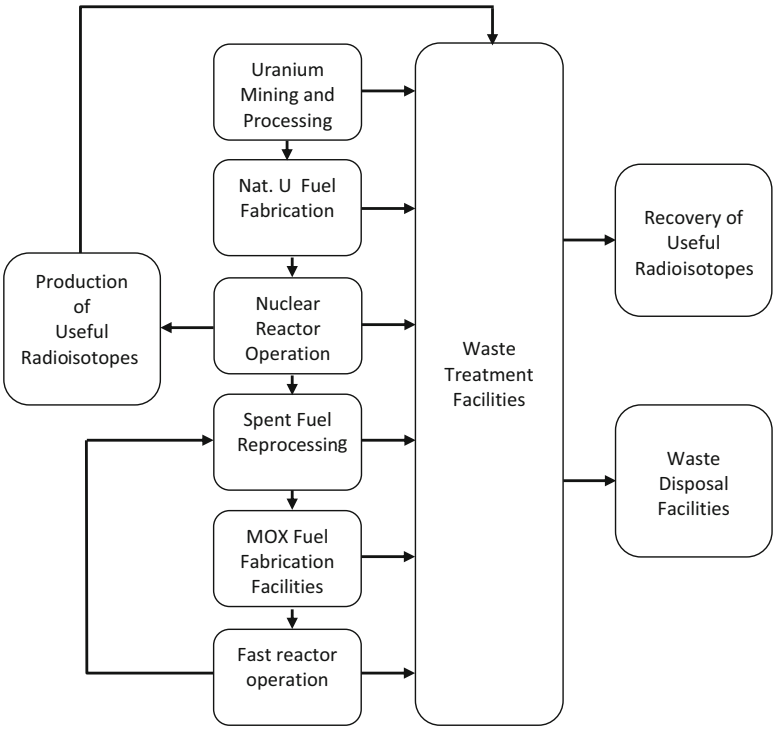

Fig. 1 Various nuclear fuel cycle facilities in the country that can result in occupational radiation exposure

upcoming Prototype Fast Breeder Reactor (PFBR). Radioisotope production and distribution is through a separate organization called Board of Radiation & Isotope Technology (BRIT). The breadth and the size of the activities under DAE lead to a well-developed radiation monitoring program for protection of occupational radiation workers employed in these organizations. Figure 1 represents various nuclear fuel cycle facilities operating in the country that can result in occupational radiation exposure to the workers.

Regulatory Infrastructures for Nuclear Industrial Activities

Occupational radiation protection activities in nuclear industry establishments except that operated by Bhabha Atomic Research Centre (BARC) are governed by the national regulator for safe use of radiation, the Atomic Energy Regulatory Board (AERB). The facilities operated by BARC are regulated by a separate regulatory body, the BARC Safety Council Secretariat (BSCS). Guidance for radiation exposure monitoring and control by both these regulatory bodies are similar and the dose

Table 1 Dose limits prescribed by the AERB/BSCS for occupational workers and public

Member of public	1	15	50	–	–	–

[a]5-year average annual effective dose = 20 mSv; maximum 30 mSv in a single year
[b]Equivalent dose limit for lens of eye is under review by AERB

limits prescribed by them are identical (AERB 2005a; BSCS 2020). Both AERB and BSCS takes guidance from international expert bodies like International Commission on Radiological Protection (ICRP), International Atomic Energy Agency (IAEA), and International Commission for Radiation Measurements and Units (ICRU), for framing radiation protection rules and implementing radiation protection practices in nuclear industrial activities. Summary of the current dose limits to the occupational radiation worker as prescribed by AERB/BSCS is presented in Table 1. These quantities used for radiation exposure control are explained later in this chapter. In addition to the national regulations, each individual plant/facility has a separate Radiation Protection Manual (RPM), detailing the facility-specific radiation protection procedures and radiation monitoring requirements.

Organizational Setup for Occupational Radiation Monitoring

Prime responsibility for monitoring and control of occupational radiation exposure to workers in a facility lies with its operating management (RPR 2004). Each facility ensures that adequate infrastructure, equipment, and expertise are available for monitoring radiation exposure of workers engaged in the facility. Radiation monitoring of workers at all NPPs is carried out by the Health, Safety & Environment Directorate of NPCIL. All other research and production organizations of DAE also have separate wings of radiation protection professionals dedicated to health physics measurements and radiation protection research. Each nuclear/radiological facility has a designated Radiation Safety Officer (RSO) who is responsible for the radiation monitoring program of a plant/facility. For effectively carrying out the radiological surveillance in each facility, RSO is aided by a team of experienced and certified health physics professionals. RSO advises the operating management on all aspects pertaining to occupational exposure and radiation safety.

Design Safety Features for Occupational Exposure Control in Nuclear Facilities

Nuclear and radiological facilities are designed to minimize radiation exposure to occupational workers and the public during normal as well as accidental conditions. To minimize external exposure to worker, facilities are designed such that ambient dose rate at any continuously occupied areas in a plant is below 1 μSv/hour (AERB 2005a). Additional occupancy restrictions are put in place if any area have ambient dose rate higher than this stipulated value (AERB 2005b). All activities with potentials for radioactivity release into air are carried out inside containments such as fume-hood, glove boxes, and hot cells. Ventilation system in radioactive facilities is well-designed for controlling the spread of radioactive contamination present in air. Air flow is designed from areas with less potential for contamination to that having more potential for the presence of contaminants. Depending on the potential for generation of air contamination, sufficient number of Air Changes Per Hour (ACPH) is provided in operating areas to prevent build-up of air contamination. In general, plant area is divided into four zones; zone 1 to zone 4 with increase in anticipated radiation and contamination levels (AERB 2005a). Allowed radiological conditions, monitoring requirements, and dress regulations for workers for each zone are well defined in RPM of the facility. This helps in monitoring and control of occupational radiation exposure. Areas in nuclear facilities are also divided into controlled areas and supervised areas (AERB 2012). Controlled areas have entry restrictions and have stipulations on area and personal monitoring provisions and use of personal protective equipment. Specific protective measures are normally not needed in supervised areas, but occupational exposure conditions are kept under review.

Metrology in Monitoring for Radiation Protection

Metrology being the science of measurement has some limitations while applying for radiation measurements employed in occupational radiation monitoring. Firstly, the quantities used in occupational monitoring, the so-called protection quantities are not physical quantities, so are not amenable for direct measurement. What is measured is a best estimate of a defined quantity, and the measurement is done with certain assumptions of the radiation field characteristics. Second, the measurement occurs in field and the full characterization of nature and quality of the encountered radiation is most often impractical or too costly to be emphasized. Thirdly, non-quantifiable uncertainty often exists in the assumptions employed for conversion of the measured quantity to the corresponding protection quantity. The ICRP on several occasions acknowledged these limitations in measuring quantities pertaining to occupational exposure. For example, on individual dose measurement the commission states (ICRP 1997);

> In the workplace, where the energy spectrum and orientation of the radiation field are generally not well known, the uncertainties in a measurement made with an individual dosemeter will be significantly greater. Non-uniformity and uncertain orientation of the radiation field will introduce errors in the use of standard models. The overall uncertainty at the 95% confidence level in the estimation of effective dose around the relevant dose limit may well be a factor of 1.5 in either direction for photons and may be substantially greater for neutrons of uncertain energy and for electrons. Greater uncertainties are also inevitable at low levels of effective dose for all qualities of radiation.

All stakeholders involved in radiation monitoring for occupational radiation protection are aware of these limitations. The system of radiation protection currently in use have sufficient safety margin to take care of such uncertainties inherent in the system (NCRP 2007b; Sasaki et al. 2021).

Quantities Used in Occupational Radiation Monitoring

The risk from radiation exposure is its ability to cause ionization in a medium, when it interacts with it. In biological medium like the human body, the damage caused by exposure to ionizing radiation is directly related to the quantum of energy deposited in the body. The quantity of energy deposited per unit mass is called absorbed dose (D). SI units of absorbed dose (D) is (J/kg) with special name Gray (Gy). But the degree of damage to the human cell is different for different types of radiation. To normalize the biological risk from different radiations, the absorbed dose is multiplied by the radiation weighting factor (W_R). The resultant quantity is called equivalent dose (H). Since W_R is a dimensionless quantity, unit of equivalent dose is also J/kg, with a special name Sievert (Sv).

There are two instances in which the whole body is not uniformly irradiated, viz., while working in non-uniform radiation field and during internal contamination. In non-uniform radiation field, some part of the body gets more radiation exposure than some other parts. Radionuclide can enter into human body by different mechanism such as inhalation (of contaminated air), ingestion (via contamination in food), and injection (via wound and cuts) (IAEA 1996). This could result in preferential accumulation of radioactivity in specific organ(s). Radio-sensitivity of organ differs. In order to convert the risk from exposure to a specific organ to that to the whole body, in such cases, an additional factor called tissue weighting factor (W_T) is used. The organ equivalent dose (H_T) corresponding to the specific organ "T" is multiplied by its W_T to get another quantity called effective dose (E) (ICRP 2007). The resultant new quantity, effective dose (E) is used to compare the overall risk from different exposure scenarios. When multiple organs are exposed, the effective dose calculated for each organ is summed to get the total effective dose (E). The value of W_T for any particular organ is less than one and tissue weighing factors for all organs in the body add up to unity (ICRP 2007).

W_R is 1 for photons and beta particles of all energies. For uniform whole-body exposure from γ, X-rays, and β radiations, the equivalent dose (H) falls to be the same as effective dose (E). For neutrons, W_R is a continuous function of neutron

energy, varying in the range of 2.5–20 with a maximum for neutrons having energy around 1 MeV (ICRP 2007). Hence, in case of exposure to neutrons, neutron energy spectrum is essential to estimate the effective dose (E).

The defined quantities, equivalent dose (H) and effective dose (E), are not directly measurable quantities and are called protection quantities. For practical measurement, ICRU has defined operational quantities which are related to the protection quantity, effective dose (E). The operational quantity defined for measurement of individual dose due to exposure from external radiation is termed as personal dose equivalent and is denoted as $H_p(10)$. Roughly, this is the dose delivered by the radiation at 10 mm depth in body and is applicable to deeply penetrating radiation such as photons and neutrons (ICRU 1993; ICRU 2011). An equivalent quantity for measurement of dose persisting in the working area is termed as ambient dose equivalent and is denoted as $H^*(10)$ (ICRU 1993, 2011).

It is observed that dose control in terms of effective dose alone is inadequate to protect two organs, namely, the skin and lens of eye. Also, due to the proximity to the source, hands and feet may receive relatively higher dose and are specially referred as dose to the extremities. Separate dose limits are established for extremities also. Skin at 20–100 μm depth is very sensitive to radiation (Curran 1986). The protection quantity corresponding to the equivalent dose to skin is the personal dose equivalent $H_p(0.07)$. This is the dose delivered by the radiation at 70 μm depth below skin surface. When exposure of the extremities is of concern, the skin of the extremities is more likely to become the limiting tissue, rather than the extremity itself. Thus, an extremity dosimeter essentially becomes a skin dosimeter and should be designed to measure $H_p(0.07)$. It should be noted that radiation like β-particles which may not be able to penetrate deep into the body to give dose to the internal organs also could result in skin dose. Skin dose evaluation is integral to most occupational radiation monitoring program.

For measurement of radiation dose to eye lens, another protection quantity called personal dose equivalent $H_p(3.0)$ is recommended. This is the dose measured at 3 mm depth. ICRP recommends equivalent dose limit of 20 mSv to the lens of eye (Bolch et al. 2013), though the national regulator still continues with the previously recommended limit of 150 mSv equivalent dose. However not many instances exist in nuclear fuel cycle activities, where eye lens receive more dose compared to the whole body exposure. Unless specific requirement arise, measurement of the eye lens dose is not a routine practice in nuclear fuel cycle facilities in the country.

Surface contamination is measured in the unit Bq/cm^2. Contamination on a surface can be fixed contamination or transferable contamination. The radiation hazard from fixed contamination is only external exposure. Transferable contamination has additional hazards such as further spread of contamination and generation of air contamination by re-suspension. Hence, transferable contamination has the potential to cause internal exposure via inhalation and ingestion. Thus, separate measurement techniques are always used to quantify and report fixed and transferable contamination separately.

Air contamination is usually represented in Bq/m^3. The quantity, derived air concentration (DAC) in Bq/m^3, is also used to report the results from measurements.

DAC is related to the annual limit on intake (ALI) for inhalation of the radioactive species by the relation

$$\mathrm{DAC} = \frac{\mathrm{ALI}(Bq)}{2400\ \mathrm{m}^3}$$

ALI depends on the radio-toxicity of the chemical species and its deposition characteristics in the respiratory system based on its particle size. The overall inhalation hazard of a specific species at given particle size is represented by its dose coefficient factor (DCF) in Sv/Bq. As 20 mSv is the yearly limit for effective dose for occupational radiation worker, ALI for a specific radioactive species at a given particle size could be obtained from the published DCF using the relation:

$$\mathrm{ALI(Bq)} = \frac{0.02\ \mathrm{Sv}}{\mathrm{DCF}\left(\frac{\mathrm{Sv}}{\mathrm{Bq}}\right)}$$

IAEA has published full list of DCFs for various radioactive materials encountered at workplace (IAEA 2014).

The dose included in DCF is the cumulative dose received by the body from the incorporated radioactivity, till its elimination by radioactive decay and biological process. A quantity called effective half-life in body or organ is used to account for the elimination process of radioactive material from body. For occupational worker, effective dose is computed up to 50 years subsequent to an intake and is represented as E(50) (ICRP 2015). Age of worker at the time of intake is not considered in this computation. This effective dose from an intake is called committed effective dose (CED) and is accounted to worker's dose account to the year in which the intake occurs. Note that CED may not be the actual dose received to the worker in that specific year. For radiochemicals having short effective half-life in the body, the entire exposure will happen in the year of intake itself. Typical example is tritium (HTO) with effective half-life of about 10 days or less. But for radionuclides with long retention time in the body, such as compounds of ^{239}Pu, the exposure is fractionated over the life time of the individual.

A different unit called working level month (WLM) is employed for measurement of exposure to radon and its progenies by workers of uranium mines. One working level is the quantity of short-lived daughter products of ^{222}Rn in any combination in one liter of air that will result in ultimate emission of alpha particles of cumulative energy 1.3×10^5 MeV. This corresponds to 100 pCi/L of ^{222}Rn gas in equilibrium with its progenies. 170 hours of work in one WL concentration results in internal dose corresponds to one WLM. To know the WL in an area, one needs to have both Rn concentration and its equilibrium status with its progenies. Both these parameters are experimentally measured in uranium mines.

Ambient dose rate due to photons are measured in exposure units milli-Rontgen/hour (mR/hr). Locally available portable or installed instruments are not conforming to measurement of photon dose rate in terms of $H^*(10)$. Many commercial portable instruments used in facilities read the ambient dose rates due to photons in terms of

absorbed dose rate (Gy/h) and equivalent dose rates (Sv/h). But there are no specific directives from the regulatory body on the units to be used for ambient dose rate measurement at workplace. Ambient neutron dose rate is measured in terms of the equivalent dose rate in milli-Rem/hour (mRem/h), and the energy spectrum of neutron field is taken care in these measurements. Neutron dose rate meters in use are conforming to the protection quantity $H_p(10)$.

ICRU recommends the use of $H_p(10)$ to measure the whole body dose for deeply penetrating radiation. Usual method is to use a tissue equivalent material as dosimeter (e.g., TLD-100, chemical formula LiF:Mg,Ti). In India, measurement of external dose from photons and beta particles is done with TLD using $CaSO_4$:Dy phosphor (Vohra et al. 1980; Pradhan 1981). Though the $CaSO_4$:Dy phosphor is not tissue equivalent, it has several advantages in comparison to TLD-100. It is almost 30 times more sensitive than TLD-100. This phosphor is amenable to large-scale preparation and has simple annealing procedure. With the use of filters over the dosimeter and proper dose evaluation algorithm, the response of this dosimeter is made almost close to tissue equivalent dosimeter. The quantity measured for external radiation using this dosimeter is the whole-body dose which closely resembles the operational quantity $H_p(10)$ in most exposure scenarios (Bakshi et al. 2007; Pradhan et al. 2009). Dose to the extremities (wrist) and skin is measured as "wrist dose" and "skin dose," respectively, using the same $CaSO_4$:Dy TLD badges. Here the reported skin dose or extremity dose is the sum of dose due to photons and electrons. Neutron dose is measured in terms of $H_p(10)$ using the CR-39-based dosimeter (Griffith et al. 1981; BARC 2011). Whole body dose equivalents measured using the TLD badge and the neutron dose measured using SSNTD are the legal quantities used for control of effective dose to the worker. Skin and extremity dose are equivalent dose quantities (in mSv) used for exposure control to these two specific organs.

Common Monitoring Practices for Control of Occupational Exposure

Occupational radiation monitoring has two major components: workplace monitoring and individual monitoring. In most cases, the synergy between these two is practically the best way to optimize the utilization of resources. Both workplace monitoring and individual monitoring have several components as depicted in Fig. 2. All nuclear facilities in the country practices both workplace monitoring and individual monitoring for control of radiation exposure.

Workplace Monitoring

Every nuclear/radiological facility is designed to minimize radiation exposure to occupational worker and member of the public. These safety features in design are the most effective and critical component for control of radiation exposure. Workplace monitoring is essential in a facility to ensure that the designed safety features

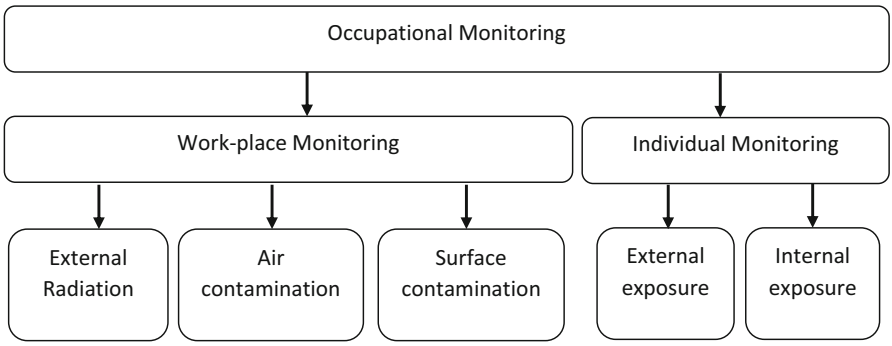

Fig. 2 Various components of occupational radiation exposure monitoring

for exposure control in the facility are functioning as per the design indent. Work-place monitoring give good assessment of the dose that worker will receive and also gives indication on the radiation quantities for which individual monitoring need to be initiated in the facility. Ambient dose rate due to β/γ radiations and neutrons and air and surface contamination are the key radiological indicators of importance for exposure control. All nuclear and radiological facilities in the country install sufficient number of monitoring equipment to continuously measure these parameters at representative locations in the facility. Quantity, locations, performance specifications, etc. of such installed radiation monitoring instruments undergoes detailed review, before commissioning of a radiological facility. This ensures the availability of such system for early warning of exposure situations to workers. Adequacy of the installed instruments are periodically reviewed and augmented from time to time, based on operating experience and expert judgment.

Installed Radiation Monitors

Area gamma monitors (AGMs) with energy-independent Geiger-Müller (G M) counter as detector is used for ambient dose rate measurement in workplace. A multi-element perforated shielding around the G M detector in AGMs makes its energy response flat in the energy region of interest. Typical AGMs used in Indian industry have operating range 0.01–100 mR/hr. No radiation field due to neutron is allowed in accessible areas of any facilities. Hence, continuous measurement of neutron field is not a requirement in workplace of most facilities. However limited number of such instruments is present in research reactors where experimental neutron beams are being provided. Moderated BF_3/^{3}He proportional counter, reading the ambient neutron equivalent dose rate in mRem/hour, is used for such purpose. Due to the special design of the moderator around the detector, these monitors have acceptable energy response for neutrons with energy from thermal up to 10 MeV/neutron.

Air contamination is continuously measured in all areas having potential for generation of radioactive aerosols or release of gaseous radionuclides to workspace. The nature and type of operations in an area provides guidance on the requirements

for air monitoring. Continuous air monitors (CAMs) are on-line air sampling instruments, essentially consisting of a motor to draw the ambient air, a collection medium, and a suitable radiation counter. Most often, radioactive particulates are collected on glass fiber filter medium. In most common instruments, an end window G M counter (for β-particulates) or a ZnS(Ag) scintillation detector (for α-particulates) facing the filter medium is used to give on-line gross count of the particulates accumulated on the filter. In general, CAMs for β-particulate measurement need additional shielding around the detector to reduce the counts from background radiation. This gross particulate activity measuring instruments usually reads in counts per minute (CPM) of the accumulated activity. Additional interpretations are often required to relate this measurement to the exposure quantities such as DAC and DAC-hour (Justus 2010). For sampling of iodine isotopes, activated charcoal filter is used as collection medium in combination with glass fiber filter. Charcoal filter is kept behind the glass fiber filter so as to collect all particulates on glass fiber filter, followed by isotopes of iodine on the charcoal filter. For adequate sensitivity, CAMs for gross α/β particulate collection and measurement are typically operated with a minimum air sampling rate of 100 liters per minute (lpm). Tests using smoke generators are used to have qualitative understanding of the air flow pattern in a room. This information along with knowledge of the most potential release locations are used to place the static air monitors at suitable locations in workplace, for early detection of radioactivity release into air (NUREG 1400 1993). On-line ^{3}H in air monitor (ECIL, Hyderabad) with gamma compensated ion chamber as detector is the usual on-line detector installed in PHWRs for measuring ^{3}H contamination in air.

Installed monitors are set to generate audio-visual alarm in case the measured parameters exceed a pre-set value. Alarm set point for instrument at a specific location is decided by considering the ambient background of the measurand at the location and the minimum detection requirement of the parameter to prevent undue exposure to the worker. Also, these instruments are hooked to a Supervisory Control and Data Acquisition (SCADA) system in plant control room. This aids the storage, trend analysis, and interpretation of radiological status of the plant on continuous basis.

For surface contamination measurement, no on-line instruments exist. Contamination on surfaces is measured and reported using direct measurement with handheld instruments. Commercial contamination counters with beta and alpha contamination probes (e.g., RadEye AB100, Thermo Fisher) are used for such measurements, and results are reported in Bq/cm^2. Direct measurement gives total contamination without discriminating its transferability. Measurement of transferable contamination is done using wipe (smear) taken from the surface using a suitable medium. A 10 cm × 10 cm absorber sheet is the usual wipe medium. In the process of taking wipe, only a fraction of the transferable contamination present on the contaminated surface gets transferred onto the wipe medium (Jung et al. 2001). Hence, the surface concentration of the contaminant actually present on the surface is usually much higher than what is counted on the wipe taken from the surface. A transfer factor, which is

usually much less than one, needs to be applied to get the true concentration of the surface contaminant using the count rate recorded from the wipe sample. However, due to wide variation in transfer factors possible and the difficulty to estimate the same on a case-to-case basis, transferable contamination using wipe method in operating nuclear facilities are usually reported without applying any transfer factor for the wipe procedure.

External contamination on clothing and body parts was identified as a source of radiation exposure to workers in nuclear industry. Ten percent of the annual equivalent dose limit to skin (500 mSv) is apportioned to contamination on skin and clothing (Krishnomony 1990). Based on this assumption, derived working levels (DWLs) are arrived for the maximum allowed contamination on skin and personal and plant clothing of nuclear energy workers in the country. DWLs applicable to nuclear facilities are provided in Table 2 (AERB 2005a).

Contamination checks on personnel are carried out at the exit of every controlled area in plants. Gross β/γ and α-contamination monitors are the most common instruments usually present at monitoring locations. Gross β/γ-contamination monitors are usually equipped with thin walled G M tubes or plastic scintillation detector whereas α-contamination monitors are usually made of large area ZnS (Ag) scintillation detector. Whole-body contamination portal monitors and vehicle portal monitors are usually installed at final exit point of nuclear facilities. This serves as an additional monitoring and prevents the release of contaminated individual or equipment from radioactive facilities to the public domain. Contamination portal monitors presently installed in plants uses an array of pancake G M detectors or large area plastic scintillation detector for radiation counting. Figure 3 shows few typical radiation monitoring instruments used in nuclear facilities.

For assured performance of all radiation monitors used in the plants, every facility have a detailed quality assurance (QA) program delineating all testing requirements including their periodic calibration. Calibration frequency of AGMs is biannual and is done following the procedure prescribed in IEC 60532 (IEC 2010). Efficiency of detectors used in CAMs is done periodically with standard sources of suitable dimensions and activity. Efficiency of contamination monitors are checked using wide area sources as prescribed in IEC 60325 (IEC 2002). Efficiency of α/β counters used in routine applications is done on a daily basis, prior to use, with standard source of appropriate strength and energy.

Table 2 Derived working levels (DWLs) for radioactive contamination

Surface	Beta emitters (Bq/cm^2)	Alpha emitters (Bq/cm^2)
Skin[a]	1.5	1.0
Hands[b]	350	250
Plant clothes	6	2
Personal clothes[a]	2	0.5

[a]Only fix contamination is allowed on skin and personal clothes
[b]Total contamination on either side of hands

Fig. 3 Examples of installed instruments for radiation monitoring in workplace: (**a**) β/γ hand, foot, and cloth contamination monitor, (**b**) continuous air monitor with PIPS detector for detection of presence of Pu in air, and (**c**) a portal contamination monitor with an array of pancake G M detector

Measurements Using Portable Instruments

Additional monitoring using portable instruments is a necessary component of occupational monitoring at workplace. Identification of radiation hot spots (location on equipment or area having relatively higher dose rate), periodic detailed radiation mapping of plant areas and equipment, monitoring of areas having accessibility issues, etc. are typically done with portable instruments. Periodic monitoring using portable instruments is done in facilities where frequent change in radiological status is envisaged. Jobs having potential for significant personal exposure, personal contamination, or air contamination is usually done under Radiation Work Permit (RWP) with supplementary monitoring using portable instruments. Teletector (Automess GmBH, Germany) is the principal portable instrument for gamma dose rate measurement in workplace. Commercially available radiation survey meters with scintillation detectors (NaI(Tl), CsI(Tl), CdZnTe, etc.), plastic scintillation detector, semiconductor detector, or G M detectors as radiation sensing element are also used for radiation field measurement, where dose rate is expected to be relatively less. Grab sampling for particulate air contamination is done with high volume air samplers (e.g., TIFIA series high volume air sampler, The Staplex Co., USA). These instruments generally use glass fiber filter media for particulate collection and work with higher suction rate for air, typically more than a cubic meter per minute, to have large sample volume within short sampling duration. All portable radiation survey meters used in facilities are subjected to calibration at least on a yearly basis. In PHWRs, collection of moisture using cold finger technique is usually done at locations expecting ^{3}H air contamination. In this method, moisture present in air is freezed out typically using dry ice. ^{3}H concentration in collected moisture is done with Liquid Scintillation Counter (e.g., TRICARB series, Perkin Elmer, USA). This measurement result along with relative humidity data is used to estimate ^{3}H concentration in air (ORNL 1976).

Individual Monitoring

Monitoring for External Exposure

Control on radiation exposure for the occupational worker is achieved by applying limits on the protection quantities: effective dose, equivalent dose to skin and extremities, and equivalent dose to eye lens (Table 1). In current practice, routine eye lens monitoring is not performed as it is unlikely that current dose limit of 150 mSv will exceed in normal occupational environment in nuclear installations. Individual monitoring is practiced for measurement and recording of radiation exposure to worker in all nuclear facilities in the country.

A TLD badge is the dosimeter employed for measuring whole-body dose to the individual from photon and β-particles. The badge consists of a TLD card and a cassette holder. The TLD card has three TLD disks made from $CaSO_4$:Dy (Dy concentration 500 ppm) and Teflon in the weight ratio of 1:3. Teflon acts as a binder and has no role to play in TL process. The detector material is $CaSO_4$:Dy phosphor (polycrystalline form). Each disk is 13.3 mm in diameter and 0.8 mm thick. Disks are clipped on hole of 12 mm diameter in a nickel plated aluminum card. The card has a "V" cut so that it can be loaded in the cassette only in one orientation. The cassette has three filter regions corresponding to the three TLD disks: (1) region of combined metal filters of copper and aluminum (total density thickness 1160 mg/cm^2) sandwiching disk element D1, (2) transparent polystyrene-666 filter (density thickness ~ 168 mg/cm^2) sandwiching disk element D2, and (3) circular open window sandwiching disk element D3 in paper wrapper and polyethylene pouch (total density thickness 12 mg/cm^2). Properly sealed TLD card is loaded in a TLD cassette made of plastic with a crocodile clip for wearing on person. Badges used for monitoring dose to other body parts such as wrist or head also are similar, except that there is a strap of suitable length to wear on the wrist/head instead of the clip arrangement. For the readout of the TLD card, a semi-automatic TLD badge reader is used. Hot N_2 gas (around 285–290 °C) is used to heat (as stimulant) the TL disk for release of the trapped energy from incident radiation in the form of light and is measured using a photo-multiplier tube (PMT). Using this TL signal from each disk and the dose evaluation algorithm (Dere et al. 1993), the whole-body dose and skin dose are evaluated. The dose evaluation algorithm is developed based on the response of the TLD badge to photons in the energy range 30 keV to 1.25 MeV and beta radiation with end point energies 0.66 MeV (^{85}Kr) and 2.2 MeV (^{90}Sr/^{90}Y). Reporting levels for whole-body dose and skin dose, using this dosimeter, are 0.10 mSv and 1.0 mSv, respectively.

Sensitivity of this dosimeter to fast neutron is negligible. Each TLD card can be used for several cycles of annealing, exposure, and readout. Though this TLD is not tissue equivalent, several studies have shown that for pure photon beams and mixed fields of X-rays and photons, the response of this dosimeter lies within the limits of trumpet curve, the criteria used for accuracy in dose measurement using TL dosimeter (IAEA 1999).

External dosimetry services for occupational radiation workers of DAE establishments are done through 12 personal monitoring laboratories (PMLs) operating at

different locations. Frequency of TLD monitoring service is monthly or quarterly depending on the exposure potential of the facility being monitored. All NPPs, fuel processing plants, and other major facilities have monthly service for TLD badges. Single TLD badge on chest is used for all cases where uniform radiation field is expected. In special situations where the radiation field is expected to be non-uniform, separate TLDs in addition to chest TLD are provided for supplementary measurement. Wrist TLD badges are provided for workers for measuring the dose to the extremities. Jobs like handling of open-radioactive sources, maintenance on equipment having high exposure rate, etc. are always accompanied with additional monitoring using wrist TLD badge.

For specific jobs with significant exposure potential, an active dosimeter is provided to the worker in addition to the TLD badge. This helps in administrative control of exposure of each individual through the progress of a planned work. Direct reading dosimeter (DRD, Arrow Tech Inc., USA) is in use in some facilities. This dosimeter, usually called as pen dosimeter, is a small ionization chamber which is charged prior to use. Gamma radiation falling on the detector leads discharge of the dosimeter which is read through an analog scale. Electronic pocket dosimeters (EPDs) (e.g., DMC 3000 series, MIRION Inc., USA) are increasingly replacing the practice of using analog DRDs in the country due to several practical advantages of the latter for field use. Provision to set alarm limit based on dose and dose rates, remote communication, etc. are some major advantages. Such dosimeter usually houses multiple miniature semiconductor detectors inside the housing in order to function for wide energies of radiation and larger operation range for measurement of dose and dose rate.

Extensive quality assurance (QA) protocols are followed in personal monitoring using TLD badge, starting from the selection of phosphor lot for preparation of TLD disk to assigning dose to the individual from reading individual TLD card (BARC 2018). Calibration of TLD is done with ^{137}Cs source traceable to the secondary standard calibration laboratory, Radiation Standard Section, BARC. External QA for all the PMLs operating in the country is done by an announced test annually done by Radiological Physics and Advisory Division (RP&AD), BARC. During this exercise, TLDs irradiated to specific dose are provided to each PMLs, without declaration of the actual dose delivered and type of radiation, and PMLs are asked to estimate the dose using their standard procedure (Srivastava et al. 2017). PMLs of NPCIL facilities are subjected to blind test every month as a part of its internal QA program. In this test, the user facilities provide TLDs irradiated to known dose along with TLD badges of regular workers, without revealing the irradiation status of the cards. Active dosimeters (DRD/EPD) in circulation are also periodically calibrated with standard source. TLD laboratories in the country participate in international inter-comparison exercises conducted by IAEA, EURADOS, etc. for proficiency evaluation.

Personal neutron dosimetry is done with SSNTD technique using the polycarbonate detector commercially known as Colombia Resin-39 (CR-39). The chemical name of the polymer is poly-allyl-di-glycol carbonate (PADC). The dimension of the detector is 3 cm $\times$ 3 cm $\times$ 0.75 mm. The detector, along with a polyethylene radiator

in front of the detector, is loaded in a triple laminated pouch and further loaded in a polycarbonate holder. Elastic scattering of neutrons with hydrogen of this polymer produces recoil protons. These recoil protons deposit its energy in the medium to cause breaks in molecular bonds. Local defects thus created in the form of track in the detector are enlarged by chemical/electrochemical etching of the detector under controlled conditions. Etching rate at damaged site is more than that at the undamaged base material. Two etching methods using KOH (concentration 7 N) as a medium and at 60 °C temperature are used for track development. In one case, known as electro-chemical etching (ECE), it is done in the presence of electric field (2200 V/mm), and the other process is called chemical etching (CE). In ECE, etching rate is faster, but many tracks could merge together resulting in loss of tracks during the process. But the procedure is faster and the track counting after ECH is done with automated image analyzer. CE is more time-consuming and track counting needs to be done manually. Due to merger of multiple tracks, ECE have lower sensitivity in comparison to CE procedure. In practice ECE is used for dose $<$10 mSv and CE for higher doses (Massand et al. 1990).

Calibration of neutron dose measurement using CR-39 detector is done following ISO 8529 (ISO 1998). For calibration purpose, detectors are irradiated on an ISO recommended water slab phantom made from poly methyl methacrylate (PMMA) using standard ISO recommended ^{241}Am-Be, ^{252}Cf, and ^{252}Cf-D_2O neutron sources. The neutron dosimeter used in neutron monitoring program is sensitive to neutron energy 100 keV to 14 MeV. Dose linearity of the dosimeter is found to be within $\pm$10% up to measured dose of 10 mSv using ECE. MDL for CE and ECE procedure were found to be 0.27 mSv and 0.10 mSv, respectively. As a practice, the minimum reporting level for neutron dose is 0.20 mSv with quarterly service period for the dosimeter. From detailed laboratory investigations, it is established that CR-39-based neutron dosimetry followed in the country is confirming to all requirements as specified in ISO 21909 (BARC 2011; ISO 2005). Individual monitoring for neutron dose is routinely done for identified workers having potential for exposure to neutron filed in NPPs, research reactors, and facilities handling significant quantity of plutonium.

Monitoring for Internal Exposure

Assessment of radiation doses arising from the intake of radioactive material by the worker is termed as internal exposure assessment. Individual monitoring is prescribed for workers with likelihood of receiving more than 1 mSv/year occupational exposure due to intake of radionuclides (IAEA 2018). Individual monitoring is performed out for all workers having such work environment. Though the radionuclides of concern depends on the type of facility, inhalation is found to be the most common route of intake at occupational workplace. Depending on the facility, internal monitoring program and methodology are carefully designed, not to miss any case of intake in usual course. The technique employed for detection of intake and the monitoring frequency are the two key parameters that will decide the overall efficiency of internal monitoring program. Monitoring for internal exposure carried out in the facilities could be broadly classified into three categories: (i) routine

monitoring to estimate the dose due to regular work in normal work environment; (ii) special monitoring, carried out in several circumstances such as heavy personal contamination, injury while working in controlled areas, high air contamination detected at workplace without adequate respiratory protection for worker, failure of respiratory protective equipment during work, etc. and also, as a part of special tasks where high probability for intake is envisaged, and (iii) confirmatory monitoring to check the assumptions of exposure conditions applied to a facility. Confirmatory monitoring is generally done on a small fraction of the workforce. Individual monitoring for intake is done using in vivo method, in vitro method, or a combination of both.

In Vivo Methods

In vivo method is the technique of quantifying the radioactivity present in specific organs or whole body using suitable detectors placed externally. Partially shielded whole-body counter (WBC) is used for quantifying high energy photon emitters (HEPs) uniformly distributed in the body. Here the subject is scanned under a scintillation detector (usually $4'' \times 3''$ NaI(Tl) detector) under partial shielding. HPGe detector is also used in place of NI(Tl) detector for high-resolution application, especially when a mixture of radionuclide is to be quantified.

A motorized scanning bed controls the movement of subject below the detector. Presence of low concentration of gamma emitting isotopes such as ^{137}Cs or ^{60}Co in the body can be easily detected using this technique. As radio-iodine concentrate in thyroid, a chair type scanning system is used to quantify such cases. A $2'' \times 2''$ NaI(Tl) detector is usually mounted on thyroid monitoring system.

To quantify low energy photons (LEPs) emitting radionuclides present in the lungs, a specially shielded steel room is used. Such room is constructed with typically 20-cm-thick mild steel walls all around which are lined inside with Pb (3 cm) + Cd (2 cm) + Cu (0.5 cm). Resultant background in steel room – only due to characteristic X-rays (8 keV) from Cu – allows sensitive measurement of LEPs such as 60 keV photons from ^{241}Am or 17 keV L-X-rays from ^{235}U which are used to estimate ^{239}Pu in the lungs. A phoswich detector, sandwich of primary thin NaI(Tl) crystal in combination with thick CsI(Tl) crystal working in anti-coincidence with the NaI(Tl) crystal, is the common configuration used for LEP measurement. An array of three HPGe detectors is also used for measurement of LEP emitting radionuclide present in the chest.

All in vivo monitoring systems are calibrated periodically using standard phantoms. In this procedure, known quantity of radioactivity is placed in the phantom and counted under standard procedure. HEP measuring systems are calibrated with phantoms made of tissue equivalent materials: Masonite phantoms or Bottle Mannequin Absorber (BOMAB) phantom. For LEP measurement in the lungs, a Lawrence Livermore National Laboratory (LLNL) phantom or Japan Atomic Energy Research Institute (JAERI) phantom is used. Energy resolution and efficiency check of all in vivo counting systems are done weekly with test sources. Theoretical calibration can also be performed for in vivo counting systems using computational voxel phantoms, where direct calibration is practically difficult. Computational

Fig. 4 Some of the instruments used for intake measurements by occupational workers (**a**) shield room facility for measurement of LEP emitters in the lungs, (**b**) NaI(Tl) based thyroid monitor for measurement of iodine intake, and (**c**) system for breath measurement for ^{226}Ra in the lungs used in uranium mining facilities

phantom is a mathematical representation of the human body which, when coupled with a Monte Carlo radiation transport computer code, can result in estimation of efficiency for the counting system. Use of these phantoms eliminates the requirement of physical phantom as well as the radiation standards.

In addition to general procedures, organs such as the skull or knees need to be monitored as a suitable site for measurement of bone seeking radionuclides. Activity estimation at wound site, especially with actinides or radionuclides with low penetrating radiations, is also done in shielded room counting facilities. Miniature pencil probes with silicon detector (e.g., Multirad LLR with α-pencil probe, Mirion Technologies) are used for detection of alpha contamination on wounds. Figure 4 shows few systems used in measurement for internal contamination. List of important radionuclides specific to nuclear industry and their detection limit for in vivo counting available in the country is listed in Table 3 (AERB 2019).

In Vitro Methods

In vitro methods are used to quantify the intake of several radionuclides, mainly for alpha and beta emitters. Quantity of radionuclide inside the body could be estimated using measurement of radionuclide concentration in biological samples collected from the internally contaminated individual. Excreta such as urine, feces, or breath are the most common samples analyzed for radioactivity. This procedure is termed as bioassay. Analysis of urine is the most common bioassay procedure due to ease of collection and analysis. Standard radiochemical procedures are used for processing, chemical separation, and analysis of the bioassay samples. Several techniques are used for measuring radionuclide concentration in processed samples. For low energy pure beta emitters like ^{3}H, ^{14}C, ^{35}S, and ^{241}Pu, liquid scintillation counting is the only viable method. Other beta emitters especially fission products are estimated using gas flow G M counter or plastic scintillation detector. Alpha spectrometry using passivated ion-implanted silicon (PIPS) detector is the most common technique applied for alpha emitters. More sensitive methods such as laser fluorimetry (LF), neutron activation analysis (NAA), fission track analysis (FTA), etc. are

Table 3 Minimum detection activities and the corresponding CED with in vivo measurement techniques available in the country

applied in specific cases. Bioassay of urine and feces are routinely done in combination with several measurement techniques at bioassay laboratories at Mumbai, Tarapur, and Kalpakkam. Bioassay laboratory is also operating at NFC, Hyderabad, for measurement of intake of uranium. Radiochemical separation and quantification procedure undergo strict quality control, and the bioassay laboratories regularly participate in international inter-comparison exercises conducted by IAEA and other laboratories. Analysis of the swab from nasal cavity is often done in case of suspected inhalation, especially for actinides. Tissue samples excised from the contaminated wound are also radio-chemically analyzed for activity content. Breath analysis of radon is used to estimate the body content of ^{226}Ra (from ^{238}U series) in uranium mine workers. This procedure requires the worker to breathe into a breath collecting apparatus for a period up to 30 min depending upon the volume required. MDA achievable for important radionuclides in DAE bioassay laboratories are presented in Table 4 (AERB 2019).

From the measured content of radioactivity in the whole body, specific organ/s, or excretion rate, it is possible to find the intake in Bq of radioactivity that has entered the body by inhalation, ingestion, or injection. Various bio-kinetics model such as human respiratory track model, human alimentary track model, National Commission for Radiological Protection (NCRP) wound models (ICRP 1994, 2006; NCRP 2007a), and other systemic models published by the ICRP are used for estimating the

intake using the data from measurements. Intake when multiplied by dose coefficient (Sv/Bq) provides the CED. When the time of intake is not known, standard procedure is to adopt midpoint of monitoring interval as the time of intake. In some cases, follow-up monitoring may provide information regarding the likely time of intake. Such cases are resolved by multiple monitoring at regular intervals on the subject. These multiple results are fitted into the relevant bio-kinetics model to arrive at the intake (AERB 2019).

Both detection and dose computation due to intake of radionuclide like ^{3}H or isotopes of iodine are simple and straight forward. When ^{3}H enters the human body as tritiated water, it equilibrates with body water within few hours. Urine is a representative of body water. ^{3}H concentration in urine, collected after few hours of exposure, can easily be used to accurately estimate the intake. Also ^{3}H measurement in urine sample using liquid scintillation counter (LSC) may not require much sample processing. Similarly, iodine isotopes preferentially get absorbed in thyroid, resulting in easy detection. But for many other radionuclides like actinides with complex bio-kinetics and bio-distribution, CED estimation is tough and time-consuming. Multiple measurements often using different techniques are used to arrive at the intake. Measurement results from different techniques such a urine, feces, lung monitoring, etc. are together used to arrive at the best estimate of intake. Commercial internal dosimetry software such as Integrated Modules for Bioassay Analysis (IMBA Internal dosimetry software, UK Health Security Agency) and Mondes-Mondal are used for estimation of intake using data from multiple measurements obtained using different monitoring techniques.

Though the occurrence of overexposure to the worker is rare in nuclear industrial activities in the country, DAE has set up a well-established bio-dosimetry laboratory

among its facilities for radiation exposure monitoring. Biodosimetry laboratory at BARC, Mumbai, has the capability to estimate dose accurately in case of suspected exposure above 100 mSv. Dicentric chromosomal aberration assay (DCA) is the most used technique while other methods like micro-nucleus assay (MN-assay), premature chromosome condensation (PCC), and fluorescence in situ hybridization (FISH) technique also are well established at this facility (Bhat et al. 2018).

Monitoring Practices Specific to Facilities

Front End Fuel Cycle Facilities

Front end fuel cycle facilities include uranium mining, milling, and uranium fuel fabrication facilities. These facilities are distinguishable from the rest of the nuclear fuel cycle facilities with respect to the volume of raw material and solid waste managed, manual mode of operation, open radiation sources, and handling of bulk quantity of low specific radioactive material.

DAE operates both underground and opencast mines, followed by the milling process to get the uranium ore concentrate. For uranium mine workers, contribution from internal exposure due to radon progeny inhalation is more than external exposure. The normal ambient dose rate in Indian uranium mines are typically 1–2 μSv/hr. due to low uranium content in ore (BARC 2020). A calibrated G M survey meter is used for ambient dose rate measurement in uranium mines. In uranium mills and tailing pond areas where the waste from milling process is contained, air-borne uranium particles are the main source of internal exposure. In uranium mining and processing facilities, measurement of ambient radiation along with occupancy factor (duration of exposure) is used to assign dose to the occupational radiation worker. For this, radon and their progeny concentration in air and ambient dose rate at the work locations are regularly monitored. Personal radon dosimeters (PRD), having dosimetry elements for both radon progeny measurement and gamma dose measurement, are additionally used for estimation of dose to workers in uranium mines. Good agreement is observed between dose estimated using data from measurement of ambient parameters at workplace and that from the use of PRD by individual worker in field.

Radon concentration in mines is measured using a cylindrical ZnS(Ag) scintillation cell. Pre-filtered air is allowed to enter into the evacuated 150 ml metallic cylinder whose inside is coated with the scintillator material. Counting is done typically after about 3 hours of sampling so as to reach equilibrium between radon and its progenies. Typical detection limit for this method, with 10 min counting time, is ~40 Bq/m^3 (Raghavayya 1981). Equilibrium factor for dose estimation is experimentally determined in most cases; otherwise, the recommended default value of 0.4 is used. In mills, low level radon detection system (LLRDS)- or SSNTD-based radon detectors are used. LLRDS is a 5 L volume aluminum chamber. Freshly formed ^{218}Po, a progeny of ^{222}Rn, is collected onto a negatively charged aluminum plate by application of high voltage to the plate. Typically, 90 min is the

collection time followed by 75 min counting – post collection – for alpha particles emitted from the progeny collected on the electrode (Srivastava et al. 1984). For radon daughter concentration measurement, the Kusnetz method (Kusnetz 1956) is often used in mines. In this method, radon daughters are collected on a filter paper by air sampling for about 10 min, and the filter paper is counted for alpha activity in between 40 min and 90 min, post sampling. This method is found to give radon daughter working level concentrations within an error of ±13%, irrespective of the equilibrium condition.

PRD is used to assess the internal dose due to radon progeny inhalation (Raghavayya et al. 1986). The device comprises a 60 mL cylindrical aluminum chamber covered with a permeable membrane which allows only ^{222}Rn to diffuse in, due to its relatively longer half-life, and serves as a barrier for ^{219}Rn, ^{220}Rn, and other particulate aerosols. A 1.8 cm × 3 cm SSNTD film (LR-115) is used to quantify the radon concentration. The SSNTD film is etched with 10% NaOH solution at 60 °C for 90 min. The tracks are electronically counted which are correlated to radon exposure using a calibration system. Service period for the detector is 2 months. PRD also have two $CaSO_4$:Dy TLD disks embedded in it which is used to estimate the external exposure to the worker. The algorithm used for dose evaluation from this two-disk TLD system is different from that of the three-disk TLD badge used in other facilities. Additionally, radon and its progeny concentrations inside mine is routinely measured using sophisticated portable instruments like Alpha Guard (Bertin Instruments, Germany). Such measurements are useful for evaluation of the equilibrium factor between radon and its daughters which is employed for dose computation using ambient radon concentration data. This data also serves as feedback for ventilation control in mines to limit intake of radon progenies.

Standard three-disk TLD badge is used for external exposure measurement of workers in uranium fuel fabrication plant (BARC 2021). Uranium handling areas are regularly monitored for the presence of air contamination. Workers in uranium fuel fabrication facilities are subjected for lung monitoring and urine bioassay for the detection and quantification of uranium intake.

Occupational Monitoring in Reactors

Ambient dose rate in all accessible areas of the reactor is measured with GM detector-based AGMs usually having operating range 0.1–100 mR/hr. AGMs having higher operating range, usually having ion chamber-based detector, are provided in certain shutdown areas in some reactors, rather to know the process deviations than occupational monitoring purpose. Calibration of the accessible area AGMs are done in situ employing radiation sources traceable to secondary standards. Additionally, electronic calibration of AGMs is done periodically applying external voltage simulating the radiation source. Neutron dose rate in shutdown areas during maintenance activities are carried out using standard neutron REM-counter based on ^{3}He/BF_3 detector (e.g., Ludlum 30 series). These neutron-Rem counters are calibrated at

secondary calibration laboratory following the procedures prescribed in IEC 61005 (IEC 2014). CAMs for particulate air activity measurements are present at Spent Fuel Storage Bay (SFSB) – where the freshly discharged hot fuel bundles are stored – and some other areas in few reactors. Continuous ^{3}H in air monitors are provided in critical areas in all reactors. These detectors are compensated ion chambers (ECIL make) capable to detect sub-DAC concentration of ^{3}H in air. Additionally, two grab sampling techniques are routinely employed for detection and quantification of ^{3}H in air from potential locations in reactors. In "cold finger" method, HTO present as moisture in air is freezed out using dry ice as the cooling medium (DOE 1994). Bubbling air through water at room temperature, typically at low flow rate of ~1 liter per minute (lpm), is another method used to sample ^{3}H in air (Wood et al. 1993). Water containing ^{3}H obtained by either of the method is analyzed using LSC. During certain special operations in reactors, air contamination due to isotopes of iodine is possible. Air sampling for iodine isotopes are done employing activated charcoal-loaded filter paper and is counted on either HPGe- or NaI(Tl)-based gamma spectrometry system.

For photons and β radiation, individual external exposure measurement in reactors is done with standard three-disk TLD badge and EPDs as active dosimeter. Neutron personal dosimetry in reactors is traditionally done with CR-39 film badge. However, commercially available neutron-sensitive EPD is used as an additional active neutron dosimeter in NPPs. All NPPs in the country follow similar procedures to monitor intake of radionuclide. Shadow shield WBMs with NaI(Tl) detector is the standard instrument used for in vivo counting. WBMs are placed in environmental survey laboratories (ESLs) as they need to be placed away from back ground radiation form reactors. Typical detection limit for such counters is around 100 Bq of ^{60}Co in body. All workers with potential for ^{3}H intake are monitored weekly by urine sample analysis.

Workplace and individual monitoring practices in research reactors are almost similar to that of NPPs. But, research reactors are principally utilized for performance evaluation of new reactor designs, isotope production, and research employing neutron beams for scientific research. Hence frequent changes in radiation field is expected in such facilities necessitating more frequent radiation surveillance of occupied areas.

Radiochemical Plants and Plutonium Handling Facilities

General radiation monitoring procedures in back-end nuclear cycle facilities like spent fuel reprocessing and radioactive waste management facilities are relatively complex to that of other nuclear facilities described earlier. This is due to handling of bulk quantity of solutions having high radioactivity concentration, whereas in other facilities, radioactivity is mostly in sealed form (reactors) or is of low specific activity (uranium mining facilities). Chemical processing is done in hot cells made with thick high density concrete wall and processes are controlled remotely. These cells and equipment are non-accessible during normal operations, but human entry is

required for contact maintenance. Such jobs are prone to significant external exposure and are having potential for intake. At the beginning of hot cell decontamination, prior to scheduled maintenance activities, exposure rate in hot cell could be beyond the maximum operating range of routine radiation field measuring instrument like teletector (1000 R/hr). In such instances, for area surveillance, gamma dose rate meter with wide operating range is employed. Detailed characterization of air samples by chemical separation and spectrometric identification of isotopes is often done to characterize the air contamination in work field. Many of the radiological hazards in uranium-plutonium mixed oxide (MOX) fuel fabrication facilities are common to that of back-end fuel cycle facilities. All stages of the fuel pellet and fuel pin preparations are carried out in glove boxes. This results in significant external exposure to plant workers from neutron and gamma radiations. ^{241}Am build-up from ^{241}Pu is found to be the major source of gamma exposure in MOX fuel fabrication plants.

Potential for intake is high in places where plutonium is handled in dispersible form. A highly reliable air monitoring program is essential to prevent intake via inhalation by workers in these facilities. CAMs for alpha particulate monitoring based on gross alpha detection are used in large numbers in such facilities but are not sensitive enough for early detection of Pu aerosol due to the presence of naturally occurring alpha emitting progenies present in air. For prompt detection Pu contamination in air, alpha dust particulate monitor based on PIPS detector is used in Pu handling facilities (Pollanen et al. 2013). These instruments are basically alpha spectrometer with provision for on-line dust collection, spectrum analysis, and quantification of isotopes collected on the filter paper and use proprietary algorithm to distinguish alpha particles of artificial origin like ^{239}Pu from that of natural alpha emitting radionuclides (Li et al. 2013). Personal air sampler are often provided to workers engaged in activities having high potential for intake by inhalation. These are small, lightweight passive air sampling units working at low flow rate, typically few lpm, and can be worn on person while working.

Individual monitoring for external exposure using standard TLD badges is done for all workers in such facilities. Neutron exposure is significant in facilities handling bulk quantity of PuO_2. Spontaneous fission of Pu isotopes is one source of neutrons. (α,n) reaction with elements like ^{18}O present in PuO_2 is also a source for neutron exposure in these facilities (McLaughlin et al. 2000). Fast neutron dosimetry using CR-39 film badges are employed for personal neutron dosimetry. Workers having potential for intake are identified and subjected for appropriate internal monitoring procedure. Bulk plutonium handling facilities are prone to nuclear criticality accidents (Reddy et al. 2018). Criticality accidents are prevented by geometrically safe design of vessels and equipment for handling fissile materials in combination with strict restrictions on maximum quantities allowed to be handled in specific processes. Criticality alarm systems are provided at all locations susceptible to such incident for the immediate evacuation of workers. These are ionization chamber-based instruments tuned to generate alarm due to a sudden surge in gamma dose rate, which is typical for a nuclear criticality event. All workers working in areas vulnerable to criticality incidents are provided with individual criticality dosimeter. Criticality

dosimeter consists of several neutron activation foil such as ^{197}Au, ^{63}Cu, ^{115}In, ^{64}Fe, ^{32}S, ^{58}Ni, ^{24}Mg, and ^{27}Al in addition to a standard $CaSO_4$:Dy TLD disk. These activation foils with different cutoff aids in building the neutron energy spectrum resulted from the accident. A standard procedure is established for evaluation of individual exposure from gamma and neutron using criticality dosimeter (Trompier and Chevallier 2019).

Trends in Occupational Exposure of Workers in Nuclear Industry in the Country

Individual dose records of all radiation workers in the country are stored in the National Occupational Dose Registry System (NODRS) managed by RP&AD, BARC. Regulatory bodies have stipulated the retention period for occupational dose records of workers as 30 years after termination of the work involving occupational exposure or until the worker attains or would have attained the age of 75 years whichever is later (AERB 2005a). Introduction of this database management system allowed the comprehensive analysis of the exposure pattern of nuclear industry workers in DAE. Figure 5 gives the trend in occupational dose of nuclear energy workers of DAE and that of radiation workers in non-DAE (industrial, R&D, and medical) sector in the country for the period 2000–2018. Number of radiation workers in nuclear industry (DAE) is almost similar in the analyzed period, but clear reduction is observed in both average dose and collective dose. This trend, despite the vast expansion of nuclear fuel cycle activities during this period, indicates the increase in safety measures, over the years, in nuclear fuel cycle facilities in the country. In addition to technological enhancements in design and operation, new regulatory measures like frequent safety review of the facilities by Regulatory Inspection Team (RIT) and introduction of dose constraints below dose limits also

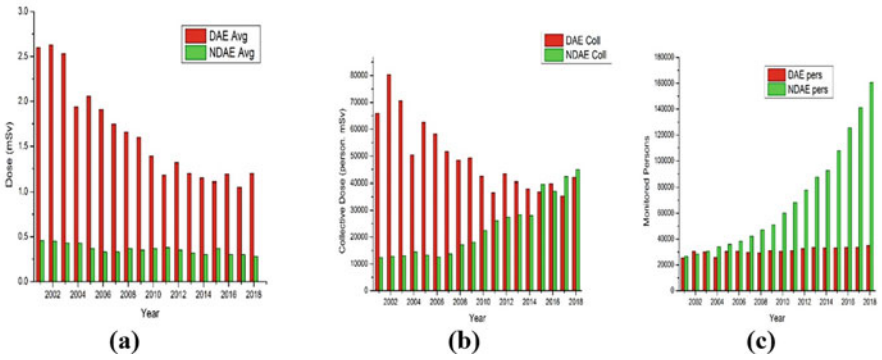

Fig. 5 Occupational exposure to radiation workers in nuclear industry in the country for the period 2000–2018; (**a**) average individual dose, (**b**) collective dose for all facilities, and (**c**) change in number of radiation workers

helped in bringing down dose to the radiation workers in nuclear fuel cycle facilities in the country.

Conclusions

Well-established procedures are practiced for monitoring and control of radiation exposure to occupational radiation workers employed in nuclear industry in the country. However, R&D activities pertaining to occupational radiation protection are in continuous pursuit for further improvement. Efforts are underway to report the TLD dose in terms of *Hp*(10) instead of the "whole-body dose equivalent," as practiced today. Neutron dosimetry at present is done with CR-39 detectors having a lower neutron energy threshold of 100 keV. Efforts need to cover neutrons of all energy in personal dosimetry services. Preliminary assessment shows that the chances of eye lens to receive higher dose than whole-body dose is very rare at workplace in nuclear industry in the country. But an appropriate dosimeter for eye lens dose measurement is desirable, especially for building database from actual measurement done in field. Many instruments used for workplace and individual monitoring are of foreign origin. Indigenous development of radiation detectors to substitute them is underway. Automation of radiation monitoring is preferred but is also linked to the progress in automation of basic production and operating procedures in plant and facilities.

safety awareness and measures in industries handling of naturally occurring radioactive materials (NORM), scant attention has been paid to radiological one. Internationally, scientific efforts are being made to identify the industries/processes laced with activity concentration greater than 1 Bq/g criteria for NORM which required appropriate control measures and regulatory instruments to protect the occupational workers, the environment, and the members of the public which is environmentally sustainable, socially acceptable, and economically affordable. Association of multi-hazards in NORM industries and diversification of operations across the NORM industries make the case more complex and difficult to regulate. In this scenario, radiometric techniques play a vital role for identification and quantification of NORM. Radiometric metrology is required to demonstrate verifiable indicator parameters for acceptability of the public, policy decisions, and development of legislative limits. However, nonexistence of overarching government policy and regulation on handling of naturally occurring radioactive materials except the industries under Department of Atomic Energy (DAE) in India make a strong pitch for introspection and evolve of scientific approach to deal with the insidious potential hazard. In the paper, authors have reviewed the published literatures related to handing of naturally occurring radioactive materials, elevated levels of these radionuclides in various industrial activities, principles of radiometric metrology, and radiological safety.

Introduction

Exploration and exploitation of natural resources, particularly ore and minerals, are an age-old practice that fuels the development of the country and its economy. These naturally occurring ore and minerals are ingrained with natural radionuclides, called as naturally occurring radioactive materials (NORM) since the evolution (UNSCEAR 2008). Long half-lives, low to high specific activities, radiological hazards due to chronic/acute exposures, and omnipresence are few characteristics of these natural radionuclides that alert the health physicists to devise appropriate monitoring program and regulations to avoid undesirable adverse impact and to reduce the possibilities of risk that arise out of it (IAEA 2014a). For a developing country like India, growing need of energy and raw materials compels for mining and processing of natural resources at an accelerated kinetics to meet the burgeoning demands of rising population, urbanization, and industrialization. All the natural resource minerals associated with radionuclides are not of much radiological significance. However, few industrial processes alter the natural abundance of NORM and resulting enhanced exposure that attracts the instruments of regulation (Garcia-Talavera et al. 2011; IAEA 2011a). Accumulation of natural radionuclides in scales

of oil and natural gas industries, resins in water treatment plants, phosphoric acids in phosphate industries, and fly ash in thermal power plants are the few examples having potential to redistribute elevated content of radionuclides in surrounding environment and pose radiological impacts on occupational workers and members of the public (Jha 2014; Koppel et al. 2022; Turcanu et al. 2022).

NORM comprises of primordial radionuclides that occur in the environment. However, the term is used particularly for enhanced radiation exposure situation due to industrial activities/processes that deals with raw materials associated with radionuclides of natural origin compared to pre-industrial activities. NORM results from various processes, namely, burning of coal/fossil fuel, manufacturing and application of fertilizers, and production of gasoline (IAEA 2003c). Extraction of uranium ore exposes the occupational workers involved in winning of ore body and processing plant for chemical extraction and isolation of economically valuable uranium from the bulk matrix. Significant radionuclides for radiological concerns are the daughter products of ^{238}U and ^{232}Th series, considering their half-lives, natural abundances, and geochemistry.

Radiation and radioactive levels associated with NORM are dominant part of the naturally occurring background radiation. Both biotic and abiotic components of ecosphere are continuously exposed to natural radiation due to existing exposure scenario. The UNSCEAR (2000) report underscored the wide variation of the natural background radiation level across the globe (UNSCEAR 2000). Relatively, a higher exposure to the habitat is anticipated in radioactive mineralized region or higher altitudes due to terrestrial radiation and cosmic radiation, respectively. A significant fraction of natural radiation exposure is attributed to inhalation of radon (^{222}Rn and ^{220}Rn), a noble gas that emanates from the earth's surface due to decay of their parent nuclide (^{226}Ra and ^{224}Ra). There are four main components of natural radiation, i.e., terrestrial radiation, extra-terrestrial (cosmic) radiation, ingestion, and inhalation of radionuclides of natural origin.

Many countries now have national legislations, where stipulated limits/guideline values are defined for naturally occurring contaminants in various environmental matrices. Implementation of these stipulated guideline/limits entails a comprehensive analytical infrastructure for appraisal of minute quantity of natural radionuclides in various environmental matrices. Quality data is a by-product of strict adoption of a prescribed quality assurance and quality control protocol. Therefore, data credibility and high degree of confidence on the generated data are crucial to our national and international programs. In the paper, a comprehensive review of NORM handling industries is presented here along with radiometric techniques for measurement of various radiological parameters. For the sake of completion, a brief overview of natural radiation and radioactivity is depicted in the following section.

Natural Radiation and Radioactivity

Radioactivity is classified as natural and artificial depending upon its origin. Naturally occurring radioactive materials (NORM) are primordial in origin consisting of uranium, thorium along with their series radionuclides, and single radioactive

elements like potassium. During operation of nuclear fuel cycle facilities, it is anticipated that effluents associated with natural and manmade radionuclides (specific to the facility) are released to the environment (UNSCEAR 2000). The quantity of release depends upon the type of facility, engineering control measures, safety standards adopted, and waste management practice implemented. Similarly, many other industries, generally called as NORM industries, which do not involve direct handling of radioactive material yet may have potential to enhance or alter the natural radioactive levels in the surrounding environment.

Human beings are being exposed to natural background radiation, medical exposure, fallout radionuclides, releases from nuclear industries, etc. Out of these sources, the significant and largest fraction is contributed by the natural background radiation which is part of the life and inescapable. It is classified into external and internal exposure. External exposure has two components, i.e., (a) terrestrial and (b) extra-terrestrial radiation (cosmic rays). Internal exposure has also two components, i.e., (c) inhalation and (d) ingestion. The components vary over a wide range across the globe which depends on the geography and geology of the location, type of house, building materials, number of air changes, source of drinking water (ground or surface water), etc. An enhanced background radiation is envisaged in a particular region associated with geochemical peculiarities related to abundance of ^{238}U and ^{232}Th and others. All existing exposures are attributed to the radioactivity content occurring in the Earth's crust, except cosmic component. Variation in natural radiation exposure depends on nature of job, type of household and construction material used, location of habitation, ventilation rate, life style and food habit, etc.

Cosmic Radiation

A major contribution to external exposure comes from cosmic rays, of extraterrestrial origin. A significant fraction of highly penetrating and high energetic cosmic rays is composed of protons (~85%). The remaining fraction is composed of alpha particles (14%) and light nuclides with Z in range of 4 to 26. Cosmic radiation varies from 0.03 μSv/h at sea level to 0.1 μSv/h at Bangalore City, India, at an altitude of about 1 km. This becomes 1 μSv/h at an altitude of 6.7 km (at the Himalayan peaks) increasing to 5 μSv/h at an altitude of 10 km (aircraft cruising altitude) and 10 μSv/h at the supersonic jet flying altitude of 15 km (UNSCEAR 2000). The annual effective dose from cosmic rays ranges between 260 μSv/y at sea level to 1070 μSv/y at an altitude of 3.4 km (UNSCEAR 2000), and the variation of it with elevation is given in Table 1. As per UNSCEAR report, the mean annual dose due to cosmic rays is observed to be 0.39 mSv/y, while the reported range is 0.3 to 1.00 mSv/y (UNSCEAR 2008).

However, in Indian Scenario, the contribution of cosmic radiation is 0.35 mSv/y to the natural background radiation considering its geography (Puranik and Ramchandran 2005).

Table 1 Altitude effect on cosmic radiation

Height from MSL (m)	Dose rate (μSvy^{-1})
0–150	260–270
150–305	270–280
305–610	280–310
610–1220	310–390
1220–1828	390–520
1828–2438	520–740
2438–3408	740–1070
> 3048	1070

Terrestrial Radiation

Naturally occurring primordial radionuclides arise in the earth, since its evolution. Primordial radionuclides are of two types, viz., "single" and "series." "Single" radionuclides are those devoid of decay series, which are naturally occurring and have stable decay products, e.g., ^{40}K, ^{87}Rb, ^{147}Sm, ^{115}Ln, ^{138}La, ^{176}Lu, etc. Most of them are beta or beta-gamma emitters. "Series" radionuclides are comprised of a parent and its daughters, which finally decay into a stable daughter product. There are three natural "series," viz., the uranium-235, uranium-238, and thorium-232 series. These series radionuclides undergo alpha and beta particle emission along with gamma radiation and end up in a stable element. The members of the series include the isotopes of the inert gas, radon (Rn-219, Rn-222, and Rn-220). The radon gas diffuses through the soil and emanates into the atmosphere. The decay products of radon being solids, they condense on the atmospheric dust particles of sub-micron sizes and form radioactive aerosols. The radionuclides of the uranium and thorium decay series are present at varying concentration levels in all compartments of the environment. The variations in their concentrations in different soils depend on the composition of their parent rocks. For example, soil derived from granitic rocks is associated with an elevated level of NORM while less in case of sedimentary rocks. It is observed that shale and phosphate rocks have relatively higher radionuclide concentrations (IAEA 2014b). Equilibrium status among the series radionuclides is a function of their physical, chemical, and radiological properties (S. Molla et al. 2021). Natural occurrence of radionuclides in rocks and soils and derived construction materials/household lead to radiation exposure to the habitat. The activity concentration of NORMs in soil in different regions is given in Table 2 (UNSCEAR 2000).

The natural radiation exposure levels in different parts of India from terrestrial and cosmic radiation vary from 0.3 mSv/y (at Lakshadweep) to 1.4 mSv/y (at Kerala) (Nambi et al. 1986).

Table 2 Natural radioactivity in soil

Regions	Activity concentration (Bq/kg)			
	^{238}U	^{226}Ra	^{232}Th	^{40}K
India	29	29	64	400
China	33	32	41	440
Japan	29	33	28	310
USA	35	40	35	370
Russia	19	27	30	520
Spain	NA	32	33	470
Global (median)	35	35	30	400

Inhalation Exposure due to ^{222}Rn and ^{220}Rn

Major contribution of natural radiation dose, particularly internal dose, arises from the inhalation of ^{222}Rn, ^{220}Rn, and their decay products. Due to decay of ^{226}Ra and ^{224}Ra, the inert gases ^{222}Rn and ^{220}Rn are produced and occur everywhere due to their chemical inert nature. After the decay, these chemically inert gases emanate from the earth/s surface into the atmosphere and migrate to other regions. Their concentration in atmosphere depends on $^{226}Ra/^{224}Ra$ content in soil, porosity, moisture content, the prevailing atmospheric conditions, etc. The global average concentration of ^{222}Rn is about 10 Bq/m^3 and 40 Bq/m^3 in outdoor and indoor condition, respectively, while for the ^{220}Rn, it is 10 Bq/m^3 for both indoor and outdoor conditions (UNSCEAR 2000).

A study carried out in India extending up to 2000 household has reported an inhalation dose of 1.2 mSv/y for members of the public (Puranik and Ramchandran 2005). Different types of dwellings made up of different construction materials located in different geological environment were included in the national survey. Integrated passive dosimeters based on LR-115 films were employed for measurements in this survey conducted for a period of 3 years. For inhalation dose assessment, an occupancy factor of 16 hours and 8 hours for indoor and outdoor was considered. About 15% of the total inhalation dose is attributed to thoron and its short-lived daughter products. From the study, it was observed that the average inhalation dose in India was 1.23 mSv/y compared to global average of 1.26 mSv/y. National and international agencies have recommended the use of action levels for protection against indoor ^{222}Rn, typically in the range 200–600 Bq/m^3 (IAEA 1996, ICRP 2007).

Internal Exposure due to Ingestion

Intake of dietary components associated with naturally occurring radionuclides contributes to the internal exposure. The activity concentration of ^{238}U and ^{210}Po in various food matrices and drinking water for India is given in Table 3 as reported in the UNSCEAR (2000) report. Globally, due to consumption of food materials and drinking water, the average ingestion dose to the member of the public was estimated

Table 3 Radioactivity in food and drinking water

Items	U-238	Po-210
Milk products	17	15
Meat products	NA	440
Grain products	7.4–67	15–120
Leafy vegetables	61–72	320
Fruits	0.4–77	16–140
Drinking water	0.09–1.5	NA

to 0.29 mSv/y. Major fraction of the ingestion dose was ascribed to intake of ^{40}K (0.17 mSv/y) followed by 0.12 mSv/y due to ^{238}U and ^{232}Th series radionuclides (UNSCEAR 2008). For Indian sub-continent, the average ingestion dose was 0.32 mSv/y due to consumption of dietary products.

Natural Radioactivity in the Body

The naturally occurring radionuclides enter into the body through the inhalation of air and ingestion of food matrices and water. Radiological characteristics and biokinetic behavior of the radionuclide also play a vital role in its retention in the body. In addition to uranium and thorium series radionuclides, cosmogenic radionuclides like ^{3}H & ^{14}C and single radionuclide like ^{40}K are observed in the human body and contribute to natural radiation exposure.

Relative Exposure in Natural Radiation Environment

The foregoing discussion leads to the inference that the natural ionizing radiation pervades the whole environment. Nature manifests itself in complexities and diversities, and consequently, there exists a wide range of variations in the external and internal exposure. The United Nations Scientific Committee on Effects of Atomic Radiation (UNSCEAR XE "United Nations Scientific Committee on Effects of Atomic Radiation (UNSCEAR)" 2008) carried out comprehensive investigations on natural sources of radiation exposure on a global scale. The radiation dose in natural high background radiation areas (NHBRA) and natural low background radiation areas (LHBRA) along with the global average dose are given in Fig. 1a, b, and c.

NORM Industries

NORM stands for naturally occurring radioactive material and is not under the purview of National Nuclear Regulatory Authority. Anthropogenic activities altered the equilibrium status in the natural resources and redistribute the naturally occurring radionuclides to a level that has potential to give radiation exposure to the

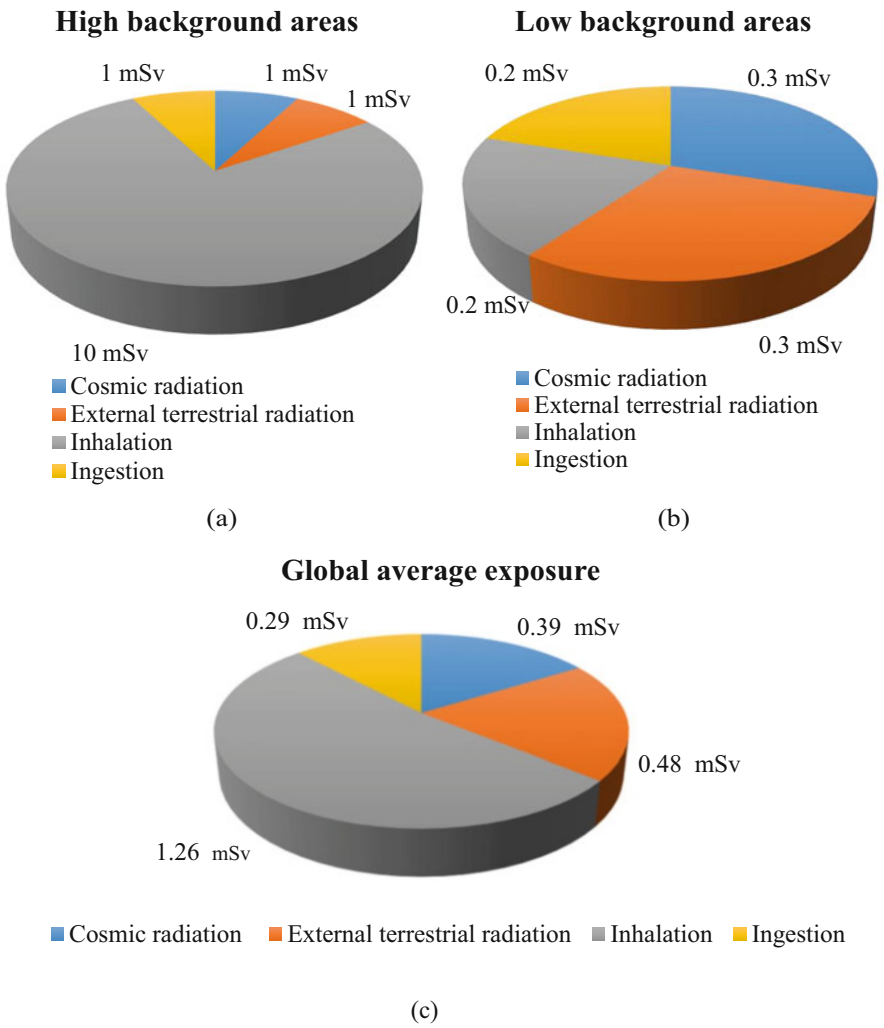

Fig. 1 Global average exposure due to radiation

occupational workers and members of the public which warrants the instruments of regulatory control measures. The alteration in concentration of radionuclides may be ascribed to physical, chemical, or radiological attributes. Radiological hazard caused by NORM depends on the activity concentration and amount of NORM, type of radionuclides, and exposure pathways (ingestion, inhalation).

Mine and mineral processing generated NORM residues due to their association with radioactive materials of natural origin. Huge quantity of NORM residues is generated every year from range of industrial processes, ranging from uranium, thorium, and phosphate mining to the treatment of groundwater (IAEA 2003a).

Copper Mining

Copper mines are known for their association with uranium and its daughter products. Several studies have been carried out on the level of NORM in existing copper mine waste and its impact on various compartments of environment (US EPA 1999).

Phosphate Production

Occurrence of U in phosphate deposits is very common due to their stable complexes and chemical bonding. Elevated levels of uranium in mineral apatite are reported across the regions. Phosphate rocks are subject to physical and chemical processing for manufacturing of phosphoric acids and subsequently phosphate fertilizers for agricultural application. Uranium concentrations in the phosphate rocks vary from 20 to 300 ppm (IAEA 2013a).

Coal Combustion

Most of the coal deposits are associated with uranium and thorium series radionuclides which are comparable with the activity concentration observed in the Earth's crust. Fly ash is the by-product of coal-based thermal power plants which contains the non-volatile elemental fraction and the heavy radionuclides. The average ash content of coal burned is about 10–40%, which means the uranium concentration is also increased by 2–10 times in the residue. Concentrated quantity of NORM in residue is a concern depending on its application in the public domain (IAEA 2018).

Heavy Mineral Sand

Few minerals are naturally resistant to chemical weathering and/or erosion process over the geologic age due to their geochemical properties, hardness characteristics, and specific gravity. Therefore, occurrence and accumulation of these heavy minerals in sedimentary sand deposits are very likely and a common phenomenon. Uranium-rich zircon, thorium-rich monazite, titanium-rich rutile, garnet, ilmenite, etc. are observed more frequently in placer deposits. All of these minerals are associated with naturally occurring radionuclides, i.e., uranium, thorium, and their daughter products (IAEA 2007; IAEA 2011b; IAEA 2012). ^{226}Ra concentration in titanium and zircon ores are reported in the range 0.73–1665 Bq/kg and 3219–48,100 Bq/kg (IAEA 2012; IAEA 2007). These minerals are used for the production of heavy metals and tiles industry.

Current Regulatory Practices

Typical activity concentration of naturally occurring radionuclides and the maximum annual effective dose, as a worst-case scenario, in various NORM industries are collated in Table 4 and Table 5, respectively (IAEA 2006). In addition to this, the annual average effective radiation dose to the public residing around NORM industries is compiled in Table 6 (IAEA 2006). From the tables, it may be inferred that the highest activity concentration in most of materials is in the order of tens or hundreds of Bq/g, but a higher activity concentration (~few thousands of Bq/g) is also measured in few NORM industries. Similar observation can be made for radiation dose received by the occupational workers and members of the public reasoning around the NORM facility. However, exceptions make a strong pitch for a regular assessment and regulatory review of NORM industries. The current national regulatory framework oversees only uranium and thorium mining and production facilities of DAE. Although there are other minerals as stated above that are associated with significant content of radionuclides of natural origin and are used for various industrial purposes, little attention has been paid to radiological safety in many cases. Currently, these industrial activities are not under the purview of radiological regulatory stipulations and warranted the national legislations to bring under the comprehensive umbrella of chemical-industrial-radiological safety. Comprehensive and long-term studies of radiation exposure to occupational workers and members of the public residing around these facilities and radiological impact on the surround environmental are limited or scarce.

Radiological Parameters and Concerns

The awareness of occurrence of radionuclides is barely necessary to adopt an appropriate radiometric technique for their quantification and implementation of appropriate radiological safety to avoid any unplanned radiation exposure to occupational workers and members of the public. Radionuclides of natural origin are classified into "series" and "single" radionuclides. There are four radioactive series having parent radionuclide of ^{238}U, ^{235}U, ^{232}Th, and ^{239}Pu; the first three are of natural origin, while the last one is manmade or synthetic. Due to very low mass abundance (0.72%) of ^{235}U and nonexistence of ^{239}Pu before the twentieth century, these radioactive series are of limited interest with respect to radiological protection in NORM industries and management of their residues/by-products, therefore not discussed further in the paper. Half-lives of ^{238}U is 4.5 billion years and that of ^{232}Th is 14 billion years and associated with 14 and 10 progenies, respectively. The radionuclides of radiological concerns in both the series are due to their relatively longer half-lives, higher specific activities, and greater potential radiotoxicity, namely, ^{238}U, ^{234}Th,^{230}Th, ^{226}Ra, ^{222}Rn, ^{210}Pb, and ^{210}Po in ^{238}U series and ^{232}Th, ^{228}Ra, and ^{220}Rn, in ^{232}Th series. In addition to series radionuclides, there are many single terrestrial and cosmogonic radionuclides, namely, ^{40}K, ^{87}Rb, ^{138}La, ^{147}Sm, ^{176}Lu, ^{14}C, ^{10}Be, ^{22}Na, ^{36}Cl, ^{39}Ar, and ^{81}Kr; however, the significance of

Table 4 Activity concentration in NORM industries requiring regulatory control. (IAEA Safety Series No. 49, 2006)

Category	Material/operation	Radionuclide(s) with highest activity concentration	Typical activity concentration (Bq/g)
Feedstocks	Monazite sand	^{232}Th series	40–600
	Metals ores (Nb/Ta, Cu, Au)	^{238}U and ^{232}Th series	Up to 10
	Zircon sand	^{238}U series	2–4
	Phosphate rock	^{238}U series	0.03–3
	TiO_2 feedstocks	^{232}Th	0.001–2
	Bauxite	^{232}Th series	0.035–1.4
Bulk residues	Red mud (alumina production)	^{238}U, ^{232}Th	0.1–3
	Phosphogypsum (H_2SO_4 process)	^{226}Ra	0.015–3
Slags	Niobium extraction	^{232}Th	20–120
	Tin smelting	^{232}Th	0.07–15
	Copper smelting	^{226}Ra	0.4–2
	Thermal phosphorus production	^{238}U	0.3–2
Scales, sludges, and sediments	Scale (oil and gas production)	^{226}Ra	0.1–15,000
	Scale (phosphoric acid production)	^{226}Ra	0.003–4000
	Residue (rare earth extraction)	^{228}Ra	20–3000
	Scale (TiO_2 pigment production)	^{228}Ra, ^{226}Ra	<1–1600
	Scale (rare earth extraction)	^{228}Ra, ^{226}Ra	1000
	Sludge (oil and gas production)	^{226}Ra	0.05–800
	Residue (niobium extraction)	^{228}Ra	200–500
	Scale (coal mines with Ra rich inflow water)	^{226}Ra, ^{228}Ra	Up to 200
	Scale (iron smelting)	^{210}Pb, ^{210}Po	Up to 200
	Scale (coal combustion)	^{210}Pb	> 100
	Sludge (iron smelting)	^{210}Pb	12–100
	Residue (TiO_2 pigment production)	^{232}Th, ^{228}Ra	<1–20
	Sludge (water treatment)	^{226}Ra	0.1–14
Precipitator dust	Thermal phosphorus production	^{210}Pb	1000
	Fused zirconia production	^{210}Po	600
	Niobium extraction	^{210}Pb, ^{210}Po	100–500

(continued)

Table 4 (continued)

Category	Material/operation	Radionuclide(s) with highest activity concentration	Typical activity concentration (Bq/g)
	Metal smelting	^{210}Pb, ^{210}Po	Up to 200
	Thorium compounds	^{232}Th	Up to 2000
	Thorium concentrate	^{232}Th	Up to 800
	Pyrochlore concentrate (niobium extraction)	^{232}Th	80
	Cerium concentrate (glass manufacture)	^{232}Th	10
	Fused zirconia	^{238}U	2–8
Products	Gas mantles	^{232}Th	500–1000
	Thoriated glass	^{232}Th	200–1000
	Thorium containing optical polishing powders	^{232}Th	150

	Zirconium containing refractories	^{238}U	1–4
	Phosphate fertilizers	^{238}U	0.4–2
	Technical grade phosphoric acid	^{238}U	0.14–2
	Phosphogypsum plasterboard (building material)	^{226}Ra	0.004–0.7

Table reproduced from IAEA Safety Series No. 49 (2006) due to limited Indian data available on all the matrices mentioned in the table.

these radionuclides is least with respect to radiation exposure point of view except ^{40}K (UNSCEAR 2000). Lower abundance in natural environment and lesser activity concentration in different compartment of the ecosystem of these single are ascribed to their non-relevance; however, study of these radionuclides aids to unravel many environmental processes. Either series or single radionuclides emit mainly alpha, beta particle and gamma radiation during their decay process which requires identification and quantification mainly using radiometric techniques. The presence of these radionuclides of natural origin makes a case for a comprehensive study to avoid radiation exposure to all the stakeholders.

Measurement Techniques

Naturally occurring radionuclides emit alpha, beta particles and gamma radiation that could not be identified by our five senses or by other traditional means and

Table 5 Annual effective radiation dose to occupational workers in various NORM. Industries (IAEA Safety Series No. 49, 2006)

Sl. No.	Industries	Maximum annual effective dose (mSv)

require specialized instrumentation for their measurement. This section illustrates the brief overview of the radiometric techniques in general practice which is based on the characteristics of radiation and their radiological properties. The methods discussed below may have few deviations for any particular radionuclide and matrix of analysis. Radiometric techniques generally adopted in most of the radioanalytical laboratories across the globe for water and soil/sediment matrices along with the required sample size, typical activity concentration range, and the observed detection limits are enumerated in Tables 7 and 8, respectively.

Table 6 Annual average effective radiation dose to members of the public residing around NORM industries (IAEA Safety Series No. 49, 2006)

NORM industries	Annual effective dose (mSv)
Mining of rare earth ore	0.044
Beneficiation of rare earth ore	0.043
Use of slag from rare earths and steel production in house bricks	~ 0.2
Mining of ore other than uranium ore	<1
Oil and gas production	< 1
Elemental phosphorous production	< 0.04

Gamma Spectrometry

Gamma spectrometry is a radiometric technique which is a non-destructive and direct analysis of samples for identification and quantification of naturally occurring

radioisotopes (^{238}U, ^{232}Th, ^{226}Ra, ^{210}Pb, ^{40}K) emitting gamma energy in the range of 10 keV to 3 MeV (generally, may be used for higher energy range) in various geological, environmental, and biological matrices. The principle of gamma spectrometry is based on the probability of interaction of gamma radiation with the detector-sensitive solid volume, and the signal (either scintillation or electric current) is proportional to the activity concentration. Mainly, NaI(Tl) detector and HPGe detectors are in practice in radiological laboratories for measurement of naturally occurring radionuclides. Selection of a suitable detector is a function efficiency, resolution, sensitivity, detection level, no. of radionuclides to be measured, sample volume, sample geometry, accuracy, precision, availability of liquid nitrogen, and objective. In case of single or selected gamma radiation energies, less expensive NaI (Tl)-based scintillation detector could be preferred, while for matrices laced with multiple gamma emitting radionuclides/complex spectra, liquid nitrogen-cooled HPGe detector is chosen. The typical resolutions of NaI(Tl) and HPGe detector are 6–7% at 662 keV and 0.05–0.2% at 1332 keV, respectively. Representative samples should be collected and processed as per the standard protocols (IAEA 1989). A representative sample is counted in an optimized geometry and for a standardized counting time to achieve the required uncertainty (1–2% counting uncertainty for environmental samples). The detectors are provided with lead shields of thickness about 7.5–15 cm to reduce the background noise. Typical counting time for samples from NORM industries varies from 60,000 sec to 200,000 sec which depends on the anticipated activity concentration, sample geometry, objective of data quality, and acceptable uncertainty. Energy and efficiency calibration of the spectrometer is carried out using a suitable standard, preferably matrix-matching one if available. ^{238}U is associated with a weak gamma energy of very low gamma emission probabilities; therefore, measurement of ^{238}U is carried out from its decay products either assuming or ensuring the radioactive equilibrium between the parent-daughter duo. In general, the gamma energy (62 keV/92.5 keV) of ^{234}Th is used for quantification of the parent radionuclides. For sediment and biological samples, the representative sample is kept in sealed condition for 6 months to ensure the radioactive equilibrium. Equilibrium time of 1 month is adequate for measurement of ^{238}U in soil and other geological samples where the radioactive equilibrium between ^{238}U and ^{226}Ra could be assumed reasonably. The activity concentration of ^{232}Th can be estimated using multiple gamma energies assuming radioactive equilibrium among the series radionuclides in sealed condition for a period of 1 month. The gamma energies employed for quantification of ^{232}Th in geological and environmental matrices are 238 keV, 911 keV, and 2614 keV. Similarly, ^{226}Ra can be identified and quantified using the several gamma energies like 186 keV, 295 keV, 352 keV, 609 keV, and 1764 keV, while 46 keV is used to trace the activity concentration of ^{210}Pb in samples. The prominent single energy of 1460.8 keV is employed for determination of ^{40}K in biological, environmental, and geological matrices. The statistically comparable activity concentration of the radionuclide is expected when it is quantified using multiple gamma energies, but the uncertainty associated with the particular gamma energy will be different due to probability of interaction of that gamma photon in detector and other inherent factors. Therefore,

weighted mean and error propagation techniques are applied to calculate the central value and its dispersion. The details of these techniques may be found in Knoll 2010.

The typical background of the HPGe detector is observed in the range of 0.2–0.6 counts per sec for the photo peaks in the energy band of 46 keV to 2614.53 keV. The minimum detection level of these radionuclides is observed to be few Becquerel which is a function of background of the detector, counting time, and efficiency of the detector. Appropriate correction was made for contribution from higher energies to lower ones (IAEA, 2010).

The following equation is applied to quantify the activity concentration of a radionuclide measured in gamma spectrometer

$$\mathrm{A\ (Bq/kg)} = (\mathrm{C} - \mathrm{B})/(\mathrm{T}^{*}\ \mathrm{E}^{*}\ \gamma^{*}\ \mathrm{W}\ ) \tag{2}$$

where C is the gross counts of corresponding photopeak of the sample, B is the background of the photopeak under consideration, T is the counting time of the sample, E is the absolute efficiency of the detector for a specific geometry and gamma ray energy, γ is the absolute gamma line emission probability of gamma energy of interest, and W is the weight of the sample in kg. The details of the gamma spectrometry technique may be found in various ISO/IAEA reports (ISO 2019; ISO 2021; IAEA 2003a, b, c).

Alpha Spectrometry

Alpha spectrometry works on the principle of interaction of characteristic alpha particles on planar silicon detectors in vacuum. Vacuum is maintained continuously during counting to ensure a sharp peak with high resolution. However, a long tailing is observed on the lower energy end due to imperfect vacuum and loss of energy in the path. The technique is recommended for measurement of alpha emitting radionuclides such as U and Th isotopes, ^{226}Ra, and ^{210}Po. Since heavy and energetic alpha particle has very low range in air and other matrices, its separation is prerequisite from the bulk material for quantitative estimation. Separation of the radionuclide of interest (U, or Th) is achieved either through solvent extraction or ion exchange process. Due to selective spontaneous deposition of Po onto silver planchettes in dilute hydrochloride medium, no tedious separation process is adopted. The optimized radioanalytical process for determination of uranium isotopes and ^{210}Po is given elsewhere (Tripathi et al. 2013; Sharma et al. 2022).

In case of uranium isotope analysis, as a first step it is necessary to separate out uranium from bulk of the matrix for alpha spectrometric analysis. After complete digestion of environmental/biological/geological samples with the aid of a mixture of mineral acids, the sample residue is subject to concentrated HCl to covert the analyte and other metals to chloride form. Then, the sample is subjected to ion exchange/solvent extraction procure for separation of uranium from the bulk material. In case of ion exchange, anion exchange resin (chloride form, 1×8 polymerization, 100–200 mesh size) is taken for isolation of element of interest from other ions. Diluted nitric acid solutions are used to strip the U from the resin which is subjected to electroplating. Electrodeposition is carried out using sulfuric

acid–ammonium hydroxide solution adjusted to a pH – 2.2 for U and other actinides (Tripathi et al. 2013). The surface cleaned buffed stainless-steel disc is used as cathode, while platinum rod is used as anode. A constant voltage of 6 V and 0.3 ampere current are applied during electrodeposition with a distance of 2 cm between the cathode surface and anode for 2–3 h. Before switching off the voltage, few ml of concentrated ammonia is added to the electrodeposition cell to avoid the uranium from going back to the electroplating solution which is acidic in nature. Similarly, ^{210}Po was spontaneously deposited onto silver planchet in dilute hydrochloric acid medium at 80–90 °C with constant stirring condition (Sharma et al. 2022). Then, the electroplated or spontaneously plated samples are counted for alpha activity using passivated implanted planar silicon detector in an eight-chamber alpha spectrometer. The active surface area of the PIPS detector is about 450 mm^2 and depletion thickness of 100 μm. The estimated efficiency of the PIPS detector is 15.2% at 8 mm source (planchette) to detector distance. An integrated 4 K MCA is connected to the alpha detector for recording and analysis of spectrum. The source and sample deposition diameter is around 19 mm on a 25 mm stainless steel planchette. A high efficient vacuum pump was used to maintain the vacuum of the detector chamber around 75 mTorr throughout the counting process. Blank, spiked samples, and electroplated samples are counted for 24 hours to achieve the counting uncertainty less than 5% at the levels observed in environmental samples. Uranium standard solutions are processed similarly along with each batch to estimate the loss. In addition to this, ^{232}U and ^{209}Po tracers are added in the samples before commencement of radiochemical separation/processing of the samples to assess the chemical recovery of the method adopted so that an appropriate recovery factor could be applied to correct the activity concentration in the matrix.

Liquid Scintillation Analyzer

Though liquid scintillation analyzer (LSA) has been in practice for measurement of tritium and ^{14}C, of late it is applied to measure various naturally occurring radionuclides emitting alpha and beta particles (gross alpha, gross beta, ^{228}Ra, ^{210}Pb). The basic principle of the technique is absorption of alpha or beta energy by the liquid scintillator which is detected by photomultiplier tube. The pulse light is proportional to energy that is employed for discrimination of radioactive particles. Gross α and gross β levels of potable water are used as screening parameters before analysis of specific radionuclide. This method is one that the ISO and EU recommended for radiological screening of drinking waters as associated with least matrix interferences and self-absorption. In addition to this, ^{228}Ra and ^{210}Pb are measured using LSA. The details of optimized method at Health Physics Division, BARC, are given further.

Measurement of individual radionuclides is taken up after conforming the levels of gross alpha and gross beta levels in drinking water (WHO 2017). Gross α and gross β activities are estimated using alpha and beta counting systems, after radiochemical processing of samples which depends on total dissolved solid (TDS) content of the samples. Self-attenuation is the major concern in case of gross alpha but lesser significance in gross beta estimation. Conventional gross α and gross β

measurement techniques are associated with high degree of uncertainty and influenced by matrix characteristics. To nullify these difficulties, a method is standardized for quick scanning of gross α and gross β levels simultaneously with adequate sensitivity and minimum sample preparation with widely varying physicochemical properties (TDS, salinity, and pH). A triple to double coincidence ratio (TDCR)-based alpha/beta discriminating liquid scintillation analyzer (HIDEX 300LS) was used to standardize the method. The system uses three PMTs and a coincidence circuit to discriminate noise from true signal and a dual MCA technology to measure both pulse amplitude and duration, which is the basis for α and β separation as α pulses are of longer duration than β pulses. The discrimination was done by a 2D graph where x-axis represents the pulse amplitude and y-axis its length (Fig. 2). Due to long pulses, alphas have greater y-coordinate than beta pulses of the same X-coordinate. Subtracting the blank and using the TDCR value, the gross α and gross β levels were estimated and compared with guideline/limit values. Details of the methodology are available elsewhere (ISO 2017a, 2018; Gupta et al. 2018).

Radon, Thoron, and Their Progeny Monitoring Methods

^{222}Rn and ^{220}Rn are the isotopes of noble and inert gas radon and named differently, based on its origin. The former one is the one of series radionuclides of ^{238}U, while the latter is a daughter product of ^{232}Th series. Natural occurrence of both ^{238}U and ^{232}Th in every compartment of the ecosystem makes a case of ubiquitous presence of ^{222}Rn and ^{220}Rn due to spontaneous radiation decay and inert gaseous nature. Greater relevance of these radioactive gases in NORM industries is due to their higher activity concentration in workplaces, particularly confined spaces without adequate ventilation/underground mines and that have potential to deliver a radiation

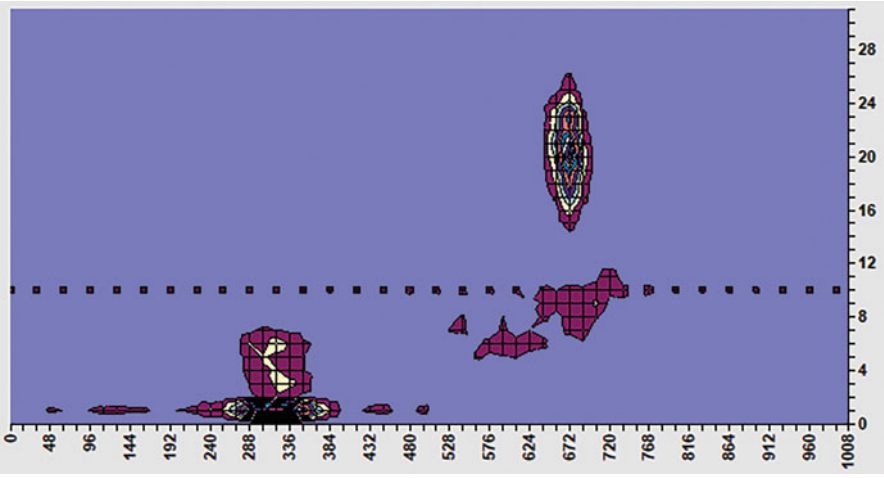

Fig. 2 2D spectrum of spiked water samples with pulse length index (PLI) denoted by the dotted line. Alpha (above PLI) and beta (below PLI) are separated by means of their pulse length

dose to occupational workers and pose an associated significant radiation risk (ICRP 1993). Though engineering control measures are implemented in uranium/thorium handling facilities, observations of higher activity concentration and radiation dose to workers are not uncommon. Also, similar observations were reported in literature for caves and confined workplaces. The immediate and short-lived daughter products of ^{222}Rn and ^{220}Rn are of more concern due to their particle nature that their inert parent radionuclides deliver more radiation dose to lung tissue/other tissue than their parents (IAEA 2003b). However, direct measurement of the short-lived daughter products is practically difficult. Therefore, in general practice, the parent ^{222}Rn and ^{220}Rn gases are measured in workplaces and transformed to progeny activity using site-specific equilibrium factor. There are many active/passive and spot/integrated analytical techniques for measurement of ^{222}Rn and ^{220}Rn in environment and various matrices. Few selected measurement techniques, in practice in India, are illustrated briefly in the follow-up section for measurements of radon, thoron, and their progenies.

Scintillation Cell Technique

Scintillation counting in the gaseous phase has been extensively used for the measurement of the radon concentration. It is one of the oldest and the most reliable techniques. Existing setup of scintillation/Lucas cell counting system has been adopted with development of protocols of sampling procedure, measurement technique, and calculation to assess the radon concentration in mine/workplaces. These radon (^{222}Rn) concentrations are used as an input parameter for occupational dosimetry program.

Scintillation (Lucas) cell, photomultiplier tube (PMT), and alpha counting system are the components of this measurement technique. The cell is used for collection of air samples from the desired location which is a cylindrical metallic chamber (preferably aluminum) coated with ZnS(Ag) sheet from all sides except the glass window for optical coupling with the PMT. In the opposite end of the glass window, the Lucas cell is provided with a Swagelok for evacuation and sample collection. Background counted pre-evacuated Lucas cells are employed for collection of air sample from the desired location through glass fiber filter paper. Application of filter paper ensures cutoff of particulate radon daughters and ingress of gaseous radon into the chamber. After collection of filtered air sample at the desired location, the Lucas cell is kept in dark condition for 180 mins to achieve radioactive equilibrium among radon and its decay products so that a statistically significant count could be registered.

Finally, radon activity concentration is estimated using the following equation:

$$\mathrm{Rn}\left(\mathrm{Bqm}^{-3}\right) = \frac{6.967 \times 10^{-3} \times \mathrm{C}}{\mathrm{E} \times \mathrm{V} \times \mathrm{e}^{-\lambda t}\left(1 - \mathrm{e}^{-\lambda \mathrm{T}}\right)} \tag{1}$$

where "Rn" is ^{222}Rn concentration in Bq.m^{-3}, "C" is background subtracted counts during the counting duration "T," "E" is efficiency of the Lucas cell (%), "V" is volume of the Lucas cell in liter, "t" is elapsed time after collection of sample in

minute, "T" is the counting time in minute, "λ" is decay constant of ^{222}Rn in minute, and 6.967 x 10^{-2} is the proportionality constant.

Two Filter Method

In this method, air is drawn through a metal tube, measuring about 50 millimeter in dia. and a length of 300 to 500 mm, equipped with a high efficiency filter at each end. The first filter removes all the radon decay products performed in the air. During transit of air through the tube, radon decays to Po-218. Some of the Po-218 atom plate out on the walls and the remaining deposit on the second filter. The second filter is quickly recovered and subjected to alpha counting for a suitable time immediately after the sampling. Typically, the counting interval is from 1 min. Post sampling to any suitable time (up to 75 min.) depending on the activity expected. Radon concentration (Bq/m3) is calculated using the formula

$$\mathrm{Rn} = 0.0167 * \mathrm{C}/\mathrm{E.Z.V.F} \tag{2}$$

where "C" is the background subtracted alpha counts, "E" is the counting efficiency (fraction), "Z" is the correction factor being a function of sampling and counting times (alpha emission factor), "V" is the volume of the tube (m3), and "F" is the fraction of Po-218 atoms formed in the tube which is deposited on the exit filter.

Thoron and Its Progeny Monitoring Method

Thoron (^{220}Rn) is a radioactive inert gas having a half-life of 56 sec. Thoron gas comes under the radioactive decay chain of ^{232}Th (4n) series. In general, indoor thoron and its progeny concentration are greater than that observed in outdoor. Out of all thoron daughter products, ^{212}Pb and ^{212}Bi are having significant radiological impact (Table 9). Due to the omnipresent nature of thoron and for the radiation protection, various methods are used internationally for the measurement of ^{220}Rn and its progeny. Working level (WL) is the historical unit used for the measurement of thoron progenies. One working level thoron represents the total potential alpha energy of 1.3 x 10^5 MeV from all the possible combinations of thoron daughters in one liter of dry air (Ramachandran 2010).

Table 9 Contribution of thoron progenies in 1 WL thoron environment

Thoron daughters	WL	No of atoms (N)	Alpha energy Mev (E)	NE (x 10^5 MeV)
^{216}Po	Scenario under 1 thoron WL or 275 mBq/l thoron is in equilibrium with its progenies	0.0595	15.55	0.001
^{212}Pb		15,200	7.79	1.18
^{212}Bi		1442.9	7.789	0.11
^{212}Po		1.2×10^{-7}	8.789	0.001
Total potential alpha energy (PAEC)				1.3

Thoron gas measurement can be done either by grab sampling or continuous sampling method. The different principles used for the measurement of thoron gas are as follows:

(i) Scintillation cell (Lucas cell).
(ii) Charcoal absorber followed by gamma spectroscopy.
(iii) Pulsed ionization chamber.
(iv) Two filter method.
(v) Scintillation detectors with ZnS (Ag).
(vi) Alpha particle spectrometer using silicon diodes.

Portable monitors are widely employed for the in situ determination of both radon and thoron and their progenies. Electronic radon detector (Make/Model: Durridge make RAD7) works use a solid-state alpha detector. A solid-state detector is a semiconductor material usually silicon that converts alpha radiation directly into electrical signal. The main advantages of the instrument are the ability to electronically determine the energy of each alpha particle which makes proper segregation of radon and thoron. Professional radon monitor (make/Model "Bertin make Alpha Guard) is an ionization chamber, and the alpha spectroscopy is the basic principle for the determination of radon and thoron simultaneously. These instruments also measure the relative humidity, temperature, and pressure.

Thoron daughters (^{212}Pb and ^{212}Bi) in air can also be measured by grab aerosol sampling followed by absolute alpha and beta counting. The delay time in counting plays important role for the calculation of thoron daughter concentration. The measurement process has a maximum error of 10% due to different equilibrium conditions.

Similar to the measurement of radon daughter concentration, a simple methodology has been used in thorium mining industries for evaluation of thoron daughter working level. Air sample is collected by passing air through a high efficiency filter paper for an appropriate time period. The alpha activity on the filter is measured for certain time period in between 180 minutes to 600 minutes post sampling. The thoron working level concentration is obtained using the relation

$$Thoron\ WL = \frac{C}{E * V * T * Z} \tag{3}$$

where
C – α count rate (cpm) on the filter paper at 300 min.
E – efficiency of counting.
V – sampling flow rate (lpm).
T – duration of sampling (min).
Z – Theoretical correction factor for thoron daughter at the counting instant (equivalent of Kusnetz's factor for thoron daughters).

The activity decay curve beyond 180 min may be approximately given by the relation

$$Z = 246 \times e^{-\lambda t} \tag{4}$$

where λ is the decay constant of ^{212}Pb (Th-B) and t is the counting time, for instant beyond 180 min.

In the past studies, the thoron is underestimated as compared to radon due to the difficulties in calibration and measurement technique, and there is no such epidemiological data regarding thoron exposure. Also, the "interference" is still a prime factor while measuring the radon and thoron in a mix environment. The importance of thoron and its progenies is high in the thorium mining industries. There is a huge gap area in the thorium mining industries for the thoron studies.

International Approach for Quality of Radioanalytical Laboratories

Demonstration of competence and traceability of the analytical results are very much essential of testing laboratories. It is very important for compliance of legislative limits, radioactivity certification of minerals, food materials for international trade, and environmental impact assessment studies. Quality data are prerequisite for policy decisions, mitigation strategies, and environmental protection. This also supports decisions on the establishment of action plans, programs, and measures to control contaminants. Accreditation and certification of radiometric measurement laboratories are essential to demonstrate their competence, technical capabilities, traceability, acceptability, and quality management system in place (ISO 2017b). Compliance of the standard ensures the technical competence and technical validity of the data. The choice of methodology for quality assurance in a radioanalytical laboratory is based on the laboratory competence for testing and calibration.

Quality Assurance

Quality assurance is a well-designed standard operating procedure based on scientific observations and experimental inferences undertaken by radioanalytical laboratories which is necessary to provide adequate confidence in the generated test results. In other words, quality assurance is a laid down procedure aligning with prevailing national/international standards that depicts overall measures undertaken in a laboratory to make sure the data quality. It is an integral part of laboratory analysis process to accomplish the reliability, repeatability, reproducibility, and accuracy of the data generated. This is required for understanding and evaluating the trends and impact of NORM on the surrounding ecosystem. The components of quality assurance are highlighted in Table 10.

Table 10 Technical components of quality assurance activities

Technical components	Practice
Suitable laboratory environment	Isolation from unwanted or spurious radiation source, electric and magnetic field, mechanical vibration, adequate ventilation, suitable equipment, etc. The radioactivity counting room should be isolated from sample preparation and separation laboratory
Educated, trained, and skilled staff	Training on analytical techniques before induction in the laboratories, regular participation in refresher capsule courses, and upgradation of latest trends in the domain
Requirements for calibrates and measurement standard	Availability of certified reference materials/Bharatiya Nirdeshak Drabya (BND) which are used for calibrating and generating the parameters required for evaluation
Requirements for reagents	Analytical grade reagents used for analytical procedures
Suitable equipment, maintained and calibrated	HPGe and NaI(Tl) gamma spectrometry system, alpha spectrometry system, liquid scintillation analyzer – monitor spectrum drift, background fluctuation, and stability in efficiency. Zn(S)-based gross alpha counter – check background and efficiency Radon monitors – check background and performance over time
Traceability, procedural lapses, and reporting results	Method validation using certified reference materials. Suitable tracers and carriers for method recovery in radiochemical analysis. Alternate technique for comparison, analysis of blind, analysis of spiked samples

Quality Control

Quality control is the final step of analysis process that certifies the results as per the national and international standards. (ISO 1994). Though the relevance of quality assurance is high to ensure the accuracy, precision, repeatability, traceability, and technical reliability of the data, quality control plays a pivotal role to demonstrate the competence and consistency of the data quality. It comprises of a set of technical operations and activities to verify each and every relevant statistical parameter (accuracy, bias, precision, reproductivity, repeatability, reliability, detection limit) to establish the data quality. It is an internal and integrated part of analysis and reporting process of testing and calibration laboratories. It is essential that the radioanalytical laboratory should develop and document standard procedures and implement on appropriate quality control program. The quality control program should comprise of steps such as analysis of CRMs/BNDs, regular participation in intercomparison exercises, cross-method checking, replicate analysis, record of blank/background regularly, and calibration of the equipment before commencement of measurement (Table 11). The documented procedure should be monitored at every step to get an indication of possible error.

Intercomparison exercises put an impetus to improve laboratory facilities and analytical techniques for measurements of radioactivity in food and other

Table 11 Common quality control activities in radiometric laboratories

	Technical components	Implementation in HPD
1.	Background determination	Determination of instrument background contributed in the region of interest. Analysis of blanks and background levels of analyte in samples as well as reagents
2.	Appropriateness of procedure validated with BND/CRM	Simultaneous radiochemical analysis and measurement of reference standards of similar matrix
3.	Analytical efficiency/ performance in each sample	Incorporation of carrier/tracer recovery factors in all radiochemical procedures
4.	Precision check	Analysis of the unknown sample at least in duplicates
5.	Calibration of counting equipment	Simultaneous calibration of counting equipment with certified reference materials
6.	Performance of counting systems	Comparison of background and calibration factors with quality control charts available and regularly updated

environmental materials. These exercises are useful to evaluate the precision of analytical methods and performance of the analytical laboratories. It is also a very powerful tool for maintaining and improving the laboratory quality and competence for measurement.

Both internal and external quality control steps are adopted to achieve the desired degree of uncertainty and to meet the objective of the analysis. Intra-laboratory intercomparison, cross-method verification, spike recovery, replicate analysis, etc. are the few activities taken up regularly to control the data quality. Moreover, successful participation in proficiency tests organized by national/international metrological institutes and intercomparison exercise confirm the laboratory competence to meet its objectives.

Quality assured data is needed to support decision-making process for preparation of action plans and remedial programs, assess the effectiveness of the control measures taken, and evaluate impact on the ecosystem. The basic purpose of intercomparison exercises is to check the reliability of the analytical method and biasness of the analytical technique. The implementation of the lessons learnt and recommendations help in the improvement of the performance and quality of data.

National Perspective and Policy

Diverse range of activities and practices, comprising of mining and ore processing, production coal, gasoline, phosphate fertilizer, thermal power plants, production and use of metals (such as uranium, thorium, niobium, zirconium), and water treatment, among others generates NORM and NORM residues (IAEA 2011a, b). Operation of NORM industries is associated with multiple hazards and, therefore, subjected to several regulatory agencies for safety compliances and conforms to the regulatory stipulations. Out of multiple hazards, radiological one may not be the dominant one but cannot be overlooked due to its associated potential adverse impacts (IAEA

2013b). However, the radiological aspects in NORM industries need to be characterized comprehensively and managed in a reasonable scientific way. Considering the long-term consequences on the ecosystem and socioeconomic attributes, a tailored approach may be devised and adopted for management of NORM residues. It is the high time to develop national policies and regulations of NORM consistency with international guidelines but without compromising the national interests and socioeconomic factors of a developing country (IAEA 2015). Moreover, a closer working relationship with NORM industries is needed to convince the radiological aspects and aid in adopting the regulatory stipulations on a logical and pragmatic manner in a cost-effective way (IAEA, 2016). The approach should encompass all the influencing parameters and attributes which is also eco-friendly, acceptable by all the stakeholders, and cost-effective. Efforts may be made to reduce, recycle, and reuse under the purview of circular economy through innovative technology for efficient use of limited natural resources (ICRP 2019). As mentioned, geological features of such rocks and minerals and the related radioactivity profile vary to a great extent. Such radioactive materials can be a potential source of the public exposure residing around such sites. The radioactivity concentration of NORM in environmental components like groundwater, surface water, and soil is mostly derived as a result of the related geological and physic-chemical weathering processes of host rocks/wastes, etc. (Sahoo et al. 2020). The activity concentration of U and Th and its daughters and their ratios could be used as environmental tracers for various governing processes and can be corroborated to their contents in substratum (base materials/soil) and water resources. Therefore, a national policy framework could be devised for site−/facility-specific NORM industry to reduce and nullify potential exposure of occupational workers, the public, and contamination of the surrounding environment.

Conclusion

NORM Industries need to bring under the regulatory purview and subject to control measures, if required after assessment. It is the high time to evolve an overarching national assessment policy framework and regulatory instruments to avoid any potential impact to occupational workers and members of the public. In addition to this, the policy shall ensure that contamination due to radionuclides of natural origin is well within the stipulated limits in accordance with the basic principles of radiation protection. An integrated graded approach of radiological protection can be adopted in NORM industries with striking balance between the different hazards/risks, adopting a reasonable and prudent attitude, and taking economic and societal factors into account. Engagement of all stakeholders, i.e., policy makers, scientific community, and facility operators, is crucial to adopt and implement the national policies for present and future generations.

Acknowledgments Thanks are due to all the colleagues of Radiation Protection Section (Nuclear Fuels), Health Physics Division, and BARC for their support and help during preparation of the manuscript.

Abstract

Currently, radiation metrology is all the standard measurement techniques for accurately detecting and quantifying the intensity and characteristics of ionizing radiation. It is also one of the most important tools for studying the processes of radiation effects on living beings and developing all measures and strategies aimed at protecting humans and the environment. Medical uses of ionizing radiation are among the longest established applications of ionizing radiation. It is utilized in a variety of diagnostic and therapeutic clinical procedures, ranging from simple chest X-rays to complicated brain tumor treatment regimens.

Ionizing radiation, on the other hand, has the potential to be harmful, so a methodical approach should be utilized to balance the risks of radiation exposure to patients, staff, and the general public with the benefits of medical ionizing radiation. The scale of radiation danger is dose-related, with larger doses of radiation resulting in higher risks. Absorbed dose is a dose quantity which is the measure of the mean energy deposited in matter by ionizing radiation per unit mass. It is a fundamental physical quantity which can be used in the different fields where ionizing radiation is used. The absorbed dose concept has a wide range of applications, and it is widely accepted as a fundamental quantity in radiobiology, radiotherapy, and radiation protection. Technological innovation has resulted in state-of-the-art instrumentation that allows for precise radio diagnosis and administration of radiation to tumor lesions with little collateral damage to healthy tissues without compromising or limiting the obvious benefits in the prevention, diagnosis, and also in effective cure of diseases. Protection in medical exposures utilizing technological innovation does not necessarily mean the reduction of doses to the patient; it is best described as the management of the radiation dose to the patient to achieve the medical purpose. The dose is then a very critical and sensitive quantity.

Introduction

Ionizing radiation is electromagnetic or particle radiation released by radioactive atoms and some technologies that can cause the ionization of other atoms directly or indirectly (Gottfried and Penn 1996). Ionizing radiations are known to be charged particles (heavy ions, alpha particles, protons, positrons, and electrons) with enough energy to ionize or excite atoms or molecules. Uncharged particles (photons, neutrons) that set-in motion directly ionizing radiation (charged particles) or can initiate nuclear transformations are known as indirectly ionizing radiations. X-rays, gamma rays, and electrons are the most frequent ionizing radiations employed in medicine.

Ionizing radiation is clearly recognized as a crucial tool for medical diagnosis and treatment, despite the fact that usage trends vary greatly across the globe. It is utilized in a variety of diagnostic and therapeutic clinical procedures, ranging from simple chest X-rays to complicated brain tumor treatment regimens. Each of these applications has a positive impact on patients. Radiology and nuclear medicine are the two main subcategories of ionizing radiation's diagnostic uses. In nuclear medicine, the radiation administered to the patient is internal as opposed to external in radiology (Gottfried and Penn 1996).

Modern diagnostic radiology permits the monitoring of a broad number of disorders and ensures faster, more precise diagnosis. Radiological procedures (simple film radiography, fluoroscopy, computed tomography) are predicted to have a significant impact on the speed of diagnosis in roughly half of instances, and they are of decisive importance in a large fraction of cases.

While some patients get direct applications of sealed radionuclide sources (brachytherapy) or therapeutic doses of radiopharmaceuticals, radiotherapy is typically administered through external radiation beams (teletherapy) (IAEA 2001).

Cancer is widely believed to be the leading cause of death and is seen as a major obstacle to raising life expectancy in practically every nation in the world. Radiotherapy is currently used in around half of all newly diagnosed cancer cases. Therapeutic procedures can be extremely complicated, putting a high premium on irradiation precision. They must be approached in an interdisciplinary manner to be effective, which necessitates effective and harmonious collaboration among radiation oncologists, medical physicists, and highly experienced technicians. However, it is important to know that radiotherapy of cancer is frequently accompanied by negative side effects. Some side effects are unavoidable, and they usually go away on their own or with therapy. Serious side effects can arise as a result of the close proximity of sensitive normal tissues to the treatment field or, in rare cases, individual radiation sensitivity. They don't compromise the purpose of radiotherapy. Every year, the proper application of radiation saves millions of lives. Even if only palliative treatment is available, the therapy reduces discomfort significantly (APLMF 2014). Figure 1 shows the application of ionizing radiation in medical science.

Regulations for the use of ionizing radiation in medicine are developed within the governmental, legal, and regulatory framework for safety. By avoiding harmful equipment usage behaviors, the intention is to safeguard the public's health and safety (Rosenblatt and Zubizarreta 2017). Radiation should only be used if it can diagnose or treat the patient and is both efficient and potentially advantageous.

In this chapter, some metrological concepts linked to clinical uses of ionizing radiation in diagnostic radiology, external radiotherapy, and radiation protection principles in medical disciplines will be concisely addressed.

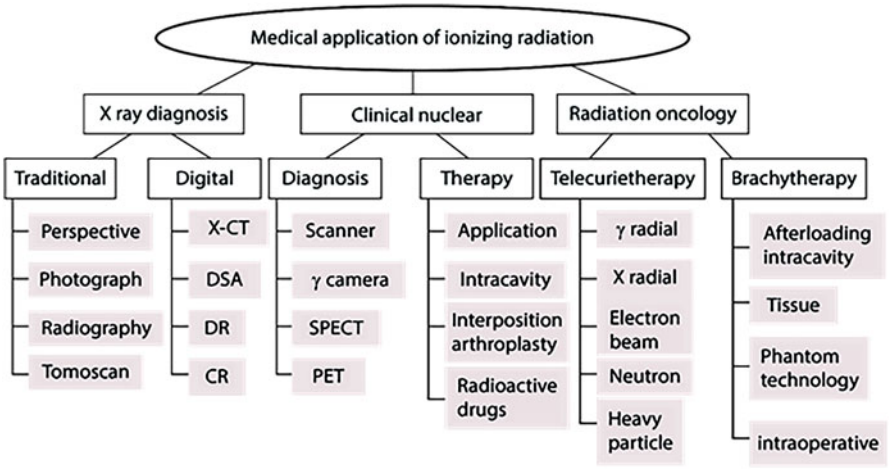

Fig. 1 Uses of ionizing radiation in medicine. (APLMF 2014)

Diagnostic Radiology

Diagnostic radiology has evolved from a scientific curiosity to an integral aspect of modern health care (Gottfried and Penn 1996). The field of radiology was originated on the use of ionizing radiation to diagnose human disease. As technology developed, imaging in diagnostic medical applications is expanded to include, beside radio diagnostic, other nonionizing radiation imaging techniques as magnetic resonance imaging (MRI) and ultrasound. In fact, the two nonionizing procedures are the ones in radiology that are growing the quickest. But X-ray imaging still represents between 80% and 90% of all imaging activities. It involves the use of three imaging techniques: radiographic imaging, fluoroscopic imaging, and computed tomography (CT).

A promising solution for acquiring high-quality CT data while the patient breathes is 4D CT or respiration-correlated CT (conventional and cone-beam tactics) (Keall et al. 2004). It uses X-ray beams with tube voltages ranging from 20 to 150 kV. In fluoroscopy, CT, and dental and general radiography, the tube voltages range from 50 to 150 kV; the anode material is usually tungsten. Mammography examinations are performed with tube voltages ranging from 22 to 40 kV and a variety of anode and filtration materials; the most common material is molybdenum for both anode and filtration (Peixoto and Potiens 2016); nevertheless, tungsten, molybdenum, and rhodium anode as well as aluminum, molybdenum, palladium, rhodium, and silver filtering for calibration may also be employed (IAEA 1994, 1999; Peixoto and De Almeida 2001, 2003a,b); Table 1.

The partial transmission of X-rays through the body is the fundamental principle that underpins X-ray imaging. X-rays from an external source interact with tissues in the patient's body either through absorption or scattering. As X-rays traverse the patient's body, the degree of interaction depends on factors such as the energy of the X-rays and density of the tissues. For detecting, examining, or recording the X-rays originating from the patient's body, the three basic imaging techniques rely on

Table 1 Radiation qualities needed to calibrate diagnostic radiology dosimeters. (Peixoto and Potiens 2016)

Radiation quality	Radiation beam	Material of an additional filter	Application
RQP	X-ray assembly	No phantom	General radiography and dental applications[a]
RQA	Added filter	Aluminum	Measurements behind the patient[b]
RQT	Added filter	Cooper	CT applications
RQR-M	X-ray assembly	No phantom	Mammography applications
RQA-M	Added filter	Aluminum	Mammography applications

various mechanisms. In all circumstances, however, the necessary interaction of X-rays with tissue has an unwelcome but unavoidable side effect; the patient receives some radiation dosage. Radiographic imaging is used to perform a vast majority of X-ray procedures. These radiographic imaging procedures are in turn typically divided into what are considered "conventional" examinations, on the one hand, and "contrast studies," on the other.

The characteristics of radiation qualities is very significant in diagnostic radiology because all dosimeter responses depend, to a certain extent, at least, on the spectral distribution of the X-rays being employed. The first half value layer (HVL) of the X-ray tube's voltage and the homogeneity coefficient are commonly used to describe radiation qualities (Pires et al. 2011).

The TRS 457 (IAEA 2007) provides, based on air-kerma determination, a detailed explanation of the dosimetry formalism, while the IEC 61267 describes the proposed radiation qualities (IEC 2005). This Code of Practice substantially follows ICRU 74 (ICRU 2005) regarding patient dosimetry for X-rays used in medical imaging.

The general methods for calibrating dosimeters used in diagnostic and interventional radiology are similar to those that apply to radiotherapy and radiation protection systems.

Radiotherapy

The basic aim of radiotherapy (RT) is to use appropriate ballistic techniques to give the highest feasible dosage to malignancies while minimizing damage to the normal and healthy tissues. However, despite all such efforts, it is never possible to irradiate only tumor cells. Therefore, radiotherapy must always strive to avoid giving the cancer a dose that is too low, which might lead to recurrence, or even to therapeutic failure, and to give the normal tissues a higher dose that cause serious side effects for the patient. The dose is then a very critical quantity.

The principles of medical physics, radiobiology, radiation safety, dosimetry, RT planning, modelling, and the interplay of RT with other therapy modalities are all part of the RT process (Satoshi 2008). Radiation oncologists, medical physicists, radiation technologists, and radiation nurses form the RT professional team, which collaborates to plan and provide RT to cancer patients through an integrated procedure. The sequential procedure is depicted in Fig. 2, and each step requires quality control (QC) and quality assurance (QA) to avoid errors and ensure that patients receive the recommended medication appropriately.

Radiation is delivered in fractions of the total dose 5 days per week in a normal course of treatment.

Depending on the type of tumor, the disease's stage, and the vicinity of organs or tissues to which only a limited dose is permitted, the total tumor dose may range from 30 to 70 gray (Gy). As was previously mentioned, teletherapy is radiation therapy delivered by an external ionizing radiation beam. Two possibilities are

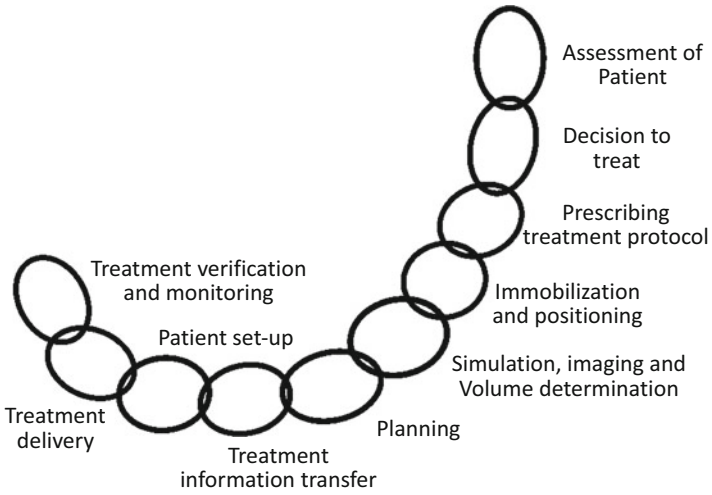

Fig. 2 Sequential process of planning and delivering radiotherapy to patients. (Satoshi 2008)

gamma rays (from a source of radioactive cobalt-60) and photons or electrons (from an X-ray generator or accelerator).

High-energy photon and electron beams are produced by linear accelerators and other electron accelerators for the treatment of cancer patients. A typical treatment employs two or more photon beams targeted at the tumor from various angles. Skin lesions, superficial lymph nodes, and various cancers that are close to the patient's surface are all treated with electrons because they have less power to penetrate tissue (Gottfried and Penn 1996).

Experts in radiation oncology have created various ways of external beam therapy in addition to "traditional" radiation therapy. Electrons are used in intraoperative radiation treatment (IORT) to treat malignancies that have been surgically exposed. After temporary repositioning of the surrounding and overlaying tissue, IORT delivers a single high dose of radiation straight to the tumor. The biggest benefit of IORT is for operable tumors in the pelvis and abdomen that cannot be physically removed.

Stereoscopic radiosurgery (SRS) uses radiation beams to precisely target a tiny tumor inside the skull. The dosage distribution that results creates the goal-containment zone that is narrow and high. SRS is now being studied for both primary and metastatic brain tumors, where it has been demonstrated to be an effective treatment for arteriovenous malformations.

In order to achieve a high-dose area of radiation that "conforms" as closely as possible to the shape of the clearly defined target and/or a lower dose to healthy tissue than conventional radiotherapy, conformal radiotherapy employs firm immobilization, three-dimensional computer treatment planning systems, and image-guidance radiotherapy (IGRT) techniques.

Shielding blocks are not necessary when using a linear accelerator equipped with a computer-controlled multi-leaf collimator (MLC) which are small tungsten leaves that are automatically positioned in the beam to enable the delivery of more complex fields to fit the shape of the tumor.

During treatment, the patient's immobilization period can be reduced (which improves radiotherapy delivery accuracy), and more treatment fields can be completed in a single session. MLCs typically have 80–120 leaves in opposing pairs (Fig. 3).

Additionally, MLC can be utilized to determine the strength of the beam in various regions of each incident treatment field separately. This method of administering radiation is referred to as IMRT, and it allows for the precise administration of higher doses to the target volume with a steep dose fall-off to surrounding areas (intensity-modulated radiation therapy). A fixed or moving gantry can change the location of the MLC's leaves over time. With MLCs, each treatment field can be divided into a variety of stationary shapes, and the radiation beam is activated as soon as the leaves stop moving at each predefined point. This is referred to as the "step and shoot method." In contrast, "dynamic multi-leaf collimation" describes the automatic computer-controlled repositioning of the leaves into beam segments without interrupting radiation.

While the linear accelerator rotates around the patient during dynamic conformal radiation therapy, a computer continuously modifies the radiation field. This technology, when used in conjunction with three-dimensional treatment planning, makes it simpler to treat tumors with intricate geometrical patterns and enables radiation oncologists to increase tumor dose while minimizing normal tissue damage. The 3D dose estimates are the next step in the treatment preparation process. Improved anatomical data processing and dependable quick dosage calculation procedures are now possible thanks to advancements in powerful computer software and

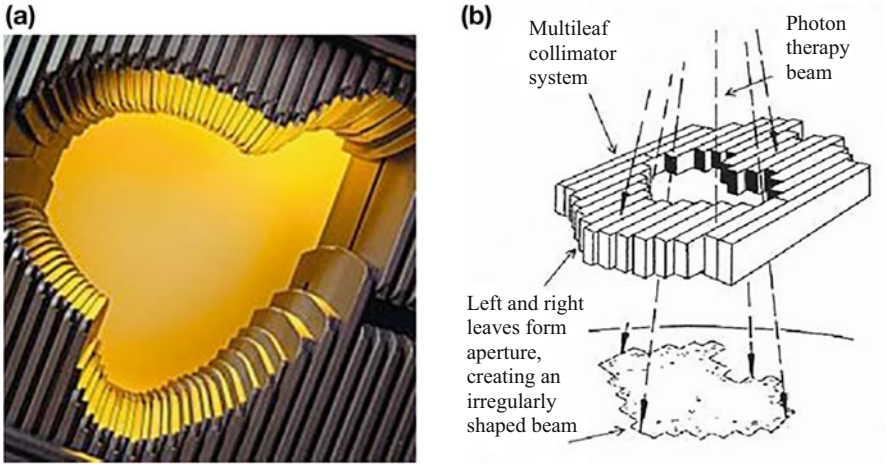

Fig. 3 (**a**) A multi-leaf collimator system (MLC); (**b**) an aperture being projected onto a patient. (Taşkin et al. 2010)

hardware. After selecting the appropriate beam weights, wedge, beam energy, and other factors, the dosage distribution is computed using computer algorithms.

After the treatment plan has been approved, the computer can produce digitally reconstructed radiographs (DRR), 2D projections based on the CT image set, and use them in the treatment planning system similarly to conventional radiographic films. Furthermore, all of the parameters are recorded and verified in the treatment unit's record and verification system.

The field of image-guided radiotherapy (IGRT) has recently realized new techniques that can be used in place of clinically used portal images (by radiographic film or EPID) to verify and control variations in patient and tumor positioning just before or during treatment. These techniques have been made possible by the prominent advancement of radiation oncology. For instance, an onboard imager combines an X-ray tube and an image detector to the therapy apparatus using robotic arms. These arms may move in three directions, allowing them to be positioned optimum for a clear view of the tumor and surrounding anatomy. High-resolution images of the tumor can be obtained using this device at a low dose to the patient.

In fluoroscopic mode, the gadget may also track tumor movements to give clinicians a clear picture of how a tumor will move during therapy due to normal breathing and other physiological processes. Furthermore, by picking a certain time in the patient's breathing cycle to scan and treat a tumor, the respiratory gating technology incorporates the impact of breathing during therapy. The goal is to achieve better target treatment, reduced margins, and lower dosages administered to healthy tissues as a result.

In addition, the patients obtain in vivo dosimetry measurements using semiconductor or thermoluminescence dosimeters during the first treatment fraction to ensure that the given dose is within tolerance. Finally, the treatment's effectiveness is evaluated by the patient's periodic follow-up. This final stage is critical for identifying patients who require salvage surgery or palliative treatment as well as for detecting local regional recurrence and preventing potentially treatable second main tumors. Potential adverse effects are confirmed during follow-up. The long-term objective of follow-up study is to determine whether there is a relationship between treatment outcomes and therapy delivery strategy (and thereby obtain knowledge about the efficacy of various treatment methods).

Treatment result must be measured in order to assess the treatment's effectiveness. Survivability, local control, and quality of life are essential outcomes in oncology.

Treatment Machines for External Beam Radiotherapy

Very little technological progress occurred during the first 50 years of radiation, with X-ray tubes, van de Graaff generators, and betatrons acting as the mainstays. H.E. Johns' creation of the 60-Co teletherapy unit in Canada in the early 1950s gave a huge push to the search for greater photon energies, putting the cobalt unit at the forefront of radiotherapy for several years (López et al. 2005). Technology has advanced to the point where state-of-the-art technology can deliver radiation with

Fig. 4 Performing portal imaging using modern cobalt machine and linear accelerator. (Van Der Merwe 2017)

remarkable precision to tumor lesions while causing minimal damage to normal tissues (Kry et al. 2017). Isocentric teletherapy treatment equipment (cobalt units or linear accelerators with a range of megavoltage energies) is commonly available in the majority of contemporary radiation departments (Fig. 4).

Medical linacs (linear accelerators), which were created at the same time as cobalt units, quickly surpassed them, evolving through five generations to become the most extensively utilized radiation source in modern radiotherapy. With its isocentric positioning and wide range of energies made possible by its compact and effective design, the linac offers good versatility for use in radiotherapy. It can also deliver either electron or megavoltage X-ray therapy. Other types of accelerators, such as betatrons and microtrons, are used in electron and X-ray radiation in addition to linacs. More striking particles, including protons, neutrons, heavy ions, and negative p mesons, are sometimes utilized in radiation; nevertheless, most modern radiotherapy is delivered with linacs or teletherapy cobalt units (López et al. 2005).

Clinical X-ray beams are often produced by decelerating electrons with kinetic energies of 10 KeV to 50 MeV in specific metallic targets, and their energy typically ranges from 10 KVp to 50 MV. Only a small portion of the electron's kinetic energy is released as X-ray photons, which are classified into two groups: characteristic X-rays and bremsstrahlung X-rays. The majority of the electron's kinetic energy is converted to heat in the target.

Calibration of Radiotherapy Sources and Machines

The administration of precise doses to the defined target volume is critical in modern radiotherapy. Based on a review of dose-response data and a clinical evaluation of

dose-delivery errors, the ICRU (1976) report 24 has suggested a 5% overall accuracy in tumor dosage delivery. The 5% accuracy recommendation is far from possible to achieve, given all the uncertainties involved in dosage administration to the patient (Andreo et al. 2005). In common clinical use practice, calibration of the output of photon and electron beams produced by external beam radiotherapy machines is a must. This basic output calibration is one of the links of the lengthy chain of the radiotherapy process (Fig. 2) constituting the accurate dose delivery to the patient. The other links of the chain include the procedures for measurement of relative dose data, equipment commissioning and quality assurance, treatment planning, and the actual patient setup on the treatment machine.

- The dose rate for a point P at a reference depth z_{ref} (often the depth of dose maximum z_{max}) in a water phantom for a nominal source to surface distance (SSD) or source to axis distance (SAD) and a reference field size (often 10×10 cm^2) on the phantom surface or the isocenter is usually stated as the basic output for a radiotherapy machine. The output of kilovoltage X-ray generators and teletherapy devices is often expressed in Gy/min, whereas the output of clinical accelerators is expressed in MUs where 1 MU corresponds to 1 cGy at the depth of maximum output.
- For superficial and orthovoltage beams, and occasionally for beams from teletherapy radioisotope devices, the basic beam output can also be expressed as the air-kerma rate in air (Gy/min) at a specific distance from the source and for a specific nominal collimator or applicator setting.

Radiation dosimeters and advanced radiation dosimetry techniques are used to calibrate the basic output of photon and electron beams. Radiation dosimetry measures and/or calculates the absorbed dose or another physically related quantity at a point of interest in a given medium, such as air kerma, fluence, or equivalent dosage.

A radiation dosimeter is any device that can provide a reading M that measures the dose D of ionizing radiation maintained in the dosimeter's delicate volume V.

- An absolute dosimeter is a dosimeter that generates a signal from which the dose in its sensitive volume can be calculated without the need for calibration in a known radiation field.
- Relative dosimeters are those that need to be calibrated in an established radiation field.

Reference dosimetry is the process of directly measuring the dosage or dose rate in water under predetermined reference conditions in order to calibrate a clinical radiation beam's basic output. There are now three different types of reference dosimetry techniques: calorimetry, Fricke dosimetry, and ionization chamber dosimetry.

These dosimeters can be used as absolute dosimeters, although they are rarely utilized in clinics for that purpose because doing so is laborious, and calibration in a

known radiation field has benefits like traceability to a standard laboratory. When used individually, an absolute dosimeter relies on its particular accuracy as opposed to using a standard that is shared by all radiation users.

Absorbed dose could be a thoroughly well-defined amount which is utilized for the measurement of presentation of any sort of fabric, counting organic objects and people to ionizing radiation. The concept and amount of "absorbed dose" have been presented by the ICRU (1998). Absorbed dose (desire esteem of the vitality bestowed to matter per unit mass at a point in a medium) could be a principal physical amount which can be utilized within the distinctive areas where ionizing radiation is utilized. In this way, the concept of absorbed dose has wide applications and is in fact recognized as the essential amount in radiation treatment, radiation assurance, and radiobiology (Chavaudra et al. 2004).

The absorbed dose for the water approach in low-, medium-, and high-energy beams of heavy ion of electron and of proton used for external radiation is determined by the Code of Practice TRS 398 (IAEA 2000). An ionization chamber or a dosimeter calibrated in terms of the absorbed dose to water in a Co-60 source is used to determine the absorbed dose to water formalism in high-energy photon and electron beams (Peixoto and Potiens 2016).

Measurement chambers for medium- or low-energy X-rays must be calibrated with similar-quality beams; however, the fundamental standards of absorbed dose to water for kilovoltage X-ray quality are only available from a small number of Primary Standard Dosimetry Laboratories (PSDLs) (IAEA 2009; JCGM 104 2009). Though using the appropriate approved protocols or the Codes of Practice for the Dosimetry of X-Ray Beams, calibration factors can be estimated in terms of absorbed dose to water from air-kerma calibration factors.

Quality Assurance in External Radiotherapy

Every one of the numerous radiation treatment processes adds to the overall uncertainty of the absorbed dosage delivered to the patients. Along with the inherent uncertainties, the necessity to transport enormous amounts of data between the many processes of radiation treatment, as well as difficulties in precisely identifying or replicating all technical and physical parameters, might result in systematic or random errors.

The analysis of clinical dose response curves yielded the accuracy requirements for assessing the absorbed dose in radiotherapy. According to Mijnheer et al. (1987), an increase in absorbed dose of 7% can result in unacceptable normal tissue problem probability. The standard requirement for the uncertainty in the delivery of an absorbed dose is, therefore, 3.5%, which should be at least twice the standard deviation in the absorbed dose. Wambersie et al. (1994) similarly found that the 3.5% accuracy criteria in the absorbed dosage provided cannot be fully met in photon therapy, even for a basic treatment scenario with two opposing beams. According to Mijnheer et al. (1987), these accuracy requirements can be expressed

as guidelines for good clinical practice and should serve as motivation to increase radiotherapy accuracy:

- At the specified point, the absorbed dose: 3.5%.
- Other target volume locations where the dosage was absorbed: 5%.

The accuracy can be less than 3.5% if the dose-response curves have shallow slopes. However, the exactness should be greater than this metric for steep dose-response curves. A high degree of precision is desired for a successful conformal therapy. As a result, quality assurance (QA) methods must be established, which is practically difficult given the complexity of the equipment and the numerous steps in the radiation therapy process (Soliman and Aletreby 2016).

The World Health Organization (WHO) has provided a clear definition of quality assurance in radiotherapy (WHO 1988), and this term is frequently used to refer to the processes that guarantee the consistency of the medical prescription and the safe fulfilment of that prescription with regard to dose to the target volume along with minimal dose to normal tissue, minimal exposure of personnel, and adequate patient monitoring aimed at determining the treatment's outcome.

There are numerous sets of national and international recommendations and protocols (IAEA 2021; AAPM TG 40 1994; AAPM TG 198 2021; IPEM 2018) that should be consulted when available since they incorporate the requirements for quality assurance and quality control for different radiation equipment items. These provide suggested tests, test frequencies, and tolerances. Some propose test methodologies, while others give practical guidance on quality assurance and quality control tests for many items of equipment.

A universal quality assurance program for equipment comprises:

- Initial specification, acceptance testing (the processes/procedure by which the supplier validates the baseline performance of the equipment to the satisfaction of the purchaser), and commissioning (after acceptance of the equipment, a full characterization of its performance for clinical applications over the all the ranges of possible operation are to be carried out) are all required before the equipment is used in a clinical setting, including calibration when necessary.
- Establishing tests for quality control after the commissioning process is complete.

Before the equipment is clinically used, quality control tests should be performed and a comprehensive quality control program should be implemented that will last the duration of the equipment's clinical life. Because treatments of patients will be decided, planned, and administered based on performance measurements taken at acceptance and commissioning, it is vital that treatment equipment performs consistently within acceptable tolerances throughout its clinical life. To test this, a continuing quality control program of regular performance checks is started soon following commissioning. If these quality control measurements detect drifts from desired performance, rectification is required.

- Further quality control tests following any significant repair, intervention, or adjustment or when there is any indication of a change in performance as observed during use or during planned preventive maintenance or routine quality control programs.
- A planned precautionary maintenance program, in accordance with the manufacturer's recommendations.

Only after the medical physicist in charge of customer acceptance is confident that the machine's performance meets all criteria outlined in the contract document, or has formally accepted any waivers as described above, can the equipment be officially accepted to be transferred from the supplier to the customer.

Uncertainties, Tolerances, and Action Levels

It is crucial to calculate the degree of uncertainty in each measurement's outcome. Typically, it is best to start with the JCGM Report 100 (BIPM 2008), commonly known as the ISO Guide on the Uncertainty in Measurement, ISO GUM (JCGM 104 2009), which provides an exhaustive approach to uncertainties. Mitch et al. also provide a very thorough overview of radiation dosimetry's uncertainties (2009). An example of an uncertainty analysis and budget for a typical measurement in a clinical radiation therapy unit was presented by Castro et al. (2008).

In any case, performance within the tolerance threshold provides adequate accuracy. Performance deviations from the action level cannot be accepted and require corrective action. Any quality control test needs to employ the right measuring equipment for the assignment. All of this equipment should have regular maintenance and quality assurance program. Conditions for irradiation and measurement methodologies are to be tailored to the task in question. Consequently, the quality control measurement ought to provide the closest approximation to the measured parameter that is correct. However, depending on the measuring procedure, there will be an accompanying uncertainty. The parameter's tolerance must take into consideration the uncertainty of the measurement technique used. Random fluctuations in measurement will result in unnecessary interruption, increased equipment standby time, and unproductive use of staff time if the measurement uncertainty is greater than the tolerance predetermined level.

Variances can be combined for combination components in quadrature to establish specific tolerance limits for individual parameters. Similar to tolerances, action levels permit more flexibility in monitoring and adjusting. For instance, it may be acceptable to continue clinical usage until the following day's measurement verifies this before taking any further action if a measurement of dose/MU constancy shows a result that falls between tolerance and action levels. Thus:

- No action is required if a daily measurement is proved to be within tolerance.
- If the measurement is higher than the action level, immediate action is required, and the equipment cannot be utilized in a clinical setting until the problem has been fixed, and the fix has been verified by measurement.

- However, if the measurement falls in the range between the tolerance and action levels, it may be provisionally accepted until the measurement on the following day.
- When repeated measurements consistently fall between tolerance and action levels, correction is required.
- Anytime a measurement exceeds the action level, a prompt inquiry is necessary, and if the investigation is confirmed, corrective action is required immediately.

Despite that some essential parameters may dictate to set tolerance and action levels much closer to each other, or even have the same value, action levels are normally set at close to twice the tolerance level. When comparing figures from multiple sources, keep in mind that recommendations may take slightly various methods to setting tolerance and/or action levels. The term "tolerance level" may be used to refer to values that are closer to action levels in specific circumstances (i.e., some workers use the term tolerance to indicate levels at which adjustment or correction is necessary). Performance standards are specifically listed under the two headings in certain suggestions. Test frequencies must be weighed against the amount of fluctuation that is allowed over the course of therapy, as well as the length of time that a parameter varies or deteriorates. Frequencies can be changed based on experience with a piece of equipment's performance and stability, with a nominal frequency established at first and then evaluated based on observations. As machines age, this may need to be revisited. The number of human resources available to conduct the tests may limit what may be checked, which may have an impact on the quality control program's structure. Tests should be designed to produce the essential information as quickly as feasible while using the least amount of time and resources.

Metrological Traceability

"The property of the result of a measurement or the value of a standard whereby it may be compared to stated references, usually national or international standards, through an unbroken chain of comparisons, all with declared uncertainties," is the definition of metrological traceability. The level of traceability determines the measurement's comparability: whether a measurement's result can be compared to a prior one, a measurement result from a year ago, or a measurement result from anywhere else in the globe (APLMF 2014). The uncertainties are influenced by each measurement result.

Uncertainty and traceability are two crucial components of the measurement itself. The determination of a given quantity has little significance outside of the immediate context without a traceability chain and an uncertainty analysis. In this instance, there can be no valid comparison with any other measurement of the same amount at a different institution, and there can also be no meaningful explanation of that comparison in the absence of an uncertainty estimate.

The calibration chain, which is the full path between the end user and a standard, must be followed in order to achieve traceability. In the domains of metrology and

quality assurance, the term "standard" has two separate definitions, but both suggest a sort of standardization. Furthermore, one should speak of a "measurement standard" or a "documentary or a reference standard," yet the qualifier is frequently left out of many conversations on the subject. In the end, both refer to anything (an artifact or technique) that is judged or compared to others of a similar type.

The primary national standard is the first artifact or measurement in the calibration chain. These are typically maintained and disseminated by the National Measurement Institutes (NMIs), also known as Primary Standard Dosimetry Laboratories (PSDLs) in the dosimetry sector.

The national government entrusts a PSDL with the responsibility of creating, maintaining, and enhancing the fundamental radiation dosimetry standards. The calibration of secondary standards is then used to distribute these standards.

The PSDLs typically maintain standards for numerous end-use applications, such as radiation protection, diagnostic radiology, radiation therapy, and industrial processing, for a variety of beam modalities, including KV X-rays, ^{137}Cs and ^{60}Co irradiators, radioactive sources for brachytherapy, and linear accelerator beams, among others (both photons and electrons. Air kerma, air-kerma strength, activity, absorbed dosage, and absorbed dose equivalent are some of the measurement parameters that depend on the modality and application.

More debate is required in cases where a nation lacks a PSDL. A Secondary Standard Dosimetry Laboratory (SSDL), a laboratory selected by the appropriate national authorities to provide the critical link in the traceability of radiation dosimetry to national/international standards for users in that nation, may be established in this situation.

An SSDL includes secondary standards calibrated at one or more PSDLs, with ultimate traceability to the BIPM. The SSDL Network (www-naweb.iaea.org/nahu/dmrp/SSDL/), which offers a platform for national SSDLs to undertake dosimetry comparisons and consequently improve radiation dosimetry consistency worldwide, is also run by the IAEA and WHO.

Although there are many different types of documents, reports, laws, and other things that can be included in standard documentation, the International Organization for Standardization (ISO) standards are the most significant in this topic. Manufacturers and service providers have accepted the ISO-9000 family of generic standards as a means of showing process conformance. To ensure a sufficient level of technical expertise in the transmission of measurement standards, ISO-17025 (ISO 2005) combines the quality assurance (QA) components of ISO-9000 with some special technical requirements for calibration laboratories (primary and secondary). End users may also have access to national guidelines, protocols, and best practice measures created by the national and/or international organizations like the IAEA (2000) or AAPM (Almond et al. 1999).

It is essential to understand that traceability is more than just a tag attached to a measurement, regardless of where you are in the chain (end user, PSDL, secondary laboratory). A look at how that traceability was achieved is a great way to examine the quality of the calibration process, as it effectively shows you "how" to make a statement like "NIST-traceable." This "how" is an essential information for any QA

program since it demonstrates both the existence of a continuous measurement chain from the end user to the initial realization of the quantity and the accuracy of the process (using the correct measurements standards and following the correct documentary standards).

Radiation Protection

Radiation has two types of effects: somatic and genetic. While somatic consequences manifest in the individual who has been exposed to radiation, genetic impacts manifest in the descendants. The likelihood of these consequences occurring, but not their severity, increases as radiation exposure increases. These effects can be explained simply by saying that when X-rays pass through a patient, they produce biological changes or even harm. There are two sorts of potential body damage: stochastic and non-stochastic, sometimes known as deterministic.

Stochastic means something that occurs as a result of the law of chance or probability and is independent of radiation dose. Stochastic effects, due to exposure to ionizing radiation, can cause cancer or have influence on gene-material affecting future generations.

Non-stochastic (deterministic) means that something will always occur but only when exposure is exceeding a certain *threshold*. The amount of damage (severity) increases the more the threshold value is exceeded (Munro et al. 2004).

The groundbreaking efforts toward establishing safety standards were initiated by a concerned group of scientists in 1915, followed by an International X-ray Unit committee in 1925 (Rollerstone 1927). This eventually led to the formation of the International Commission on Radiation Protection (ICRP) in 1928 (Clarke and Valentin 2009). While keeping the fundamental protection principles, the ICRP updated its guidelines and expanded its philosophy to include a system of radiation protection in publication 60. ICRP released Report 103 in 2007 as an updated general guideline for a radiation protection system (ICRP 2007). This new guideline offers direction on the fundamental ideas that might underpin effective radiation protection (Do Kyung-Hyun 2016). The Commission makes a distinction among three types of exposures: occupational exposures, public exposures, and medical exposures of patients.

1. Occupational exposures are all exposures that workers experience while performing their jobs (with the exception of exposures excluded from the International Basic Safety Standards for Protection against Ionizing Radiation and for the Safety of Radiation Sources (BSS) and exposures from practices or sources exempted by the BSS.
2. Public exposure is defined as radiation exposure that is received by the public, excluding occupational or medical exposure, background radiation, and intervention situations but including exposure to authorized sources and procedures.

3. Medical exposure is the exposure of patients when receiving diagnosis or treatment, people exposed while willingly providing support and comfort to patients, and of volunteers participating in biological research programs.

Under the circumstances, radiation sources and installations should include the best protection and safety measures so that while taking into account economic and social factors, the magnitudes and likelihood of exposures, as well as the number of people exposed, are as low as reasonably achievable (ALARA), and the doses they deliver and the risk they entail are controlled (i.e., protection and safety should be optimized).

In medical diagnostic exposure, patient protection is maximized by limiting exposure to the absolute minimum necessary to achieve diagnostic goals, but in therapeutic exposure, patient protection is maximized by maintaining normal tissue ALARA exposure in accordance with administering the necessary dose to the planning target volume (cancer). To ensure that the embryo or fetus receives the same level of protection as the broader public, pregnant employees must be protected.

Principles of Radiation Protection

The following goals must be met through optimizing the design of installations, machinery, and operational procedures (López et al. 2005):

- Prevent or reduce the likelihood that events may occur that could result in unplanned exposures.
- Prevent or reduce the magnitudes of exposures that could be caused if such events were to occur.

The International Commission on Radiation Protection functions to this day in developing and compiling recommendations on effective management of radiation and the risks it causes (Zainuddin 2018). It suggested that the general principles of radiation protection apply in all exposure situations the three keywords: justification, optimization, and dose limit (ICRP 1977):

- **The principle of justification**: Any decision that changes the radiation exposure situation should be beneficial rather than harmful. This means that by introducing a new radiation source, reducing existing exposure, or reducing the risk of future exposure, enough individual or community benefit should be produced to offset the harm.
- **The principle of optimization of protection**: The probability of exposure, the number of individuals exposed, and the volume of each of their individual doses should all be kept as low as is technically feasible, taking into account the economic and societal considerations. This indicates that the amount of protection should be the best possible under the circumstances, optimizing the benefit-to-harm ratio.

- **The principle of application of dose limits**: The total dose from regulated sources to any individual shall not exceed the permitted limits defined by the Commission in planned exposure situations other than medical exposure of patients. Within optimization of protection context, the concepts of dose constraint and reference level are used to limit individual doses. Individual dose levels must always be defined, whether as a dose limitation or a reference level.

Radiation Protection Fundamentals in the Medical Field

Medical exposure of patients typically entails particular considerations; dose limits or dose limitations are not appropriate. Dose limitations are meaningless since ionizing radiation, when applied at the proper dose for the right medical reason, is a valuable tool that does better than harm. As a result, medical radiation has no dosage restrictions, and the diagnostic reference level (DRL) is commonly employed as a reference value (ICRP 2007). To reduce the hazards of radiation exposure, any medical radiation exposure must be justified, and ionizing radiation exams must be optimized. The examination must be medically indicated and useful in order to be justified. The use of doses that are as low as reasonably achievable (ALARA) in respect to the diagnostic task is referred to as "optimization" (Do Kyung-Hyun 2016).

A different approach to radiological protection is required for some aspects of radiation exposure in medicine for patients than for other types of radiation exposure. Patients are purposefully exposed.

With the exception of radiation therapy, the objective is to use the radiation to perform an interventional procedure or provide diagnostic information rather than to deliver a radiation dose. Patients who receive medical radiation do so voluntarily, with the hope that it would improve their health. The voluntary decision is made with varied degrees of informed consent, which takes into account both the expected benefit and the potential hazards. The amount of information offered to acquire informed consent varies depending on the level of radiation exposure (diagnostic, interventional, or therapeutic) and the possibility of developing medical conditions as a result of radiation exposure. Each application of ionizing radiation for the purpose of assessing asymptomatic individuals should be evaluated and supported in terms of its clinical utility.

Application of Principles of Radiation Protection in Medical Fields

It concerns the proper use of the main concepts of radiation protection (justification, optimization of protection, and application of dose limits) because medical exposure of patients has unique considerations. Dose restrictions are not acceptable when it comes to medical exposure of patients because they often cause more harm than good. There are frequently other medical issues that are more serious, severe, or even life-threatening than the radiation exposure. The focus is placed on the medical operations' rationale and on optimization of the radiological protection. The best

ways to prevent unnecessary diagnostic and interventional treatments are to justify procedures (for a specified patient and purpose) and administer the patient dose proportionate to the medical objective. The equipment features that aid in patient dosage management and the creation of diagnostic reference values at the proper national, regional, or local level are likely to be the most efficient measures. Accident avoidance is a major concern in radiation therapy. Dose restrictions are acceptable for comforters and occupations, as well as for volunteers in biomedical research.

Justification

Validation for radiological patient protection differs from justification for other radiation applications in that the benefits and dangers associated with a course of action are often experienced by the same person. Furthermore, just because a procedure or course of action is appropriate in general does not mean that it is justified in the context of the individual patient under consideration (Do Kyung-Hyun 2016).

In medicine, a radiographic practice has three levels of justification:

(a) At the fundamental level, it is widely understood that the right use of radiation in medicine benefits society rather than harming it.
(b) A specific technique with a specific goal is established and justified at the second level.
(c) The aim of the second level of justification is to ascertain whether the radiological technology will enhance the diagnosis, treatment, or provision of vital information on the exposed individuals.
(d) At the third level, the procedure's application to a specific patient must be justified. As a result, each particular medical exposure should be justified beforehand, taking into account both the individual and the exposure's features as well as its specific goals.

Optimization

It's also one-of-a-kind to optimize patient protection. Individual limitations on patient dose could be detrimental to the medical objective of the operation, and in order to optimize patient protection in diagnostic interactions, the same person reaps the benefit and bears the risk. Radiation protection for patients is often optimized in medicine on two levels: (1) the design, appropriate selection, and construction of equipment and installations and (2) the daily working procedures.

This radiation protection optimization's primary objective is to control the protective actions for a radiation source in a way that maximizes the net benefit. It's not always necessary to lower patient dosages in order to maximize protection from medical exposures. The term "optimization of radiation protection" refers to the control of the radiation dosage to the patient to be proportionate to the medical goal while keeping doses "as low as reasonably achievable, taking economic and societal aspects into account."

Diagnostic reference levels (DRLs) are a type of research level that applies to medical exposure. DRLs are meant to supplement professional judgement, not to draw a line between "good" and "poor" medicine. They make a positive difference.

Models of Risk Assessment

The degree of radiation risk is dose-related, with larger doses resulting in higher risks. Diagnostic X-ray and nuclear medicine diagnostics may provide clear health advantages while also posing a modest risk (probability) of side effects. When using ionizing radiation sources for diagnosis, this fact is taken into account. Because radiation therapy necessitates huge doses of radiation, the risk of radiation-related side effects is significantly increased. The goal of regulating radiation exposure is to reduce the potential risk without jeopardizing or restricting the clear benefits of illness prevention, diagnosis, and successful treatment (optimization) (Gottfried and Penn 1996).

Radiation-induced malignancies are a well-known side effect of the treatment. The chance of getting a second cancer is determined by the total irradiation volume as well as the volume of the high-dose zone. The high doses of radiation delivered by these radiotherapy treatment techniques may cause long-term adverse effects and primarily second cancers due to larger out-of-field doses (Howell et al. 2006; Kry et al. 2007; Bednarz and Xu 2009; Cho et al. 2011; Zemanova et al. 2014; Soliman et al. 2020). With radiation therapy as a predisposing factor, the cumulative risk for the development of second malignancies has been predicted to range from 5% to 12% after a 25-year follow-up interval.

Radiation-induced tumor knowledge (and the basis for epidemiological response models) is mostly based on atomic-bomb survivor data, and the most often used risk models are based on these data. To predict the risk of second malignancies as a result of radiation treatment, several risk models have been devised and applied (Soliman 2019). A "linear no-threshold" (LNT) model is recommended by both the BEIR VII Committee (2006) and the ICRP (1991) for doses below 0.1 Gy.

In order to properly assess the time-integrated risk of a specific event following high-dose (more than 1 Gy) exposure, competing risks for other radiation-related outcomes must be included, and the resulting excessive lifetime risk estimate has an essentially nonlinear dose response (Alexander et al. 2019).

Because the LNT model tends to overestimate the risk for tissues near the treatment volume at high doses, while the competition model (CR model) underestimates the second cancer risk, Sachs and Brenner (2005) proposed a biologically based and minimally parameterized model that incorporates carcinogenic effects, cell killing, and proliferation/repopulation effects that were consistent with clinical data for high-dose second cancer data.

Additional aspects such as the varying sensitivity of different tissues and absorbed dosages to different organs must be considered when evaluating biological consequences of radiation after partial body exposure. A quantity called effective dose is used to compare the dangers of partial and whole-body irradiation at doses seen in diagnostic radiology and nuclear medicine. It is measured in sieverts (Sv). In radiation therapy, where very large absorbed doses affect particular tissues or organs, effective dose does not apply (Gottfried and Penn 1996).

Radiation Protection Quantities

The absorbed dose is the most fundamental physical dosimetry quantity; however, it is insufficient for radiation protection since the efficiency of different forms of ionizing radiation in destroying human tissue varies. Other dose-related values were included in addition to the physical numbers to account for both biological and physical effects of radiation on tissues. Organ dose, equivalent dose, committed dose, and collective dose are the four quantities (López et al. 2005).

The mean dose D_T in a certain tissue or organ T of the human body is known as the organ dose and is given by the following:

$$\boldsymbol{D_T = 1/\mathrm{m_T} \int_{m_T} D dm = \frac{\varepsilon_T}{m_T}} \tag{1}$$

where
m_T is the mass of the organ or tissue under consideration,
ε_T is the amount of energy that radiation has given that tissue or organ.

Equivalent Dose H_T

The biological harm (damage) to an organ is proportional to the physical average dose received by the organ, as well as the dose distribution pattern resulting from the radiation type and energy. When compared to gamma rays or electrons, alpha or neutron radiation causes more harm to the organ for the same dose. The equivalent dose H_T is the result of multiplying the organ dose $D_{T,R}$ by a radiation-weighting factor (w_R) to account for the radiation's effectiveness in producing health consequences. The equivalent dose is determined by H_T:

$$\boldsymbol{H_T = W_R D_{T,R}} \tag{2}$$

where

$D_{T,R}$ is the average absorbed dose of radiation of type R delivered to a tissue or organ T, where T is the tissue or organ and w_R is the radiation-weighting factor for radiation of type R.

- For X-rays, γ rays and electrons, w_R =1 while for protons $w_R = 5$, and for α particles $w_R = 20$. As for neutrons, based on the energy, w_R ranges from 5 to 20.
- The units of equivalent dose in SI system is J/kg and called sievert (Sv), the long-standing unit is the (rem) and the relationship between the two is as follows: 1 Sv = 100 rem. In order to further explain, if 1 Gy of photon dose given to an organ, then the equivalent dose will be 1 Sv. However, for the same dose of 20 keV neutrons, the equivalent dose is 10 Sv, since the detriment is 10 times larger, i.e., $w_R = 10$ for 20 keV neutrons.

- The dose to the organ $D_{T,\,R}$ is a measure of the absorbed energy per unit mass averaged over the organ volume, while the equivalent dose H_T is a measure of the resulting biological harm (detriment) to the organ or tissue *T*.
- The equivalent dose is determined by the sum if an organ is exposed to more than one type of radiation.

$$\boldsymbol{H_T = \Sigma\, W_R\, D_{T,R}}. \tag{3}$$

- Weighting parameters relating to radiation quality were applied to the absorbed dose to a point in previous ICRP recommendations, and the radiation weighted absorbed dose was referred to as the dose equivalent H. (not referred to an organ, but to a point).

Effective Dose *E*

The link between the chance of stochastic effects and the equivalent dosage is discovered to be dependent on the irradiated organ or tissue. This means that the effects of exposure on different organs or tissues for the same equivalent dose are varied. Tissue-weighting variables are required to account for these discrepancies.

Tissue-weighting factors $\boldsymbol{W_T}$ should represent the relative contribution of an organ or tissue to the total detriment due to the effects resulting from a uniform irradiation to the whole body.

To show the combination of diverse doses to numerous different tissues in a way that correlates well with all stochastic effects combined, ***the effective dosage E*** is defined as the total of tissue equivalent doses, each multiplied by the appropriate tissue-weighting factor $\boldsymbol{W_T}$, (ICRP 60 1991), i.e.:

$$\boldsymbol{E = \Sigma\, W_T\, H_T} \tag{4}$$

- ***Tissue-weighting factors*** $\boldsymbol{W_T}$ are tabulated in the ICRP 60 JCGM 104:2009 report and in the IAEA safety standards.
- The unit of effective dose is J/kg, and its special name is sievert (Sv).
- A uniform equivalent dose over the whole body gives an effective dose that is numerically equal to the uniform equivalent dose.
- The weighing factors $\boldsymbol{W_T}$ and $\boldsymbol{W_R}$ are equally independent, i.e., the tissue risk factors $\boldsymbol{W_T}$ are independent of radiation type, and the radiation weighting factors $\boldsymbol{W_R}$ are independent of tissue type, allowing us to write:

$$\boldsymbol{E = \Sigma_T\, W_T\, \Sigma_R\, W_R\, D_{T,R} = \Sigma_R\, W_R\, \Sigma_T\, W_T\, D_{T,R}} \tag{5}$$

- When a setting contains only one type of radiation, the effective dosage is calculated by the following:

$$\boldsymbol{E = \Sigma\, W_T\, D_{T,R}} \tag{6}$$

- The effective dose is a dosage measurement that reflects the amount of radiation harm that the dose is expected to cause. Direct comparisons of effective doses from various radiation types and exposure scenarios are possible.
- Annual dosage limits for occupational and public exposure are indicated in terms of annual effective dose, and in the case of exposure to an organ, hands, or feet, an equivalent dose is the given quantity.
- Effective dose equivalent, which was utilized in earlier ICRP studies, has been replaced with effective dosage.
- The equivalent dosage H to specific organs or the effective dose $\boldsymbol{E}$ can be determined for distinct irradiation geometry using an anthropomorphic phantom that simulates the human body. However, because no primary standards have been established for these variables, they are not directly measured.

Collective Dose

The abovementioned radiation protection quantities refer to an individual's exposure. The term "collective dose" refers to groups or populations that have been exposed, and it is calculated by summing the products of the mean dosage in each group of exposed people and the number of people in each group. The man-sievert is the unit of collective dose (man-Sv).

Conclusion

Modern medicine would be impossible without ionizing radiation. The importance of metrology in the study of biological phenomena and the creation of high-standard inspection or treatment approaches is highlighted by the use of ionizing radiation in medicine. Imaging with X-rays, computed tomography scans, diagnostic and therapeutic nuclear medicine, brachytherapy, the gamma knife, and linear accelerators are examples of the technologies that have greatly improved diagnosis and treatment in medical applications.

Radiotherapy, in particular, is a critical tool for cancer treatment that necessitates the highest level of precision to optimize the absorbed doses delivered to the tumor and surrounding normal tissues. Meeting the precision requirements for the dose provided to the patient for a specific treatment necessitates a high level of precision in each of the procedure's several steps. From precise beam calibration to beam data collecting, beam monitoring, and dose calculation, errors are introduced.

Although using ionizing radiation in medicine has many advantages, there is also a risk that it could have negative effects on patients, health-care workers, and the population. Acute injuries and chronic illnesses, like cancer, can be brought on by the same diagnostic and therapeutic procedures used to treat cancer. The overall goal of radiation protection is to safeguard humans and the environment from the dangers of ionizing radiation. The principles of radiation protection were then supported with the concepts of justification, ALARA (as low as reasonably achievable), and "benefits against the risks." But these could not ensure that the application of radiation protection has been optimized.

Abstract

Nuclear forensic analysis is a relatively new approach to provide technical support for the investigation of security incidents that may arise due to unauthorized use of nuclear or radioactive materials. The increasing rate of smuggling, trafficking, illegal possession, and theft of nuclear or radioactive material has become a worldwide challenge. Considering the potential hazards associated with the nuclear/radioactive material, the proper investigation and

identification of the material are extremely important to prevent illegal trafficking and other unauthorized activities. The nuclear forensic analysis provides clues on the origin and intended use of nuclear materials which supports nuclear attribution. In a designated nuclear forensic laboratory, seized nuclear/radioactive material will be analyzed for the characteristic signatures using several established analytical techniques. To establish the origin and nature of samples, it is important to investigate elemental composition, isotopic composition, chemical impurities, macroscopic appearance, microstructure, etc. Comparison of the signatures using the nuclear forensic library consisting of a database of known samples, processes, etc. also is an important requirement. The analyses should be carried out following certified procedures and standard techniques. Intercomparison exercises and certified reference materials play an important role in the quality assurance of data.

Introduction

Nuclear/radiological threats have become a major concern globally in recent years. Despite strict safety and security norms, many nuclear/radiological incidents have been reported involving fissile materials in the last three decades (IAEA 2021). Radioisotopes are being used widely in various fields including industries, research, medicine, etc. Some of these radioisotopes would be suitable for radiological terrorism and in the fabrication of radiological dispersion devices (RDD or dirty bomb). A large number of orphan sources are generated due to the loss of administrative control over radiation sources, resulting in high radiation exposure cases as a consequence of radiological emergencies (Dey et al. 2012; IAEA 2002a; NTI 2021). There are about 3857 nuclear/radiological confirmed incidents, reported to the Incident and Trafficking Database (ITDB) as of 31 Dec 2020. The year-wise breakup of the incidents is shown in Table 1. Among them, about 59% of incidents involve radioactive sources/isotopes, 14% are nuclear materials, and 27% are radioactive contaminated or other materials.

Nuclear forensics (NF) is comparatively a new approach that plays a vital role in the detection or investigation of nuclear/radiological incidents (either pre/post) through technical support by providing crucial information about the evidence found at the crime scene. During the examination of any security incident, certain information regarding the production and history of the material/evidence will be required. NF study supports these inquiries by the analysis of confiscated nuclear or radioactive materials. In NF, different analytical techniques are used for characterization of the material either intercepted intact or retrieved from post-explosion debris, in terms of elemental, isotopic composition, chemical, and other physical parameters using validated signatures. The results are compared against reference

Table 1 Year-wise breakup of the confirmed incidents involving nuclear/radioactive materials out of regulatory control reported to ITDB

Year	Number of incidents	Year	Number of incidents
1992	5	2007	236
1993	57	2008	177
1994	72	2009	169

samples of known materials from reactors, weapons, and enrichment facilities or the materials from medical, academic, commercial, and other radiation facilities. NF includes an iterative and deductive approach where the results from one analysis support in guiding the selection of subsequent analyses. Proper selection and sequencing of analytical techniques and consequential analyses are most vital during NF investigation. The selection of analytical techniques or parameters depends on the type and nature of evidence/incident and the questions asked by the investigating agencies. For successful NF investigation, validated procedures concerning sample collection, analysis, interpretation and reporting results, and documentation are very important. In various stages of NF, starting from radioactive sampling to analysis and interpretation in NF, radiation metrology plays a significant role. The same are summarized below along with various challenges and limitations associated with nuclear forensic capacity building.

Guidelines and Methodology for Nuclear Forensic Analysis

Nuclear Forensic Model Action Plan

Nuclear forensic examination and related activities toward the investigation of a nuclear security event are described in the NF model action plan shown in Fig. 1, prepared by the combined efforts of the International Atomic Energy Agency (IAEA) and International Technical Working Group (ITWG) (IAEA 2006, 2011a). It provides a uniform platform for responding to the seizure of nuclear/radioactive materials. Detailed phase-wise action plans and sequences that come subsequent to

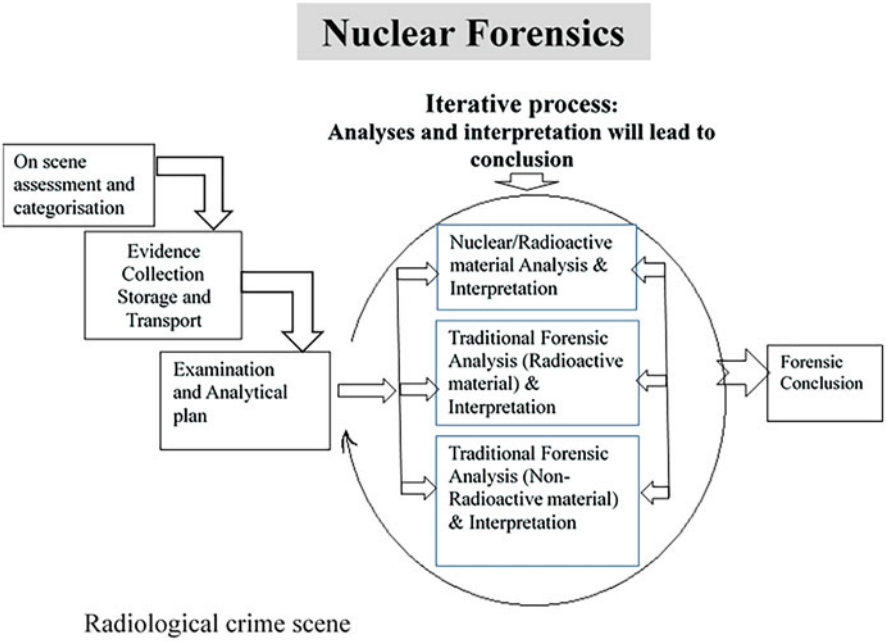

Fig. 1 Nuclear forensic model action plan. (Source: IAEA 2011a)

an incident are described in IAEA Nuclear Security Series No. 2, Technical Guidance (IAEA 2006).

The various stages in nuclear forensics where radiation metrology plays an important role are summarized below:

A. Identification of the nature of the material (nuclear or radioactive nature) and thereby identifying the potential radiological or chemical hazard
B. On-site material categorization by mobile nondestructive assay (NDA) equipment
C. Sample collection, storage, and transport of nuclear/radioactive evidence
D. Bulk and microanalysis of nuclear forensic signatures (elemental, isotopic, chemical, physical) in nuclear/radioactive materials at the specialized national nuclear forensics laboratory
E. Comparison of the results with the database and interpretation and attribution of the material to its source, production, origin, etc.

On-Scene Assessment and Categorization of Materials

Following a nuclear incident (pre/post), the first step toward nuclear forensic investigation is on-scene assessment and categorization of the material for the hazard assessment and rapid identification of primary radioactive components, thereby

generating the further action plan. This is very much essential for the personal protection and early identification and macroscopic characterization of the material. Before proceeding with the action plan, it is always advised to confirm the absence of hidden explosives along with the material/device. A portable X-ray radiography device is used in the field for explosive identification through imaging of material in solid form and containers (IAEA 2006). The portable X-Ray system shall meet or exceed the requirements for compliance with IEC 60529, as amended, classification IP54 (NIJ 2007).

Nuclear materials are broadly categorized in terms of element (e.g., U or Pu), isotopic composition (i.e., fissile isotope concentration), physical and chemical form, extent of dilution, quantity, and irradiation and radiation level. The categorization is mainly based on a graded approach for protection against unauthorized removal of nuclear material that could have direct or indirect use in a nuclear explosive device (IAEA 2006, 2011b). Important radioisotopes, which could be directly or indirectly used for the construction of nuclear weapons/explosive devices, are ^{233}U, ^{235}U, ^{238}U, ^{239}Pu, ^{241}Pu, ^{230}Th, and ^{232}Th. Similarly, the categorization of radioactive sources is mainly based on the element and the radiation level. Radioactive sources are categorized into five groups on a scale of 1 (most dangerous) to 5 (least dangerous) to human health (IAEA 2006). Radioisotopes in RDD are expected to typically include ^{90}Sr, ^{137}Cs, ^{226}Ra, ^{60}Co, ^{192}Ir, ^{75}Se, ^{170}Tm, ^{169}Yb, ^{252}Cf, ^{241}Am, ^{239}Pu, ^{241}Pu, etc.

Nondestructive analysis using gamma-ray spectrometry coupled with neutron detection is used to categorize the suspected radioactive material without disturbing the evidence (IAEA 2006). Portable sodium iodide detector-based handheld identifiers or portable high-purity germanium (HPGe) detector-based spectrometers are examples among others. Currently, HPGe coupled with neutron detector is being used for macroscopic characterization of special nuclear material (SNM), e.g., Pu materials in confiscated materials at the crime scene (IAEA 2006). To prevent the trafficking of radioactive materials, stationary gamma and neutron detectors are commonly being deployed at borders and ports (IAEA 2002b). For checking the instrument's performance in the field, small, radioactive sources should be accompanied by the instrument. For most of the NDA equipment, Th-impregnated mantle (used in lantern) is used as a check source in the field. ^{252}Cf for a ^{248}Cm source is required for calibration and performance verification of a neutron detector. The fundamental principles of radiation detectors and an overview are given in the reference (Knoll 2010).

Nuclear Forensic Sample Type, Collection, Storage, and Transport

In NF investigation, the type and nature of samples or pieces of evidence and their collection methodologies play an important role in the data quality and subsequent NF interpretation. The NF sample type will depend on the nature of the incident, i.e., pre-/post-detonation. In case of pre-detonation or confiscation of nuclear/radioactive material, the type of sample includes (a) intact nuclear or other radioactive material

and (b) radioactive-contaminated and radioactive-non-contaminated evidence/material for traditional forensic analysis. Similarly, during post-detonation, NF evidence will include (a) traces of nuclear/radioactive source or device (unexplored part), nuclear or radioactive debris, and associated contaminated and non-contaminated materials for traditional forensics which may include environmental, geological, biological, or packaging materials. During the collection of the radioactive evidence, responders should comply with the radiation protection measures. They should follow national rules for evidence collection which include scene documentation, a chain of custody procedures, sample labeling, etc. (IAEA 2006). Collection of both traditional forensic and nuclear forensic samples should follow appropriate timing without compromising any of the evidence. The tools commonly used for the collection of specimens include disposable gloves, spatulas, forceps, sticky tapes, razor blades, transfer pipettes, swipe papers, etc. Multilayer ziplock polythene bags with proper leveling can be used for collection of NF evidences, e.g., radioactive-contaminated specimen or associated transport materials like hair, soil, dust, paper, pollen, etc. (Moody et al. 2014). Many investigations require temporary storage place for the evidence, before transfer to forensic laboratory. In that case, sufficient security measures should be in place to prevent evidence tampering.

Many times, for bulk nuclear or radioactive material samples, the entire sample may be larger than the sample size requirement for nuclear forensic analysis. Therefore, there is a need for a subsampling prior to transport to a designated laboratory for analysis. Subsampling protocols require special consideration and methods to ensure subsamples are truly representative of the bulk material. During subsampling, appropriate caution should be taken to avoid cross-contamination without compromising any evidence (IAEA 2011a).

Laboratory and Analyses Requirement

In NF investigation, the type of samples and type of analyses are chosen based on the queries asked by the investigating authority. Depending upon the incident and available evidence, there will be requirements for different analytical laboratories and analytical expertise in different disciplines (IAEA 2011a). For example, specialized radiological facility for handling and characterizing bulk nuclear or other radioactive material along with the expertise and knowledge on nuclear fuel cycle technology for interpretation of results are required. Similarly, for characterization of evidences (contaminated with nuclear or other radioactive material), there is a requirement, for analytical capability and expertise for accurate and precise determination of specific radionuclides/isotopes in trace or ultra-trace quantity involving separation or isolation from the bulk matrix. Capability for analyses of small samples/particles along with traditional forensic expertise is necessary. For biological samples (e.g., urine, blood, hair, tissue, etc.), experience with bioassay analyses or blood dosimetry, and environmental (e.g., minerals, dust, pollen, etc.) or geologic samples, and experience with environmental and geological sample analysis and interpretation are also required.

The nuclear forensic analysis should be carried out in designated nuclear forensic laboratories recognized by the country. It should operate under a quality assurance plan. Laboratory should preferably have accreditation to an international quality standard (e.g., ISO 9001, ISO 14001, ISO/IEC 17025, OHSAS 34 18001) along with validated analytical methods, documented procedures, and manpower with demonstrated capabilities and expertise. It should have a license to receive and handle the nuclear and other radioactive material for bulk and microanalysis. The NF laboratory should have appropriate operational procedures to prevent cross-contamination between samples, environmental safety and health protocols, hazardous material handling and waste disposal, storage and physical protection measures, and most importantly the accounting and control of nuclear material (IAEA 2011a).

Analysis of Nuclear Forensic Signatures

Several analytical techniques are applied in NF for the analysis of different NF signatures (elemental, isotopic, physical, chemical, morphology, etc.) for deriving information mentioned in Table 2, and detailed description can be found in Kristo (2012); Straub et al. (2020); Moody et al. (2014); Stanley et al. (2013); Mayer et al. (2013); ITU (2003); IAEA (2011a); and Krunal (2014).

Not necessarily all the techniques should be applied simultaneously for a particular case study. Depending upon the information required and the nature, type, and quantity of the available evidence/sample, suitable techniques are to be selected for the analysis of required parameters. However, the analysis and selection of analytical methods should follow a proper sequence in order to derive important information within the requisite period. Analytical tools used for NF with a typical timescale for completion of analysis are described in IAEA Nuclear Security Series No. 2 (Rev.1), Implementing Guide (IAEA 2011a). Similarly, prioritization of nuclear forensic analysis plan is required for smaller size sample analysis. Mostly nondestructive techniques along with trace and microanalytical techniques for small-sized samples are advised before other analyses.

Physical and Microstructural Analysis

Visual inspection of a sample helps in the identification of the material and identifying marks and serial numbers and determination of shape, size, weight, and density, and even color can be a good indicator for deriving certain firsthand information regarding the seized nuclear or radioactive material. Information on sample composition and homogeneity can also be obtained viewing samples under transmitted polarized light. The surface roughness of the material can be measured by profilometry (Pajo 2001). Electron microscopes, through a focused beam of high-energy electrons, can make images on a very fine scale. Through microstructural fingerprint, information on topography, morphology, elemental composition, and crystallographic structure can be obtained. SEM is the most powerful surface

Table 2 Example of analytical techniques used for different NF signature analysis in U or Pu materials with forensic information

NF signature	Analytical technique	Forensic information
Physical characteristics (form, shape, size, density, morphology, appearance, etc.)	Particle size analyzer, radiography, profilometry, dimensional measurement, optical microscopy, SEM-EDS, TEM	Radioisotope
Radioisotope composition	HRGS, AS, LSC, ICPMS, TIMS	Category, intended use, reactor type
Uranium isotope ratio	HRGS, AS, TIMS, ICPMS, SIMS, RIMS, AMS	Intended use, enrichment
Plutonium isotope ratio	AS, TIMS, ICPMS, SIMS, RIMS, HRGS	Type of reactor, burn up
Minor constituents/impurities in bulk radioactive material (elemental, ionic, chemical, concentration patterns)	IC, ICPMS, ICP-OES, GD-MS, FTIR, Raman, GC-MS, XRF, NAA, XAS, XRD	Process history, geolocation
Stable isotope ratios (O, S, Sr, Pb, Nd)	IRMS, TIMS, MC-ICPMS	Geolocation, process history, ore formation age
Age	AS, ICPMS, TIMS	Production date
Particle/microanalysis	SIMS, AMS, FT-TIMS, μ-XRF, μ-Raman	Clandestine nuclear activity, post-detonation information, device design

SEM-EDS scanning electron microscope with energy-dispersive sensor, *TEM* transmission electron microscopy, *HRGS* high-resolution gamma spectrometry, *AS* alpha spectrometry, *LSC* liquid scintillation counting, *ICPMS* inductively coupled plasma mass spectrometry, *TIMS* thermal ionization mass spectrometry, *SIMS* secondary ionization mass spectrometry, *RIMS* resonance ionization mass spectrometry, *AMS* accelerated mass spectrometry, *IC* ion chromatograph, *ICP-OES* inductive coupled plasma optical emission spectrometry, *GD-MS* glow discharge mass spectrometer, *FTIR* Fourier-transform infrared spectrometry, *GC-MS* gas chromatograph-mass spectrometer, *XRF* X-ray fluorescence, *NAA* neutron activation analysis, *XAS* X-ray absorption spectroscopy, *XRD* X-ray diffraction, *IRMS* isotope resolution mass spectrometry, *MC-ICPMS* multi-collector inductively coupled plasma mass spectrometry, *FT-TIMS* fission track thermal ionization mass spectrometry, *μ-XRF* micro X-ray fluorescence, *μ-Raman* micro-Raman spectroscopy

imaging technique frequently used in NF analysis with excellent special resolution on the order of 1 nm (Hawkes 2013; Volland 2016). SEM coupled with energy-dispersive X-ray (EDX) or wavelength-dispersive X-ray (WDX) is used to map the abundance and spatial distribution of the elements in the sample. Sample preparation is relatively easy and got applications for powder samples or inhomogeneous samples in NF (Murakami et al. 2005). Transmission electron microscopy (TEM) makes use of the energetic electron beam that can pass through thin layers of the specimen. Using TEM ultrathin layers (~100 nm thickness) can be examined with higher magnifications (several million times higher) than SEM and can image extremely fine structures with sub-nanometer resolution (Anderson 1978). These techniques are extremely useful during investigation of nuclear activities through environmental monitoring and chemical analysis of post-detonation samples owing to the availability of very small-sized (submicron level) particles (Eriksson et al. 2005).

Chemical Analysis

Concentration and Isotopic Ratio Analysis of Radionuclides

For measurement of activity concentration and isotopic ratio of radionuclides in NF materials, different nuclear/radioanalytical techniques are used. The prominent radioanalytical techniques based on measurement of different radiation emission (alpha, beta, gamma, and neutron). For trace-level measurement, both alpha and mass spectrometries are mostly used. Radiochemistry, in combination with radioactive counting techniques and mass spectrometry, has the potential to measure very low levels of isotopes, down to femtograms. Also with selective detectors, isotopic ratio with sufficient accuracy and precision is possible and thereby finds enormous applications in nuclear forensic studies.

Radiometric Techniques in Bulk Matrices

A. *High-Resolution Gamma Spectrometry (HRGS)*

Gamma spectrometry plays the most important role in NF investigation where nuclear and radioactive materials are involved. Some radionuclides emit characteristic gamma rays in the range of few keV to many MeV which can be very well used for the identification of the radionuclide present and to estimate its concentration in the sample. The technique being nondestructive, portable, with minimal sample preparation requirement and field-deployable, is used for on-site categorization described in section "Nuclear Forensic Model Action Plan." However, this technique is less sensitive for the analysis of actinides as the abundance of gamma emissions is very low. With a well-shielded low background detector system and longtime spectra acquisition, it is possible to analyze even uranium isotopes. Mostly more sophisticated high-resolution gamma spectrometers (HRGS) are used.

To produce quality data of radionuclides in the sample for use as a nuclear forensic signature, it is necessary to ensure stringent quality control in terms of the procedures used for the gamma spectrometry measurement and subsequent estimation of activity data of radionuclides at the laboratory as well as for in situ measurements. For the qualitative analysis of radionuclides, mainly two types of calibrations are required, namely, energy calibration and resolution calibration. Proper calibration of the spectrometry system for the energy and resolution contributes to the accurate identification of radionuclides based on complex photo peaks in the gamma-ray spectrum. These calibrations are performed using gamma sources of known and accurate gamma energy emissions. The resolution calibration or shape calibration is done on the spectrometer using well-spaced and prominent gamma energy peaks from the radionuclides. The standard procedures for the energy and efficiency calibration of the high-resolution gamma-ray spectrometry system have been described in ANSI; ASTM; ISO (2007); Gilmore and Hemingway (1995); ANSI (1999); and ASTM (2003).

Gamma spectrometry technique is a nondestructive radioanalytical technique where accurate and reliable efficiency calibration of the detector system is essential for the assessment of radionuclide concentration in the sample. For the quantitative analysis of the gamma-ray spectrum for the estimation of radioactivity content in

various matrices, it is essential to have efficiency calibration of the detector for the gamma energy of the nuclide and geometry of the sample. In view of the wide energy range of gamma emissions from radionuclides, few keV to several MeV, it is recommended to carry out efficiency calibration in the applicable energy range. For the efficiency calibration, standard reference sources with known activity and gamma emission probability are recommended. Standard reference materials traceable to international standard organizations are recommended for this purpose. Different types of radionuclides are involved in the nuclear forensic scenario. They may be of long-lived or short-lived nuclides in various forms, gaseous, liquid, or solid forms. Hence, it is very difficult to get proper reference standards for all nuclides of concern to nuclear forensics or any other analytical work. Many times, it is not practical or feasible to have radionuclides in gaseous or liquid samples with a short half-life, as normally encountered in radionuclides commonly used in nuclear medicine (^{77}Lu, ^{131}I, ^{99m}Tc, etc.). In such situations, alternative methods are used for the calibration of the system for assaying these nuclides. Other radionuclides having nearby gamma energy and sufficiently long half-life can be used for this purpose. Alternatively, simulation techniques are also used for the generation of efficiency calibration of the HPGe detector system for all geometries and energies of concern. The detector response generated using various simulation codes is validated using available standard reference sources and further adopted for the other radionuclides of interest. A built-in simulation routine is introduced in spectrometry software for the efficiency calibration and estimation of activity in common geometries for all radionuclides of concern (Venkataraman et al. 2005).

The characteristic values from the gamma spectrometry measurements, such as the minimum detection limits and associated standard measurement uncertainty, are of importance in metrology in general and for nuclear forensics in particular (ISO 2010). The assessment of measurement uncertainty provides confidence in a measurement result; similarly the detection limit quantifies the lowest activity that can be detected with the technique. The series of documents from ISO describes the procedure, in the field of ionizing radiation metrology, for the calculation of these parameters in gamma spectrometry.

B. *Alpha Spectrometry*

Alpha spectrometry is a prominent radioanalytical technique used for the nuclear forensic analysis of samples where actinide radionuclides are involved. Radioactivity with alpha emissions is observed in actinide radionuclides. The energy of the alpha particles emitted is characteristic of the nuclide and can be very well used for the qualitative and quantitative analysis of radionuclides present in the sample. Alpha spectrometry is a destructive analytical technique, highly sensitive for alpha particles with energies in the range of 4–8 MeV. Silicon detectors (PIPS: passivated implanted planar silicon) are commonly used for the detection and energy measurement of alpha particles from radioactive sources. Sample preparation is tedious and requires radiochemical preparation of samples including dissolution, chemical separation, and source preparation. The most common practice is to separate the

elements radiochemically from the sample and electrodeposited in stainless steel planchets for spectrometry measurements. Suitable tracer activity (an isotope of the same element) is also introduced to account for the recovery of the various radiochemical procedures. It is also essential to maintain the detector and source under vacuum during the measurement to minimize the degradation of the alpha spectrum due to air attenuation.

Alpha spectrometry offers low detection limits due to relatively high detection efficiency and the low background of the detection system. In order to ensure the quality of the data obtained from the analysis, it is essential to follow proper calibrations of the spectrometry system for qualitative and quantitative analysis. ^{239}Pu (5.15 MeV) and ^{241}Am (5.48 MeV) are commonly used for energy calibration. The energy resolution of the spectrometry system is specified for the width of the 5.48 MeV peak of ^{241}Am in the spectrum. The detection efficiency is estimated using a standard reference source prepared in the same dimension of the sample by electrodeposition. Standard procedures recommended by various agencies are to be adopted in the laboratory to ensure the quality of the data from the alpha spectrometry measurement (ISO 2010; ASTM 2018).

The accurate estimation of activity by alpha spectrometry technique is essential for the radio chronology studies involving pairs of nuclides like ^{234}U-^{230}Th, ^{235}U-^{231}Pa, etc. The uncertainty in the activity estimation contributes significantly to the calculation of the age of the sample after processing. Very low detection limit can be achieved for Pu analysis, considering the relatively short half-lives of the plutonium isotopes (e.g., the half-life of ^{238}Pu is 87.7 y). However, Pu/Am separation in the samples prior to analysis should be done in order to avoid the overlap in the alpha spectrum. As measurement of ^{240}Pu and ^{239}Pu separately is difficult, since both are having very close alpha energy, therefore it is usually measured as a sum only. Atomic ratio of ^{240}Pu/^{239}Pu can be measured by using mass spectrometer.

C. *Active Interrogation Techniques for SNM Characterization in a Sealed Source*

Active interrogation technique is an active method used to detect and measure special nuclear material (SNM) mainly U and Pu in sealed conditions. Either photon or neutrons are used for the interrogation, and consequently the gamma rays or neutrons emitted by the fission of SNM are measured for mass and isotopic information.

Photon interrogation techniques include (i) photofission and (ii) nuclear resonance fluorescence (NRF). The presence of highly enriched uranium (HEU) in cargo has been detected by irradiating the container with high-energy gamma rays (6–10 MeV) from bremsstrahlung source. The fission signatures of the material can then be detected by using suitable detectors. Penetration through multilayer of material and, thereby, application in sealed condition are the advantages of this technique. Requirement of heavy shielding at the same time is the disadvantage of the technique. A photon source is used in nuclear resonance fluorescence (NRF) for active interrogation. When an electron beam from an accelerator bombards a tungsten converter, bremsstrahlung gamma rays are produced. The gamma rays interact

the sample material and generate excitations in the nucleus. During de-excitation, discrete energies characteristic of the nucleus are emitted in the order of several MeV, which can penetrate through many layers of material. However, the use of an intense 3 MeV source for enrichment information may require heavy shielding. Isotopic as well as enrichment information in SNM can be obtained by this technique. ^{235}U has been identified within the energy range of 1.0–2.5 MeV using a continuous bremsstrahlung source. NRF gamma peaks of statistical significance in ^{235}U and ^{238}U occur at 1733, 1815, and 1862 keV and at 2176, 2255, and 2468 keV, respectively. The ratios of these gamma-ray lines can be used to determine the uranium enrichment.

Neutron interrogation techniques include active well coincidence counters (AWCC), californium shuffler, and differential die-away (DDA) technique. AWCC can operate either in a thermal-neutron or fast-neutron mode. In thermal-neutron mode, a cadmium liner is placed in the well to assay small or low-enriched uranium (LEU) samples, whereas, after removal of Cd liner, in fast-neutron mode, large quantities of ^{235}U can be assessed. Americium-lithium (Am-Li) or a neutron generator can be used as the interrogating source, and counting of the induced fission reaction neutrons from the uranium is carried out using coincidence techniques. With the help of HPGe detector, 185 keV peak from HEU and the 100l keV peak from depleted uranium can be measured with the appropriate attenuation corrections, and the ratio of the peak areas gives the enrichment. The AWCC has a minimum detectable mass for ^{235}U of a few grams, whereas the differential die-away (DDA) technique can detect fissile materials in milligram quantity in dispersed form and can also be used for the determination of explosives in sealed conditions. Similarly, californium shuffler, an alternative to AWCC, uses ^{252}Cf sources to induce fissions. The energy of the neutrons from the californium is higher, 2.2 MeV, as compared with the 0.4 MeV Am-Li source used in the AWCC, which generates a high-precision measurement for bulk uranium. More details on these interrogation techniques are discussed in LA-UR-10-06l15P (De Simone et al. 2010).

Mass Spectrometry in Traces

Mass spectrometric (MS) techniques are important analytical tools for NF analysis. MS techniques can be used for both qualitative and quantitative characterization of radioactive elements especially actinides and fission products when they are present at very low concentrations. Both elemental and isotopic composition for bulk and microsample analysis with extremely high precision and accuracy are possible by mass spectrometry. Isotope dilution mass spectrometer (IDMS) can be used for quantification of radioactive elements at pico to femtogram level using an isotopic spike or through calibration against standard solutions. MS is having the best application in NF for the determination of isotope ratio with the highest precision and accuracy. In mass spectrometry, atoms or molecules are ionized into positive or negative ions using an ionization source. These ions are separated using a mass analyzer according to their mass-to-charge ratio. The intensities of the produced mass segregated ion beams are measured and plotted with respect to mass-to-charge ratio. The accuracy, precision, sensitivity, or selectivity of the measurement can be

enhanced by selecting a particular MS system with a particular ionization source, mass analyzer, or detector.

A. *Thermal Ionization Mass Spectrometry (TIMS)*

TIMS is the most commonly applied measurement technique for U, Th, and Pu concentration and isotopic composition with the highest accuracy and precision. The quantification (elemental assay) is also possible by IDMS (isotope dilution mass spectrometer, by addition of a spike, another isotope not present in the sample). In TIMS, a small amount of purified sample (some nanograms up to a few micrograms) is deposited on a metallic filament, consisting of refractory high-work function metal such as Re, Ta, Pt, or W. Ions are produced by resistive heating of the filament. For U samples, the U+ ions are formed and accelerated by applying a high voltage and subsequent mass separation (^{234}U+, ^{235}U+, ^{236}U+, ^{238}U+) using a mass analyzer which may be a magnetic sector or quadrupole along with Faraday cups or secondary electron multipliers for ion detection (Fedchenko 2015). Before the actual measurement, a sample preparation step is required. This involves a series of chemical separations of the element of interest from other elements using ion exchange or extraction chromatography (Hou et al. 2005; Aggarwal 2016). TIMS routinely measures differences in isotope mass ratios on the order of 1 ppm. Modern instruments with multi-collector detection enable the simultaneous measurement of the ion currents of different isotopes and provide isotope ratio data of high precision and accuracy which is of utmost requirement for NF analysis. In TIMS the accuracy in measurement is affected by both the mass discrimination observed in the ion optical system or ion detector and the mass fractionation that may occur during evaporation of the sample because of which the isotope ratio measurement may change with time. By different internal calibration techniques or by using isotopic standard reference materials with well-known isotopic ratios for an element, high accuracy can be achieved (Mishra et al. 2017). By applying the internal normalization methodology, correction for the isotope fractionation during analysis is made. Similarly, with interfering element correction methodology, isobaric interference can be avoided, and thereby high internal precisions in isotope ratio measurement (0.001% or better) can be achieved.

For calibration and routinely checking the performance of TIMS, certified reference materials (CRMs) are required. For Th, U, and Pu materials, a number of CRMs (certified for elemental content, isotope content, and isotope ratio abundance) are available from the Institute for Reference Materials and Measurements (IRMM), Geel, Belgium. A few reference materials like NBS-946, CRM 137/138/126A earlier known as SRMs 947 and 948, U-350, U-500, U-800, and U-850 are certified reference materials applied for the production date/age of the material in NF applications. Mostly these reference materials are prepared by mixing gravimetrically, highly pure and well-characterized metals or compounds. And some of them are also certified by data from well-calibrated equipment and techniques. TIMS is only suitable for elements with a low first ionization potential, and the laborious sample preparation prior to analysis limits its application. In addition to U, Th, and

Pu, TIMS has also been used for many other radionuclides, such as ^{41}Ca, ^{241}Am, ^{242}Cm, ^{126}Sn, ^{226}Ra, and ^{228}Ra, and also applied for measurement of stable isotope ratios like Pb, Sr, Nd etc., which are also very much required and reveal important information in NF (Hou and Roos 2008). TIMS can be used essentially for burn-up calculation, enrichment ratio, and age dating (Alamelu and Aggarwal 2016). Currently, the fission track-thermal ionization mass spectrometer is being used for actinide analysis in particle samples with high sensitivity.

B. *Inductively Coupled Plasma Mass Spectrometry (ICPMS)*

ICPMS is found to be the best alternative for estimation of both concentrations and the isotopic ratio of radioactive elements at trace level for NF applications. ICPMS is used for precisely quantifying radioisotopes as well as elemental impurities in bulk radioactive material like U or Pu material with detection limits ranging from 0.1 to 10 ppb (parts per billion) (Fedchenko 2015; Moody et al. 2014). ICPMS allows the sample in aerosol form through nebulizer techniques like a pneumatic nebulizer, ultrasonic nebulizer, or electrothermal vaporization, or laser ablation in an ion source operating at atmospheric pressure. Then, it follows the ionization of the aerosolized sample at a very high plasma temperature (5000–8000 K). These positively charged ions are then allowed to pass into a high vacuum region through an interface. Ion separation is done by using several types of analyzers and detection of these ions by Faraday cup or electron multiplier. Several calibration approaches can be used for accuracy in quantitative measurements by ICPMS. They include the use of pure standards obtained from Merck, Sigma Aldrich, matrix-matched standards from the National Institute of Standards and Technology (NIST, USA), or relevant certified reference materials, assuring traceability of the reported results.

The major limitation in the determination of radioisotopes using ICPMS is isobaric interferences of other elements at the same mass, e.g., ^{129}Xe with ^{129}I and ^{238}U with ^{238}Pu. With the use of high-resolution mass spectrometer (inductively coupled plasma sector field mass spectrometer, ICP-SFMS) with mass resolution up to 10,000, most of the isobaric interferences can be eliminated, thereby increasing the detection limit in the range of 10^{-12}–10^{-15} g/g. Similarly, using multi-collector inductively coupled plasma sector field mass spectrometer (MC-ICP-SFMS) with simultaneous detection of different isotopes, the isotopic ratio of different radionuclides can be measured with the similar precision and accuracy as obtained by TIMS (0.002–0.02%). MC-ICPMS also plays an important role in chronometry or age determination of the materials, measuring the parent-to-daughter ratio (^{234}U/^{230}Th or ^{239}Pu/^{235}U). For measurement of radio-chronometers, in comparison with other applicable techniques, such as alpha spectrometry and TIMS, ICPMS has the advantage of a better detection limit. In chronometry, the parent-to-daughter ratios of uranium materials are typically in the picogram to nanogram per gram range, thereby requiring systems with high sensitivity for their measurement. For analysis of trace impurities in U or Pu materials, e.g., rare-earth elements, trace-level activation, or fission products (e.g., indicating the use of reprocessed materials), or for the decay products of the host nuclear material (for age determination) prior to analysis,

chemical separation or pre-concentration is used to enhance the measurement capabilities. Chemical separation procedures from various matrices are described by Croudace and coworkers (Croudace et al. 2017). However, use of laser ablation (LA) as an ionization technique in ICPMS and minimal to no chemical pre-treatment are required, and can also be applied in the solid state. This offers isotopic measurement very precisely on very small areas of a sample and also provides additional information about sample homogeneity (Straub et al. 2020). However, in LA-ICPMS the accuracy and precision are limited by many factors, like sensitivity drift, elemental/isotopic fractionation, matrix effects, interferences, and most importantly the unavailability of appropriate matrix-matched reference materials. Therefore, it requires laborious and suitable calibration and correction methods for quantitative data. ICPMS is widely used for the determination of isotopes for U, Th, and Pu measurements and finds extensive application in NF for trace elemental impurity measurements as well as for isotope ratio measurements in seized samples and in samples of known origin (Keegan et al. 2014; Mayer et al. 2005; Wallenius et al. 2003). Apart from actinides, ICPMS is also used for the determination of other radionuclides like ^{79}Se, ^{90}Sr, ^{99}Tc, ^{129}I, ^{135}Cs, ^{210}Pb, ^{226}Ra, ^{228}Ra, ^{231}Pa, ^{237}Np, ^{241}Am, ^{243}Am, and ^{244}Cm in environmental and waste samples (Hou and Roos 2008).

C. *Secondary Ion Mass Spectrometry (SIMS)*

SIMS is used to provide both elemental and isotopic information of radionuclides even in micro-sized particles along with special and depth-dependent concentration of the constituent of interest on the surface of solid materials. It has got excellent application in nuclear safeguards as well as nuclear forensics (e.g., post-detonation scenario) when only small amounts of sample (particle) or inhomogeneous samples are to be investigated (Betti et al. 1999; Tamborini et al. 2002). In SIMS a beam of ions with high energy ranging from 0.5 to 20.9 keV, such as O^-, O_2^-, or Cs^+, is bombarded on the surface of the sample to sputter off atoms. A fraction of the sputtered species is emitted as electrically charged particles as secondary ions. These ions pass through mass analyzer (magnetic sector field or TOF or quadrupole analyzers) and are finally detected by the detectors. The main advantage of SIMS is its capability for microparticle analysis. In NF there are many cases which require analysis of U particles to complement the more traditional bulk measurements. Particle analysis is very challenging. Firstly, the particle is extracted (e.g., from cotton swipe) through vacuum impactor in a clean room; then, extracted particles are deposited on a graphite planchet through homogeneous dispersion. SIMS performs the particle of interest screening among the deposited particles in a short time with a high detection capability. Both the exact location of the particle (U or Pu) and the first estimate of their enrichment are possible by this technique (Hedberg et al. 2011). Almost nil or very limited CRMs are available for particle actinide analysis. Particles produced from certified reference materials (U005, U010, and U030-NBS) with known ^{234}U/^{238}U and ^{235}U/^{238}U mass ratios are employed to check the instrumental response during the analysis (Betti et al. 1999).

D. *Resonance Ionization Mass Spectrometer (RIMS) and Accelerator Mass Spectrometer (AMS)*

Measurement of very low isotope abundances or ultra-trace quantities of a radioactive isotope in the presence of huge excess of matrix material poses a big challenge in nuclear forensic analysis. A typical example is the measurement of ^{236}U and ^{233}U in the uranium matrix. For this measurement, discrimination of the interfering masses is required which may arise due to a variety of molecular and atomic species and also due to tailing of neighboring masses, nearly at the same mass position as the isotopes of interest. In resonance ionization mass spectrometer (RIMS), the ionization of atoms can be done through optical excitation of atoms by resonant absorption of laser light in a stepwise process followed by the photo-ionization of the excited atom. Combined with selective and nearly background-free detection of the resulting photo ions proves RIMS is an efficient technique to address such difficult challenges (Erdmann et al. 2008; Trautmann et al. 2004). Similarly, accelerator mass spectrometer (AMS) offers adequately high abundance sensitivity for measuring extremely small isotope ratios. The presence of ultra-trace amounts of ^{236}U and ^{239}Pu even in natural uranium through measurement is possible by the use of AMS (Buchholz et al. 2007; Steier et al. 2008).

Analysis of Minor Constituents in Bulk Radioactive Materials

Activation Analysis

A. *Neutron Activation Analysis (NAA)*

NAA is a nondestructive, nuclear analytical technique used to analyze minor/trace elements in a matrix based on atomic number, neutron cross section of the isotope, and its abundance. The elements present in the sample are excited by nuclear reaction, through irradiation with neutrons (from a reactor) and thereby the radioactivity is induced. Radiation counting techniques (e.g., HPGe) are used for activity measurement. Following the bombardment completion, the measurement of characteristic radiation is indicative of the elements of interest. Multielement analysis with excellent sensitivity in ppb level and high selectivity are the major advantages for this technique. No time-consuming separation procedures are required. However, one limitation of this technique is the requirement of a nuclear reactor/neutron source for sample activation, and being a comparator technique requires matrix-matching reference materials for quantification.

B. *Particle-Induced Gamma-Ray Emission (PIGE)/Particle-Induced X-Ray Emission (PIXE)*

For identification of elemental signatures in samples containing uranium of different enrichments, both particle-induced X-ray emission (PIXE) and particle-

induced gamma-ray emission (PIGE) methods are used for NF analysis. The samples are irradiated by 3–5 MeV proton beam. The characteristic X and gamma rays are measured using high-purity germanium (HPGe) detectors. Quantification is done by using certified comparator standards (Apostol et al. 2017). Sensitivity of the analysis for different elements using these techniques is in the order of ppm to percentage level.

Analysis Using X-Ray-Based Techniques

A. *X-Ray Florescence*

X-ray fluorescence spectrometry (XRF) is a rapid and nondestructive technique for the determination of elemental composition in nuclear material and is based on the detection of characteristic X-rays. When a sample is irradiated with a collimated X-ray beam, electrons from the core orbitals are promoted to valence orbitals, causing the prompt emission of fluorescence X-rays as the empty core orbitals are filled by other electrons. The characteristic energies of these fluorescence X-rays are element-specific, and the resulting spectrum can be interpreted to quantify multiple elements in a matrix. XRF techniques are nondestructive, require minimum sample preparation, are highly sensitive (parts per billion), and with rapid data acquisition are an excellent analytical tool for elemental characterization (West et al. 2010) and found enormous application in nuclear forensics requiring only micrograms of material (Donohue 2002; Charlton et al. 2009). Direct sample irradiation allows for minimal sample preparation and portable instrumentation for field deployment (Tsuji et al. 2005). Handheld portable XRF spectrometers are used for on-site detection of RDD components (Steeb et al. 2016). This technique tends to be hindered by the matrix effect, which must be corrected by using matrix-matching SRMs. Total reflection X-ray fluorescence spectrometry (TXRF) for ultra-trace element analysis at the femtogram level is used.

B. *X-Ray Diffraction*

In addition to elemental and oxidation state analysis, X-rays are also used to study the phase and chemical structure of materials by X-ray diffraction (XRD) (Zolotoyabko 2014). For identification of the chemical structure of crystalline material, X-ray diffraction (XRD) is used. When an X-ray beam interacts through ordered crystalline lattice, a characteristic X-ray diffraction pattern is produced through constructive and destructive interference. This will depend on the spacing of the lattice, the wavelength of the X-rays, and the angle of incidence of the X-ray beam. However, this technique cannot be applied to amorphous (noncrystalline) material. XRD has got a wide application in nuclear material characterization, because of nondestructive and quick analysis (Teterin et al. 2016). Soil sampling near a nuclear site, followed by analysis by XRD/XAS, could be used for finding out any clandestine activity like U enrichment or fuel reprocessing by measuring the concentration and chemical form of trace actinides in soil.

Nuclear Forensic Interpretation

The results from nuclear forensic interpretation provide technical conclusions to decision-makers. This is mainly carried out by evaluation of analytical results from a suspected sample through validated material characteristics or signatures. Through sample signature, a potential linkage is established between sample and people or place or process. Validated analytical methods, validated signatures, and most importantly the accurate and precise characteristic data are of utmost importance to generate high-confidence technical conclusions. A pictorial representation of various steps involved in nuclear forensic interpretation is presented in Fig. 2.

Analysis of a single signature may not be sufficient to answer all the relevant questions raised by the investigating agency. Many times multiple signature analyses in total may increase the specificity of the interpretation results. Validated signatures considered in NF analysis are broadly classified into two types, i.e., comparative signature and predictive signature.

Comparative Signatures

Comparative signatures are basically material characteristics of one or more known samples which are compared with unknown samples. For fruitful interpretation, a nuclear forensic database, on hundreds or thousands of known samples or nuclear forensic sample archives, is required along with suitable analytical tool. The nuclear forensics database mainly comprises of a complete set of validated material

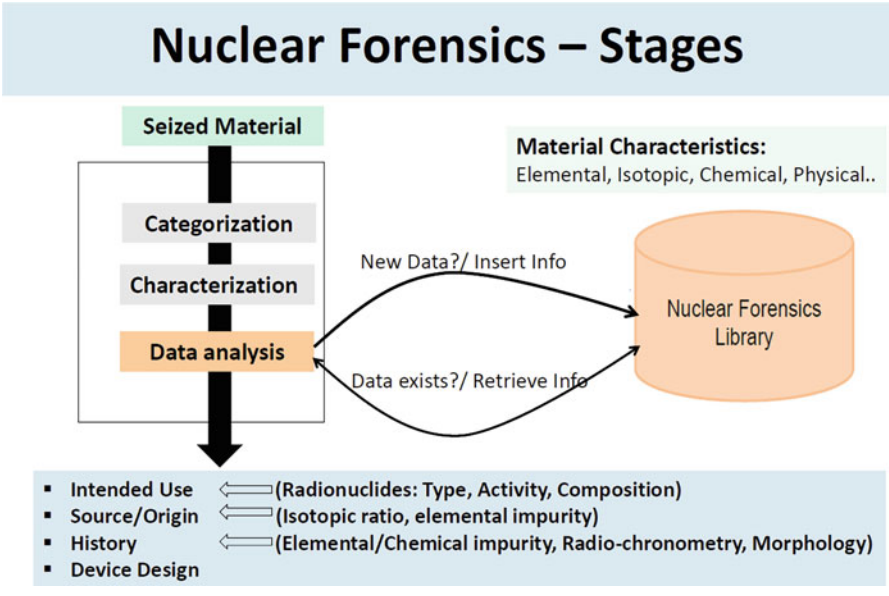

Fig. 2 Various steps involved in the nuclear forensic interpretation process

characteristics of the known samples across different stages of nuclear fuel cycle and also across the globe. Therefore, the accuracy in the interpretation result by this comparative approach will very much depend upon validity and comprehensiveness of the generated data included in the database and/or the sample archive.

During any transboundary incident, involvement/assistance from international agencies in nuclear forensics will be a vital requirement. This will again demand for accessibility toward international nuclear forensic databases. Therefore, development of own nuclear forensic databases is very much advantageous. All countries should have high confidence in each other's databases. Also, databases should comprise of high quality and the right materials characteristics for nuclear forensic purposes. Therefore, the international agencies like ITWG (International Technical Working Group for Nuclear Forensics) through multilateral or through bilateral programs are engaged to drive standardization of methods, techniques, standards, reference materials, etc. in order to provide uniform platform and harmonization in nuclear forensic practices throughout the globe. Nuclear forensics being a new discipline, international exercises, or round-robins are absolutely crucial and advantageous for developing and testing the comparability of nuclear forensic data acquired by different countries.

Predictive Signatures

Apart from comparative signatures, predictive/derived signatures from some other measured parameters are also used for nuclear forensic interpretation. A detailed understanding of the physical or chemical mechanisms responsible for producing the signatures in the material and subsequent modeling of those mechanisms for derivation of predictive signatures are very important. Predictive signatures mostly rely on our knowledge base and upon scientific inference; that's why it is more challenging than the comparative approach. These signatures will be very important, when the materials are from historical processes or tightly held materials from foreign countries, where availability of similar kind of known samples will be rare for comparison. However, significant effort is required not only to develop but also to validate the capability.

For example, the source identification of a uranium ore concentrate (UOC) through predictive approach will rely on the geochemistry of the precursor ore from which it has been produced. It will involve the interpretation from the signatures measured in a sample of interest to determine characteristics associated with both the parent ore and the mining and milling processes used to produce the UOC from the ore (Švedkauskaitė-LeGore et al. 2008; Varga et al. 2011). For example, the relative concentration distribution of the rare-earth elements (REE) can be typical of the type of ore body from which the uranium was mined (Varga et al. 2010). New predictive signatures are also being developed by establishing improved understanding of the signature and developing sensitive methodology for their measurement. Now using sensitive mass spectrometers, even natural variations in the $^{238}U/^{235}U$ ratio, once thought to be invariant in nature, can be used as an effective NF signature. The depositional environment of an ore appears to strongly influence the $^{238}U/^{235}U$ ratio with low-temperature ores having higher ratios than deposits formed at high

temperatures (Richter et al. 1999; Brennecka et al. 2010). Another important predictive signature applied in NF is radio-chronometry, the determination of the time since last purification using a technique commonly known as "age dating" (Wallenius and Mayer 2000; Morgenstern et al. 2002; Williams and Gaffney 2011). Radionuclides linked to one another by radioactive decay have relative concentrations, which can be calculated by simple laws of radioactive ingrowth or Bateman equation (Moody et al. 2014). Accurate age dating relies on several assumptions. Precise determination of parent-daughter activity concentrations is very important for accuracy in age dating.

QA/QC in Nuclear Forensic Data and Interpretation Methodology

Radiation metrology has got a significant role in NF analysis, since the analytical data and the subsequent results from nuclear forensic interpretation would support as evidence for criminal prosecution or can affect international assessments of proliferation, nuclear/radiological threat, or terrorism. Therefore, it is highly recommended that the NF data and their interpretation should be of high credibility. Validated procedures/methodologies should be followed throughout the process. Proper quality assurance (QA) and quality control (QC) procedures should be followed in each and every stage within the nuclear forensics laboratory to ensure confidence in the analytical data. Quality systems, such as ASCLD International, ISO 9000 (ISO 2000), and ISO 17025 (ISO 1999), should be implemented in the NF laboratory. Proper documented procedures should be established for sample control and analysis, which will not only improve repeatability and traceability of the results but also provide a mechanism for continuous quality improvement. Analytical instruments should be under a relevant statistical process control (SPC) program wherever feasible (IAEA 2006). All analytical results should reveal the measurement precision, and any potential sources of error not reflected in the precision should also be indicated or documented. The field of potential sources or processes that produced the material could be narrowed with an increase in the precision of a given measurement. The confidence and specificity often increase with more independent measurements. Sensitivity of chosen analytical technique will be vital in case of small-sized sample analysis. Similarly, for large quantity/bulk of material, the analytical techniques should be as sensitive as possible because trace species are often the significant components of a signature. With the analytical sensitivity, the susceptibility for cross-contamination also increases which necessitates strict control measures.

Challenges in the Quality Assurance of Nuclear Analytical Measurements in the Nuclear Field

For developing, testing, and validating nuclear and radioanalytical methods for quantification of radionuclides, availability of certified reference materials (CRMs) is of utmost requirement. The use of certified reference materials (CRMs) is a critical component in any QA program and is very essential for the accurate and precise

measurements and assessment of the quality of any acquired analytical data. Such matrix-matched CRMs are unfortunately not available for most investigations relevant to the nuclear domain. The nuclear CRMs present particular challenges for both users and producers (Neacsu 2020; Inn et al. 2013). Also CRM production requires specialized nonexistent facilities and is time-consuming, labor intensive, and costly. The lack of matrix-matched certified reference material can be overcome by comparing the analytical results obtained from different instruments whose analyte detection is based on different physical principles. Additionally, inter- or intra-laboratory comparison exercises or simulation models can also help in gaining confidence in the robustness of the developed method. In the absence of CRMs for radio-chronometer, a methodology of comparing with the age of a known material can be developed (Prabhath et al. 2022). The uncertainty associated with the response of a detection device in nuclear analytical techniques is mainly contributed from calibration standard, from the curve fitting process, and from the model used to describe the response function. Radiation detection devices and associated electronics might show saturation effects and dead time at high count rates induced by high-intensity radiation. The saturation and the dead-time effects are usually compensated, but the compensation will still introduce some uncertainty, which has to be evaluated. Many times, there is a requirement of measuring low activity samples in the presence of background; the uncertainty in quantification for the results close to detection limit requires special attention.

Challenges and Requirements in Nuclear Forensics

Nuclear forensics has tremendous potential to not only respond but also prevent nuclear/radiological incidents arising due to use of nuclear/radiological materials out of regulatory control. However, its practice is limited to a few countries only, since many challenges are associated with NF analysis. State-of-the-art instrumentation, identification of undisputed signatures, extremely high fidelity measurement capabilities to withstand legal scrutiny, strong metrology backbone, availability of CRMs, complexity in the data interpretation, nonavailability of reference database, and the required high-level expertise limit its application only to a few laboratories throughout the world. There is a strong requirement of standalone methodology, dedicated R&D on NF signature development, advanced nondestructive and destructive analytical techniques for evidence analysis, urgent CRMs to support state-of-the-art measurement capabilities and metrology infrastructure, QA/QC programs for data analysis, accredited laboratories, and proficiency testing capabilities. It is also very crucial to develop a national nuclear forensic database and validated analytical tool for accurate and precise interpretation.

Abstract

This chapter briefly introduces a prelude that encompasses the history of measurement and measurement uncertainty, tracing the development of modern metrology from ancient Egypt, to the early renaissance with the advent of calculus by Newton, to the late renaissance with the advent of statistics by Laplace, to the dawn of the industrial age with Kelvin, to the post World War II age of Kline and McClintock, and finally to the introduction of the Guide to the Expression of Uncertainty in Measurements also known as the GUM and its supplements in the early part of the twenty-first century. The utility and functionality of the GUM, both with its current limitations and its future outlook for the evolution of measurement uncertainty, are contextualized and discussed.

Introduction and Historical Perspectives

Measurement analysis inclusive of uncertainty analysis has within available historical records origins that are traceable to technical work undertaken by the ancient Egyptians in the course of the construction of the pyramids. In this time period, length measurements were primarily anthropomorphic based, mainly in terms of the human anatomy of the prevailing reigning pharaohs of the time-incorporating standardized units such as the pharaoh's finger size, palm size, hand size, foot size, and shoulder size among other elements of human anatomy, such as a cubit being the distance from the elbow to the tip of the middle finger. Extending these length "standards" which were "calibrated" from time to time as the pharaoh's anatomy changed with age, medical and health circumstances. The derived units were used such as the kha and setat for the measuring of areas of land in pyramid constructions, farms, and other agricultural locales where conversion factors were utilized such as measuring a square khet as being a square of 100 by 100 cubits. in area. Similar extensions of length and area units were introduced to measure volumes of quantities such as for water, wine, and grain in terms of cubic cubits incorporating derived volume units of varying magnitudes such as *khar*, *heqats*, and *henu*. As a result, all dimensional measurements in ancient Egypt were in essence "traceable" to prevailing contemporary length standards. Weight measures by contrast used physical standards such as the *deben*, *qedet*, or *shematy* which were defined in terms of artifact standards constructed with copies of physical stones/rocks that were measured and calibrated against the prevailing mass standards using simple lever arms and scale balances, while time measurements were determined for longer periods in terms of the lunar cycles and for smaller intervals using simple water clocks. Consequently, in ancient times there existed a coherent mass/length/time system of measurements that is essentially an artifact system equivalent to the more recent artifact system of the centimeter/gram/second (CGS) of the nineteenth century and subsequently the meter/kilogram/second (MKS) system of units from the turn of the twentieth century which preceded the eventual adoption of the International System of Units (SI system) that was established and is maintained by the General Conference on Weights and Measures (CGPM), where the uncertainty of weights and related measures was based on integer increments of the underlying discrete units of measurements prior to the later inventions of arithmetic and mathematics.

With the passage of time, this ancient situation for measurements and measurement uncertainties largely prevailed until the period of the later renaissance in the late 1600s when Isaac Newton remarked in Book III of *Principia Mathematica* in his attempt to analyze and reconcile differing and inconsistent experimental observations of comets in 1680 for the orbital calculation of a parabolic trajectory of a comet as reported by (Stigler 1986) that:

> This being a problem of great difficulty, I try'd many methods of resolving it; and several of those problems, the composition whereof I have giv'n in the first book, tended to this purpose. But afterwards I contrived the following solution, which is something simple.

These earlier astronomical observations ultimately led to the discovery of calculus by Newton and the later adoption of the method of least squares in the seventeenth and eighteenth centuries by Pierre-Simon Laplace in his five-volume monograph *M'ecanique c'eleste* (Celestial Mechanics) and other contemporary philosophers and scientists for the fitting and quantification of experimental measurement uncertainties. During this period, Lord Kelvin remarked in the context of scientific measurements in a 1883 lecture to the Institution of Civil Engineers that (Kelvin 1891):

> When you can measure what you are speaking about, and express it in numbers, you know something about it.

Consequently, the use of statistics as a branch of mathematics with the invention of calculus underpinned the majority of scientific studies of metrology uncertainty prior to the twentieth century from the mid-1800s to the early 1900s prior to World War II, most notably in astronomy- and physics-related studies for the fitting of experimental data to measurements in which it was desired to determine an optimal selection of equation parameters and their associated uncertainties. This area of work, now known as statistical regression, is considered a subset of metrology uncertainty and includes the fitting of uncertainty quantification of straight-line parameters as discussed in more detail by (Ramnath 2020). In subsequent years, the use of statistical regression as a branch of measurement uncertainty has been extended to nonlinear and multivariate measurement models where the uncertainties are incorporated as accuracies into the model equation parameters for statistical consistency.

After World War II, a key development in the concept of measurement uncertainty was developed by Kline and McClintock (1953) in their pioneering work that incorporated the use of statistics that extended the work by the American Society for Testing Materials that had hereto relied on controlled multiple sample experiments, i.e., repeat experimental measurements where the uncertainties were determined through statistical standard deviations of all relevant quantities in a measurement. This fully statistical approach to uncertainty is limited in the sense that not all data can be experimentally observed and quantified through repeated tests and measurement observations. Key conceptual aspects introduced by Kline and McClintock were the introduction of probability distributions for measurements and in the reporting of measurements with uncertainties in terms of an expected value with an uncertainty expressed in terms of odds of the form $m \pm w$ (b to 1), e.g., a pressure could be quoted as 50.2 ± 0.5 psia (20 to1) which signifies that "*This states that the best value for the pressure is believed to be* 50.2 *psia and the odds are* 20 *to* 1 *that the true value lies within* ± 0.5 *psi of this best estimate.*" Their final result stated that:

Theorem 3. *If R is a linear function of n independent variables, each of which is normally distributed, then the relation between the interval for the variables* w_i, *and the interval for the result* w_R, *which gives the same odds for each of the variables and for the result is*

$$w_R = \left[\left(\frac{\partial R}{\partial w_1} w_1\right)^2 + \left(\frac{\partial R}{\partial v_2} w_2\right)^2 + \cdots + \left(\frac{\partial R}{\partial v_n} w_n\right)^2\right]^{\frac{1}{2}}.$$

The above formula is essentially the historical predecessor and connection to modern Guide to the Expression of the Uncertainty of Measurement (GUM) (BIPM, IEC, IFCC, ILAC, ISO, IUPAP, and OIML 2008a) which specifies the measurement uncertainty for a univariate measurand $Y = f(X_1, \ldots, X_N)$ and which incorporates refinements such as correlation and nonlinear effects, such that the combined uncertainty $u_c(y)$ for sampled values for Y and $X_1, \ldots, X_N$, consistent with the underlying probability density functions (PDFs), is of the form

$$u_c^2(y) = \sum_{i=1}^{N} \left(\frac{\partial f}{\partial x_i}\right)^2 u^2(x_i) + 2\sum_{i=1}^{N-1}\sum_{j=i+1}^{N} \frac{\partial f}{\partial x_i}\frac{\partial f}{\partial x_j} u(x_i, x_j) + \sum_{i=1}^{N}\sum_{j=1}^{N} \times \left[\frac{1}{2}\left(\frac{\partial^2 f}{\partial x_i \partial x_j}\right)^2 + \frac{\partial f}{\partial x_i}\frac{\partial^3 f}{\partial x_i \partial x_j^2}\right] u^2(x_i) u^2(x_j)$$

where $u(x_i, x_j) = r(x_i, x_j)u(x_i)u(x_j)$ is the covariance term and $r(x_i, x_j)$ is a dimensionless correlation.

Limitation in the above formula is the requirement that all relevant terms follow Gaussian distributions; however, this has subsequently been mitigated by the GUM Supplement 1 (BIPM, IEC, IFCC, ILAC, ISO, IUPAP, and OIML 2008b) which allows for non-Gaussian PDFs for $X_1, \ldots, X_N$ as independent distributions $g_{X_1}(\xi_1), \ldots, g_{X_N}(\xi_N)$ where ξ_i, $i = 1, \ldots, N$ are random variables associated with $X_1, \ldots, X_N$ or alternately a joint PDF $g_{X_1,\ldots,X_N}(\xi_1, \ldots, X_N)$, and in the extension with the GUM Supplement 2 (BIPM, IEC, IFCC, ILAC, ISO, IUPAP, and OIML 2011) for multivariate models $\mathbf{Y} = \mathbf{f}(\mathbf{X})$ where $\mathbf{X} = [X_1, \ldots, X_N]^\mathsf{T} \in \mathbb{R}^N$ and $\mathbf{Y} = [Y_1, \ldots, Y_m]^\mathsf{T} \in \mathbb{R}^m$ for $N, m \in \mathbb{N}$, where the GUM Supplement 1 and GUM Supplement 2 extend the earlier GUM through the use of the Monte Carlo Method (MCM).

While the GUM and its supplements have significantly extended the techniques of measurement uncertainty, there are nevertheless still significant mathematical and statistical issues that must still be addressed, some of which will be explored in this handbook in various chapters.

Contemporary Perspectives and Current Limitations with the GUM

Within the current GUM framework, uncertainties are delimited into *Type A* uncertainties which adopt a statistical framework and *Type B* uncertainties which adopt a probabilistic framework. As a result, the current GUM framework mixes frequentist

statistics concepts and Bayesian statistics concepts and is therefore mathematically inconsistent.

For Type A uncertainties, a quantity X is usually sampled a few times and the arithmetic average $\overline{X}$ calculated, along with the experimental standard deviation of the mean (ESDM) σ which is estimated in terms of standard formulae, so that the expected value μ is estimated with $\overline{X}$ and the standard deviation is similarly estimated with the ESDM along with an associated "degrees-of-freedom" ν. Due to this approach which uses a frequentist statistics approach (all quantities are based on observed measurements or frequency statistics), the uncertainties obtained with Type A evaluations are themselves always uncertain.

Considering, on the other hand, type B uncertainties, in this case it is not possible to use frequency statistics since, for example, no repeat experimental measurements are possible. For this situation, a metrologist makes a subjective assumption based on expert knowledge as to what the probability density function $g_X(\xi_X)$ for the quantity X is and interprets the probability as a degree of belief. Then using knowledge of the analytical functional form of the PDF and its associated formula parameters, the mean of X and its variance are calculated using the available information. A consequence of this approach is that the calculated mean μ and standard deviation σ are exact and have no associated uncertainty. The inconsistency within the GUM is therefore that the degrees-of-freedom ν_i are always attached to terms X_i and that the measurement uncertainty scheme is essentially an ad hoc procedure that attempts to imperfectly align Type B estimates with Type A estimates. Consequently, there is then a fundamental and conceptual mathematical statistical inconsistency in how the GUM modeling framework for uncertainty analysis is formulated; however, this inconsistency has no practical effect in a majority of practical measurement uncertainty cases as discussed and elaborated by (Bich et al. 2016).

A more serious limitation with the GUM is in the calculation of the expanded uncertainty obtained by multiplying the standard uncertainty $u(y)$ by a numerical factor k and where $2 \leq k \leq 3$ according to the GUM. Two issues complicate this calculation, namely, i) the shape of the output PDF for Y is unknown particularly for the tails of the distribution, and ii) the standard uncertainty itself is also unknown (because it incorporates type A uncertainties as inputs). At the present time of writing within the GUM uncertainty framework, the only way out to resolve this conundrum is to make the assumption that in most practical cases that the output PDF for Y will be a scaled and shifted Student's t-distribution, to then use either the Welch-Satterthwaite formula for uncorrelated terms or alternately the extended Welch-Satterthwaite formula for correlated terms, and to determine the effective degrees of freedom ν_{eff}. Challenges with this assumption are that a) there should be many independent inputs $X_1, \ldots, X_N$ with N large, say $N \geq 30$, for the overall behavior of $Y = f(X_1, \ldots, X_N)$ to converge to a Gaussian distribution (if N is small, then Y may be distinctly non-Gaussian and hence cannot be approximated with a Student's t-distribution), or that b) all the inputs for X_i should themselves be actual Gaussian distributions (and not approximations of Gaussian distributions with say

square or triangular distributions and transformation mapping approximations using scaling conversion factors).

A possible remedy to address these inconsistencies within the GUM is to change the way Type A uncertainties are incorporated by using nonstatistical tools by, for example, using the principle of maximum entropy and Baye's theorem that would then be able to yield a scaled and shifted Student's *t*-distribution. Another alternative is to simply forgo the original GUM which uses mixed frequentist statistics and Bayesian statistics, and only use the GUM Supplement 1 for univariate measurement uncertainty analysis or the GUM Supplement 2 for multivariate measurement uncertainty analysis as both of the GUM supplements use a wholly Bayesian statistics framework and are fully mathematically consistent.

Current research efforts are presently in progress by scientists and statisticians working in international bodies such as the BIPM working groups and various international National Metrology Institutes and national measurement laboratories to refine and modernize both the GUM as well as the GUM supplements to adopt a wholly Bayesian statistics modeling framework for mathematical consistency. Until such time that the BIPM publishes a new revised GUM for the international scientific and engineering community, the present recommendation for high-accuracy measurement uncertainty analysis is to use the Monte Carlo Method (MCM) as documented in the GUM Supplement 1 and GUM Supplement 2 for performing advanced uncertainty calculations.

Future Outlook and Anticipated Developments with the GUM

A new development by (Cox and van der Veen 2021) explores why correlation/covariance effects must always be considered even when correlations are missing or ignored through, for example, assuming them to be automatically zero. It is shown, using an example of interpolation of chemical pH values, that missing/ignored correlations can lead to poor decisions or logical absurdities, as interpolated value uncertainties may be erroneously smaller than known value uncertainties at specified temperatures if correlation effects for pH values at different temperatures are ignored. Recommendation for addressing this issue is to use a vector-matrix formulation for incorporating correlation effects either with the GUM supplement or using a covariance matrix as recently reported by (Ramnath 2022), and it is anticipated that future uncertainty analysis work will slowly migrate from spreadsheet-based calculations and increasingly incorporate modern scientific software such as Matlab, Python, etc. which can more fully and easily perform vector-matrix calculations for more advanced analysis on measurement uncertainty calculations.

For metrology problems in which the GUM framework is not applicable, the GUM supplements may conveniently and easily be used as an alternative approach for measurement uncertainty; however, the limitation with the GUM supplements is that they are not able to incorporate additional measurement uncertainty information. For this situation, a full Bayesian statistics approach using Markov chain Monte Carlo (MCMC) methods is discussed by (Klauenberg and Elster 2016) which

presents the use of the Metropolis-Hastings algorithm as a useful tool in which additional information such as the posterior shape of the measurement output may be incorporated to refine the uncertainty analysis. This approach is particularly useful in which the measurement model may be very complicated in, for example, systems defined by partial differential equations and in which it is computationally expensive and impractical to perform many simulation events in a traditional GUM supplement uncertainty calculation. An example of the potential application and utilization for the combined use of the GUM supplements with the MCMC method for advanced uncertainty analysis is in the use of "virtual laboratories" where a system or systems of PDEs are numerically solved to study the measurement system. It is anticipated that in the future with increasingly available and cheap cloud-based computational power this synthesis of techniques will increasingly lead to a widespread adoption of advanced measurement uncertainty that utilizes the underlying physical and chemical laws of nature for ab initio simulations from first principles.

Summary of the Section

The section on Advanced Techniques in evaluation of Measurement Uncertainty discusses the various technical aspects pertaining the evaluation, analysis, and prediction of measurement uncertainty using the LPU, MCS, and Bayesian approach. The chapter presented by Ramnath deals with the methodology of formulation and implementation of Monte Carlo simulations in order to calculate uncertainties of measurements that are modeled in terms of partial differential equations. It concludes that the Monte Carlo approach is conceptually straightforward to implement partial differential equation solvers for both low-dimensional as well as high-dimensional models provided the model inputs can be suitably sampled and introduced into the solver/postprocessor to generate discrete output statistical data. The chapter by Gupta, Rab, and Garg presents the various distribution functions used in calculation of measurement uncertainty and the technical attributes associated with various techniques like LPU, Monte Carlo Simulation, and Bayesian approach. The chapter presented by Kalina, Vidnerová, and Soukup describes and discusses selected nonstandard statistical techniques for analyzing measurements, or in fact selected classes of advanced available statistical tools. This chapter gives a warning that linear regression performed on data contaminated by measurement errors yields biased estimates and requires specific estimation tools for the so-called measurement error model. The chapter presented by Hawam A A suggests that GUM uncertainty framework is the most popular as it is simple, straightforward, and easy to implement in both the industrial and scientific field, while the Monte Carlo simulation is much more complex and cannot be implemented by hand. However, it has become a necessity if the measurement model has a great deviation from linearity to the extent that the GUM framework becomes inaccurate due to its inherent linear approximation. The chapter by Rao C V gives an overview of measurement uncertainty analysis, with a focus on modeling. The chapter presented by Rab et al. shows application of contemporary techniques of evaluation of measurement uncertainty in

digital pressure transducer (DPT) as a case study. It highlights a very important aspect about the measurement models which must be documented, in that the documentation should be written in a way such that other metrology professionals who are not necessarily experts in the field may understand it.

Abstract

Uncertainty quantification in metrology is formally undertaken using the Guide to the Expression of Uncertainty in Measurement (GUM) in all major industrial, commercial and national measurement laboratories in order to model and predict measurement accuracies of equipment, instruments and processes in systems. Although model complexity may formally encompass explicit, implicit, univariate and multivariate measurement equations, in a majority of cases algebraic models are the predominant mathematical formulation for many practical calibration systems. Due to this prevailing condition, many metrology practitioners are unfamiliar with how the GUM supplementary guides for Monte Carlo simulations may be usefully applied and extended to formally determine uncertainties in metrology systems modelled in terms of partial differential equations. The objective of this chapter is to introduce to the reader the methodology of how to formulate and implement Monte Carlo simulations in order to calculate uncertainties of measurements that are modelled in terms of partial differential equations.

Introduction

The Guide to the Expression of Uncertainty in Measurement (GUM) (BIPM, IEC, IFCC, ILAC, ISO, IUPAP, and OIML 2008a) presently utilizing a mixture of frequentist statistics and Bayesian statistics is the internationally accepted legal and scientific method for formally quantifying an uncertainty in a measurement using equipment and instruments in various laboratories and testing facilities. Originally the GUM was developed by the international metrology community to refine the earlier Kline–McClintock (1953) approach for univariate explicit measurement models uncertainty calculations, and to extend and standardize the uncertainty analysis approach for models of the form $y = f(x_1, \ldots, x_N)$ using correlation effects, however with the introduction of the GUM Supplement 1 (BIPM, IEC, IFCC, ILAC, ISO, IUPAP, and OIML 2008b) it has subsequently been extended to incorporate implicit measurement models of the form $h(y, x_1, \ldots, x_N) = 0$, and then later again extended with the GUM Supplement 2 (BIPM, IEC, IFCC, ILAC, ISO, IUPAP, and OIML 2011) to incorporate multivariate measurement models of the form $\mathbf{h}(\mathbf{y}, \mathbf{x}) = \mathbf{0}$. As a result, the GUM and its two supplements with ongoing refinements to fully encapsulate a wholly Bayesian statistics modelling framework (Bich et al. 2016) presents a complete self-contained mathematical framework for metrology practitioners that is comprehensive enough for determining the uncertainty in any relevant physical experimental measurement system.

Although the mathematical framework is formally documented with the main stages in uncertainty evaluation as (i) formulation, (ii) propagation, and (iii) summarizing, the methodology of applying this method to measurement systems defined in terms of partial differential equations is not well known within the broader metrology community. This challenge mainly occurs as many existing measurement systems feature either algebraic models in which the input/output relationships are conceptually straightforward albeit with complex constituent relationships, or in which the measurement equation system utilizes a phenomenological model with empirical parameters that is algebraically or analytically solvable and tractable. Examples of an algebraic input/output model include pyrometry based temperature measurements (Dziarski and Hulewicz 2021) that utilize optical radiometry theory, vacuum pressure based static expansion systems (Franco et al. 2021) that utilize gas equation of states, and dynamic force measurements (Gelany and Mahmoud 2021) that utilizes Newton's second law. The key observation in these illustrative examples is that in algebraic input/output formulated measurement models that in these systems the formulation is ultimately based on the application of underlying physical laws in which the constituent equations are simplified and then manipulated so that they can be transformed to be analytically solvable either via hand calculations or

with Computer Algebra System (CAS) assistance, such that all the inputs $x_1, \ldots, x_N$ and outputs $y_1, \ldots, y_M$ may be manipulated and clearly written down in terms of governing systems of equations such that sensitivity coefficients $\partial y_j/\partial x_i$, $i = 1, \ldots, N, j = 1, \ldots, M$ for calculating the uncertainty output uncertainty contributions in terms of the input uncertainties may be either explicitly calculated through partial derivatives or implicitly computed through covariance matrices (Ramnath 2022).

Phenomenological based formulated measurement models by contrast differ from analytically solvable systems since they incorporate empirical analytical relationships of scientific phenomena that whilst consistent with underlying physical theories through for example statistical regression analysis or the Buckingham π - theorem (Buckingham 1914), utilize measurement equation parameters that are not ultimately directly derivable from first principles even if the theories are based on partial differential equations. Typical examples of systems that are ultimately defined in terms of partial differential equations but which are not considered analytically solvable include the watt Kibble balance (Robinson and Schlamminger 2016) for the new SI realization of the kilogram that is based on the Maxwell electromagnetic equations but which is typically numerically solved with the finite element method, and in orifice plate flow rate studies (Yin et al. 2021) based on the Navier-Stokes equations incorporating turbulence effects to determine a coefficient of discharge and related parameters and which is typically numerically solved with the finite volume method. It may thus be observed that the overall aim and motivation for metrology practitioners in determining uncertainties from measurand partial differential equation based models is to formally and accurately quantify measurement uncertainties of laboratory equipment and instruments as shown in Fig. 1. Typically at national metrology institutes the apex or primary laboratory standards, such as the

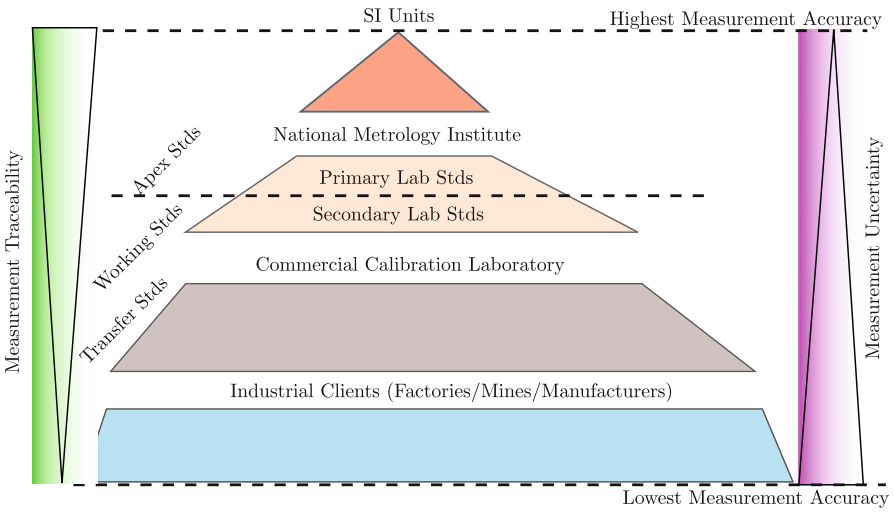

Fig. 1 Schematic illustration of measurement traceability and uncertainty propagation in metrology systems

kilogram standard or a pressure or flow standard, are characterized by a partial differential equation based model. If the uncertainty for the primary or apex laboratory standard is appropriately characterized with statistically consistent accuracies/uncertainties then it then may in turn be used to calibrate a secondary or working measurement standard, that in turn can be used to calibrate equipment/instruments for commercial calibration laboratories, which in turn ultimately pass on these accuracies/uncertainties into clients working in industries and factories. As a result, this 'measurement traceability pyramid' for all countries with modern industrial economies is ultimately dependent for its trade and industry competitiveness that is based on its respective national metrology institute's apex measurement standards accuracy that is in many practical mechanical and electrical equipment/instrument measurement parameters ultimately specified in terms of uncertainties emanating from partial differential equation measurement models. The importance in understanding the broader scientific and economic context in which this research activity takes place, may thus be readily understood in terms of the practical measurement pyramid traceability scheme and how this influences and impacts on metrology practioners from the top level national measurement laboratory, to the commercial calibration laboratory, and finally to the end user in a factory, mine or manufacturer in terms of technical and Occupational Health and Safety (OHS) consequences.

Consequently in both cases, either for algebraic/analytical equations derived from physical laws or for empirical derived equations from phenomenological observations, regardless of how the measurement equations are formulated and simplified to transform them into a tractable form that is amenable for a GUM based uncertainty analysis, the propagation of the measurement inputs inclusive of estimates of expected values and uncertainties of model parameters through for example expert knowledge or International Standards Organization (ISO) testing and quality standards specifications (Ramnath 2011), and the subsequent summarizing of the measurement model output uncertainty, is conceptually straightforward. By contrast, whilst the first step of the formulation of a model defined in terms of a partial differential equation is in principle straightforward, the second step that involves the incorporation into and subsequent propagation of input uncertainties through the model that is not analytically solvable is not as straightforward an exercise for many metrology practitioners since it is a relatively new research development in measurement system uncertainty analysis. The final third step of summarizing the Monte Carlo information once the second step is achieved is in principle straightforward, and may readily be reported and summarized in terms of the existing GUM methodology for Gaussian uncertainty characteristics (Harris et al. 2014) or if necessary using copulas (Possolo 2010) for the reporting of non-Gaussian uncertainty characteristics.

Earlier work in the uncertainty quantification of partial differential equations involved more advanced mathematical spectral based theories for an indirect approach. Subsequent later work has incorporated a direct approach by utilizing a Monte Carlo alternative to spectral based uncertainty analysis by incorporating 'virtual experiments' that include atomic force microscopy (Mohammad and Suvorov 2019) and ultrasonic flow meters (Straka et al. 2022) simulations of partial

differential equations. Recent investigations by (Wubbeler et al. 2022) using a virtual coordinate measuring machine simulation has demonstrated that when a virtual experiment is combined with a Monte Carlo method that the resulting measurement uncertainty is consistent with a GUM-compliant uncertainty evaluation if forward models involving the numerical solution of partial differential equations are used. As a result the use of uncertainties emanating from solutions of partial differential equations that more fully model a physical system in a 'virtual experiment' is a newly emerging field in metrology uncertainty quantification that may over time supersede earlier modelling efforts that were based on algebraic/analytical simplifications to governing equations and/or empirical/phenomenological modelling approaches.

The objective of this chapter is to therefore to introduce to the reader the methodology of how to formulate and implement Monte Carlo simulations using a 'black box' type of approach of numerical solutions for partial differential equations by relying on the GUM supplementary guide framework for Monte Carlo simulations, in order to calculate uncertainties of measurements that are modelled in terms of partial differential equations and to understand how the input uncertainty information may be conveniently propagated through the model and ultimately summarized. Due to the fact that practical partial differential equation based models such as the Maxwell electromagnetic equations for a national kilogram measurement standard or the Navier-Stokes fluid mechanic equations for a national pressure/flow measurement standards both require domain specific specialist scientific/engineering knowledge, in this chapter a Poisson partial differential equation is considered for simplicity in order to illustrate the main conceptual ideas of how to formulate a 'black box' approach that can then be conveniently adapted and generalized for more complex domain specific measurement systems that are aligned to the reader's own specific interests and focus. The underlying Poisson equation model considered in this chapter may be considered as a special case of the incompressible Navier-Stokes fluid equations and can in principle be adapted and refined to incorporate commercial or open source Computational Fluid Dynamics (CFD) codes to model venturi nozzles and orifice plates as flow measurement uncertainty standards in calibration laboratories for the oil and gas sectors, and also in the analysis of air duct systems in offices and hospitals for the designing and sizing of Heating Ventilation Air Conditioning (HVAC) equipment based on the flow uncertainties in ventilation ducts and passages.

Spectral-Based Uncertainty Quantification

Uncertainty analysis of measurement equations may be broadly delineated into spectral methods and Monte Carlo methods as discussed by Le Maitre and Knio (2010). If an operator $\mathcal{M}$ for a model is known such that

$$\mathcal{M}(\mathbf{s}, \mathbf{d}) = \mathbf{0} \tag{1}$$

where **s** is the solution output, **d** is random input data and $\mathcal{M}$ may be informally be considered as a system of equations, then the uncertainty analysis seeks to determine the probability distribution of **s**. In a spectral approach the data is usually parametrized using a parameter vector $\boldsymbol{\xi} = \{\xi_1, \xi_2, \ldots, \xi_N\}$ so that $\mathbf{d} \equiv \mathbf{d}(\boldsymbol{\xi})$ and a series expansion is obtained such that

$$\mathbf{s}(\boldsymbol{\xi}) = \sum_{k=0}^{\infty} \mathbf{s}_k \Psi_k(\boldsymbol{\xi}) \tag{2}$$

In the above equation Ψ_k are functions of the random variables and $\mathbf{s}_k$ are coefficients, and if both of these terms are known then the above expression may be conveniently analysed to calculate the statistics of the model output $\mathbf{s}(\boldsymbol{\xi})$. For an uncertainty analysis using the spectral approach the Polynomial Chaos Expansion (PCE) method is the standard approach as discussed by Lacor and Savin (2019) where a model $\mathcal{M}$ with a random output variable $\varphi(\mathbf{x}, t, \boldsymbol{\xi})$ may be represented with a PCE as

$$\varphi(\mathbf{x}, t, \boldsymbol{\xi}) \approx \sum_{i=0}^{P} \varphi^i(\mathbf{x}, t) \cdot \psi(\boldsymbol{\xi}) \tag{3}$$

In the above scheme φ^i is a deterministic unknown expansion coefficient that must be determined for a random mode i of φ and $\psi(\boldsymbol{\xi})$ are N-variate polynomials where N is the number of input uncertainties. It is known from Xiu and Karniadakis (2002) that if p is the highest order of polynomial that is used then the total number of terms that must be used in the PCE is

$$P + 1 = \frac{(N + p)!}{N! \times p!} \tag{4}$$

Considering for example a partial differential equation for a two-dimensional domain Ω as shown in Fig. 2 where there are $N = 12$ input uncertainties corresponding to Δx and Δy uncertainties for each of 6 points in a polygon and where a $p = 5$ order polynomial is used, it is seen that $\frac{(N+p)!}{N! \times p!} = \frac{(12+5)!}{12! \times 5!} = 6188$ terms must be determined in order to adequately model the output PDE uncertainty. As a result a traditional spectral based uncertainty analysis whilst extremely mathematically powerful for a general analysis either with a PCE or a generalized polynomial chaos (gPC) approach as discussed by Couaillier and Savin (2019) can quickly become impractical and computationally infeasible for typical PDE systems encountered in metrology problems.

Due to this observation this chapter will therefore focus on the use of the Monte Carlo method for obtaining an uncertainty of a measurement model defined in terms of a PDE, as this approach is conceptually simpler to implement and more convenient for the analysis of uncertainties based on PDE models particularly when utilizing input/output "black-box" PDE solvers.

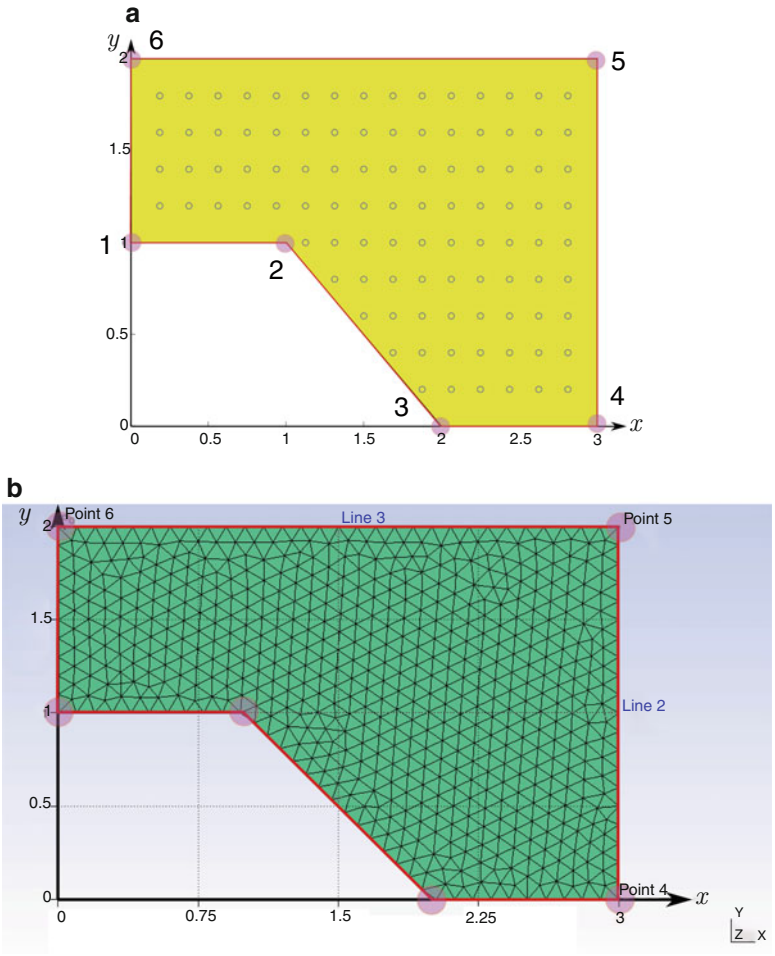

Fig. 2 Illustration of typical PDE domain discretizations

Review of the Monte Carlo Method for Uncertainties

Metrology based uncertainty analysis is by convention conducted with the Guide to the Expression of Uncertainty in Measurement (GUM) (BIPM, IEC, IFCC, ILAC, ISO, IUPAP, and OIML 2008a) for analytical models, the GUM Supplement 1 (GS1) (BIPM, IEC, IFCC, ILAC, ISO, IUPAP, and OIML 2008b) for univariate models, and the GUM Supplement 2 (GS2) (BIPM, IEC, IFCC, ILAC, ISO, IUPAP, and OIML 2011) for multivariate models. PDE based models are in practical terms equivalent to multivariate models since the inputs for any PDE are combinations of appropriate boundary conditions, initial conditions and parameters, which may be

conveniently abstracted as multivariate inputs that are plugged into the PDE which when solved produces scalar or vector field solutions that may again be conveniently abstracted as multivariate outputs.

As an example if there is a two-dimensional domain $\Omega = \{(x_1, y_1), \ldots, (x_n, y_n)\}$ that is composed of a set of n pairs of vertices, some PDE parameters $p_1, \ldots, p_m$ for a PDE defined as $\mathcal{L}u = 0$ where $\mathcal{L}$ is some linear/non-linear differential operator with r parameters $D_1, \ldots, D_r$, and $\mathcal{B}u = 0$ is a linear/non-linear boundary condition operator with s parameters $K_1, \ldots, K_s$ using the notation as discussed by Fairweather and Karageorghis (1998), then the model inputs may be grouped as $\mathbf{X} = [x_1, y_1, x_1, y_1, \ldots, x_n, y_n, p_1, \ldots, p_m, D_1, \ldots, D_r, K_1, \ldots, K_s]^\top$ with a total of $N = (2n + m + r + s)$ inputs. The formal solution of the PDE $\mathcal{L}u = 0$ will be field u-(x, y) $\forall$ $(x, y) \in \Omega$ that satisfies the boundary condition $\mathcal{B}u = 0$, and this would in general be obtained by a Finite Difference Method (FDM), Finite Element Method (FEM), Finite Volume Method (FVM) or Boundary Element Method (BEM) numerical scheme.

Although each of these methods differ in approach they may all in principle be used to compute known values of the solution $u(x, y)$ at discrete points $(\xi_1, \eta_1), \ldots, (\xi_t, \eta_t)$ in the domain Ω corresponding to an appropriate choice of numerical mesh, that would typically be solved from a linear system of equations $\mathbf{A} \cdot \mathbf{u} = \mathbf{b}$ where the matrix $\mathbf{A}$ and vector $\mathbf{b}$ are based on the particular choice of numerical method. If the coordinates and solution values are grouped as $\mathbf{Y} = [\xi_1, \eta_1, u(\xi_1, \eta_1), \ldots, \xi_t, \eta_t, u(\xi_t, \eta_t)]^\top$ then the PDE model may be considered to yield a total of $M = 3t$ outputs. This underlying modelling scheme may be abstracted and extended to systems of PDEs that have a time dependence.

Within this mathematical framework if $\mathbf{X} = [X_1, \ldots, X_N]^\top$ is a multivariate input, and $\mathbf{Y} = [Y_1, \ldots, Y_M]^\top$ is a multivariate output, then a PDE model may be written in the general explicit or implicit form as

$$\mathbf{Y} = \mathbf{f}(\mathbf{X}) \tag{5}$$

$$\mathbf{h}(\mathbf{Y}, \mathbf{X}) = \mathbf{0} \tag{6}$$

The application of the GUM Supplement 2 to calculate uncertainties from the above equation is formally achieved by solving the Markov formula to obtain the probability density function (PDF) $g_{\mathbf{Y}}(\boldsymbol{y})$ of the output as

$$g_{\mathbf{Y}}(\boldsymbol{y}) = \int_{-\infty}^{\infty} g_{\mathbf{X}}(\boldsymbol{x}) \times \delta(\boldsymbol{y} - \mathbf{f}(\boldsymbol{x}))\mathrm{d}x_1 \cdots \mathrm{d}x_N \tag{7}$$

In the above scheme $\boldsymbol{x}$ is a random value that is sampled from the joint PDF $g_{\mathbf{X}}(\boldsymbol{x})$ for the input $\mathbf{X}$, and $\boldsymbol{y}$ is a corresponding random value that is either calculated from the explicit equation $\boldsymbol{y} = \mathbf{f}(\boldsymbol{x})$ or alternately the implicit equation $\mathbf{h}(\mathbf{y}, \mathbf{x}) = \mathbf{0}$, that is equivalent to a sampled output value for the joint PDF $g_{\mathbf{Y}}(\boldsymbol{y})$. The function δ is the Dirac delta function and is either zero or unity based on whether $\boldsymbol{y}$ is equal to $\mathbf{f}(\boldsymbol{x})$ as discussed by (Cox and Siebert 2006). Regardless of the particular mathematical form

of the PDE based model if M Monte Carlo simulations are performed then discrete multivariate outputs $\boldsymbol{y}_1, \ldots, \boldsymbol{y}_M$ will be generated from repeated solutions of the PDE based model, and this output data may then be post-processed to generate the corresponding PDF of the output $\mathbf{Y}$.

Although a probability density function (PDF) is usually more intuitively appealing for visualizing an uncertainty, in the case of multivariate models a cumulative distribution function (CDF) $\mathbf{G}(\mathbf{y})$ is a more straight-forward approach to construct, and takes the simple form

$$\mathbf{G} = (\boldsymbol{y}_1, \ldots, \boldsymbol{y}_M) \tag{8}$$

Noting that the input $\mathbf{X} = [X_1, \ldots, X_N]^\top$ is a vector of dimension $N \times 1$, the output $\mathbf{Y} = [Y_1, \ldots, Y_m]^\top$ is a vector of dimension $m \times 1$, it follows that $\mathbf{G}$ is a matrix of dimension $m \times M$. This matrix may then be used to compute the expected value of $\boldsymbol{y}$ denoted by $\tilde{\boldsymbol{y}}$ of dimension $m \times 1$ and covariance matrix $\mathbf{U}_{\tilde{y}}$ of dimension $m \times m$ of the output as

$$\tilde{\boldsymbol{y}} = \frac{1}{M}[\boldsymbol{y}_1 + \cdots + \boldsymbol{y}_M] \tag{9}$$

$$\mathbf{U}_{\tilde{y}} = \frac{1}{(M-1)}\left[(\boldsymbol{y}_1 - \tilde{\boldsymbol{y}}) \cdot (\boldsymbol{y}_1 - \tilde{\boldsymbol{y}})^\mathsf{T} + \cdots + (\boldsymbol{y}_M - \tilde{\boldsymbol{y}}) \cdot (\boldsymbol{y}_M - \tilde{\boldsymbol{y}})^\mathsf{T}\right] \tag{10}$$

For most practical cases any model output is usually sufficiently Gaussian in nature and as a result an expected value $\tilde{y}$ and covariance matrix $\mathbf{U}_{\tilde{y}}$ as indicated above can accurately represent any multivariate Monte Carlo data with sufficient accuracy. At the present time of writing the GUM and GUM supplements assume Gaussian probability density functions for measurement model outputs unless otherwise specified.

In the special case of a univariate output y_r, $r = 1, \ldots, M$ the statistical uncertainty may be summarized by constructing the univariate distribution function $\mathbf{G}$ with the following steps:

1. sort the model unordered values y_r into a non-decreasing order i.e. into a sequence of increasing values with possible repeated values
2. assign uniformly spaced cumulative probabilities $p_r = \frac{1}{M}\left(r - \frac{1}{2}\right)$ for $r = 1, \ldots, M$ where p_r are mid-points of M contiguous probability intervals of width $\frac{1}{M}$ between $p = 0.0$ and $p = 1.0$
3. form a continuous strictly increasing piecewise linear function joining the M points (y_r, p_r) for $r = 1, \ldots, M$ with the formula for a random output η as

$$\tilde{G}_Y(\eta) = \frac{1}{M}\left(r - \frac{1}{2}\right) + \frac{(\eta - y_r)}{\left[M\left(y_{r+1} - y_r\right)\right]}, y_r \leqslant \eta \leqslant y_{r+1}, r = 1, \ldots, (M-1) \tag{11}$$

A two-dimensional PDE based model equation with two random variable inputs and a univariate random variable output will be demonstrated in the next section to illustrate the general solution approach.

Poisson Partial Differential Equation

Different general approaches to solving PDEs include transformation mappings from physical domains to computational domains to apply regular finite difference schemes by Tannehill et al. (1997), the generalized finite difference method (GFDM) of Benito et al. (2001) and Fan et al. (2015), the boundary element method (BEM) by Beer et al. (2008), and the finite element method by Rao (2005).

Specific approaches to particular types of PDE based models such as for plane stress/strain elasticity problem include power series solutions of the Airy function by Jayne and Tang (1970), complex variable and symbolic software by Ioakimidis (1992), the element free Galerkin method by Belytschko et al. (1994), and the meshless local Petrov-Galerkin (MLPG) approach with earlier work by Atluri and Zhu (2000) and later refinements by Liu (2010) that guaranteed matrix invertibility for solutions. A common partial differential equation encountered in many branches of physics and engineering is the Poisson equation as discussed by (Burden and Faires 2001) of the form

$$\nabla^2 \varphi = f \tag{12}$$

where $\nabla^2 \equiv \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}$ is the Laplace operator in two dimensions and f is a source term for points $(x, y) \in \Omega \subset \mathbb{R}^2$ where Ω is a domain and $\Gamma = \partial\Omega$ is a domain boundary. In the special case where f is zero the Poisson equation reduces to the Laplace equation $\nabla^2 \varphi = 0$, however it is generally more advantageous for generality to model systems in terms of the Poisson equation since plane stress/strain elasticity (Reddy 2010) and incompressible fluid dynamics problems (Tannehill et al. 1997) may conveniently be modelled in terms of the Poisson equation. An extension of the Poisson equation is the Helmholtz equation (Goldstein et al. 2000) which takes the form $\nabla^2 \varphi = -k^2 f$ where k is a wave number, k^2 is the eigenvalue and f is an eigenfunction, and the equation models wave propagation in a continuum medium such as a metal plate in a drum.

Consider the geometry shown in Fig. 3 which is an adaptation of a potential flow in a duct by White (2003) that may be modelled using a stream function approach in terms of a Poisson equation that avoids a full Navier-Stokes system of PDEs for simplicity. In this figure the geometry represents a ventilation duct that may be encountered in an air duct in an office building or a hospital where air flows into the duct and then flows out of the duct to introduce some air circulation to either cool/heat a room, or alternately to transport away air-borne pollutants such as may be encountered by sick or vulnerable patients. Referring to this figure L_1 is the total length of the duct, L_2 is the outlet length of the duct, L_3 is an inlet length of the duct,

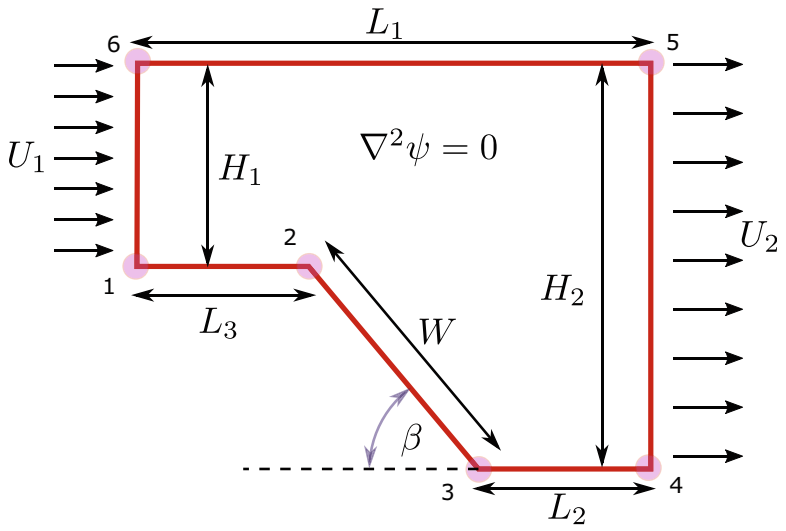

Fig. 3 Schematic illustration of PDE based measurement model of incompressible fluid flow in a duct

H_1 is the height of the inlet to the duct, H_2 is the height of the outlet to the duct, W is the length of an incline within the duct as the flow transitions from the inlet region to the outlet region, β is an angle that indicates how the duct height transitions from the inlet to the outlet region, U_1 is the inlet velocity of the fluid in the duct, and U_2 is the outlet velocity of the fluid in the duct respectively. The physical units of L_1, L_2, L_3, W, H_1 and H_2 are all in meters [m], the unit of β is in radians [rad], and finally the units for U_1 and U_2 are in meters per second [m s^{-1}].

In this model the potential flow for an incompressible fluid with a constant density ρ, horizontal velocity $u(x, y)$ and vertical velocity $v(x, y)$ is governed by a stream function $\psi(x, y)$ that within a domain Ω satisfies Laplace's equation

$$\nabla^2\psi = 0 \tag{13}$$

$$u = \frac{\partial\psi}{\partial y} \tag{14}$$

$$v = \frac{-\partial\psi}{\partial x} \tag{15}$$

In order to solve Laplace's equation appropriate boundary conditions must be specified, and for a stream function model this is achieved by specifying either known free-stream velocities through inferring applicable Neumann boundary conditions through a specification of gradients $\frac{\partial\psi}{\partial n}$ where n is an outwards unit vector where $\frac{\partial\psi}{\partial n}$ is calculated from the known values of $u_\infty = \frac{\partial\psi}{\partial y}$ and $v_\infty = \frac{-\partial\psi}{\partial x}$, or alternately by specifying known values of the stream function through enforcing applicable Dirichlet boundary conditions.

For the particular example problem that is considered assume $U_1 = 10\ \text{m s}^{-1}$, $L_1 = 3$ m, $H_1 = 1$ m, and $H_2 = 2$ m are all constant and known, whilst $L_2 = 1$ m and $\beta = \frac{\pi}{4}\text{rad} = 45^\circ$ are nominal expected values that are modelled as random variables that influence the solution of the PDE through for example manufacturing tolerances and fabrication errors.

In many metrology problems random variables may be modelled as Gaussian distributions, rectangular distributions with upper/lower limits, or triangular distributions. Assume for simplicity and illustrative purposes that L_2 and β have expected values of μ_{L_2} and μ_β with symmetric upper and lower tolerance limits of $\pm\Delta_{L_2}$ and $\pm\Delta_\beta$. Using the GUM guidelines it then follows they these random variables may then be modelled as equivalent Gaussian distributions i.e. normal distributions $N(\mu, \sigma^2)$ with an expected value μ and variance σ^2 such that, for example a duct error length of $\Delta_{L_2} = \pm 20$ cm and duct angle error of $\Delta_\beta = \pm 15^\circ$ yields

$$L_2 \sim N\left(\mu_{L_2}, \left(\frac{\Delta_{L_2}}{\sqrt{3}}\right)^2\right) = N\left(1, \left(\frac{0.20}{\sqrt{3}}\right)^2\right) \tag{16}$$

$$\beta \sim N\left(\mu_\beta, \left(\frac{\Delta_\beta}{\sqrt{3}}\right)^2\right) = N\left(\frac{\pi}{4}, \left(\frac{\frac{\pi}{12}}{\sqrt{3}}\right)^2\right) \tag{17}$$

Since the fluid within the duct is incompressible its density is constant thus using a simple mass flow rate $\dot{m}$ from the continuity equation it may be shown that $\dot{m} = \rho_f U_1 A_1 = \rho_f U_2 A_2$ where A_1 and A_2 are the cross-sectional areas at the flow inlet and outlet respectively. Setting $A_1 = H_1 t$ and $A_2 = H_2 t$ where t is the thickness of the duct out of the plane of the paper it immediately follows that $U_1 H_1 = U_2 H_2$ thus $U_2 = \left(\frac{H_1}{H_2}\right) U_1$.

To complete the mathematical description of the problem note that the volumetric flow of the fluid per unit depth is $Q = (10\ \text{m s}^{-1}) \times (1\ \text{m}) = 10\ \text{m}^2\ \text{s}^{-1}$ per unit depth so for convenience let the value of the stream function along the top of the duct be $\psi_{\max} = 10$ and along the bottom of the duct be $\psi_{\min} = 0$ so that

$$\psi = \psi_{\max}, 0 \leqslant x \leqslant L_1, y = H_2 \tag{18}$$

$$\psi = \psi_{\min}, \begin{cases} 0 \leqslant x \leqslant L_3, y = H_2 - H_1 \\ L_3 \leqslant x \leqslant (L_1 - L_2), y = (H_2 - H_1) + \left[\dfrac{-(H_2 - H_1)}{(L_1 - L_2) - L_3}\right] \cdot [x - L_3] \\ L_1 - L_2 \leqslant x \leqslant L_1, y = 0 \end{cases} \tag{19}$$

Since the inlet velocity U_1 is constant for $H_2 - H_1 \leqslant y \leqslant H_2$ and the outlet velocity U_2 is constant for $0 \leqslant y \leqslant H_2$, it may be shown using the relationship $u = \frac{\partial \psi}{\partial y}$ that ψ must linearly vary from $\psi_{\min}$ to $\psi_{\max}$ for both the inlet and outlet velocities. Accordingly the remaining boundary conditions are then

$$\psi = \psi_{\min} + \left[\frac{\psi_{\max} - \psi_{\min}}{H_1}\right] \cdot [y - (H_2 - H_1)], x = 0, H_2 - H_1 \leqslant y \leqslant H_2 \tag{20}$$

$$\psi = \psi_{\min} + \left[\frac{\psi_{\max} - \psi_{\min}}{H_2}\right] \cdot [y], x = L_1, 0 \leqslant y \leqslant H_2 \tag{21}$$

This completes the mathematical specification of the PDE problem since the PDE is simply Laplace's equation as a special case of the Poisson equation with a zero source term and the boundary conditions are now all specified, however a solution of the PDE by itself without additional post-processing of the underlying fields is seldom sufficient to fully characterize a measurement model. It may be observed that is this particular model the only terms that are not constant are the random variables L_2 and β which are modelled by appropriate PDFs.

In this particular example suppose that it is desired to calculate the dimensionless pressure coefficient C_p at any particular point of interest, that is defined as the ratio of the static pressure gradient $\Delta p = p - p_1$ to that of the dynamic pressure $\frac{1}{2}\rho_f U_1^2$ such that

$$\begin{aligned} C_p &= \frac{p - p_1}{\frac{1}{2}\rho_f U_1^2} \\ &= 1 - \left(\frac{V}{U_1}\right)^2 \\ &= 1 - \frac{1}{U_1^2}\left[\left(\frac{\partial \psi}{\partial y}\right)^2 + \left(-\frac{\partial \psi}{\partial x}\right)^2\right]. \end{aligned} \tag{22}$$

Referring to the above equation, it may be observed that once the random variable values are introduced into the PDE and the PDE is solved to "propagate the statistical information," then the PDE solution may be further post-processed to generate additional numerical data that may be analysed and further manipulated to generate statistical information for the model outputs.

For this particular PDE based model the general steps to apply the Monte Carlo method are therefore:

1. Pick a number M of Monte Carlo simulation events, say $M = 50$.
2. Sample $M = 50$ random independent values of $L_2 = \left(1 \pm \frac{0.20}{\sqrt{3}}\right)$m from Eq. (16) and $\beta = \left(\frac{\pi}{4} \pm \frac{\frac{\pi}{12}}{\sqrt{3}}\right)$ rad from Eq. (17) as PDE inputs that are known to have a statistical variation.
3. Solve the PDE with Eq. (13) with the specified boundary conditions Eqs. (18), (19), (20), and (21) and the sampled random values of L_2 and β.
4. Post-process the PDE solution with Eq. (22) and use the results to calculate the quantity of interest namely the C_p value that will have a statistical variation and collect the results $y_1 = C_p^{(1)}, \ldots, y_M = C_p^{(M)}$.

5. Apply the formulae Eq. (11) to calculate the distribution function to encapsulate the statistical information of the model output, and then post-process the model's statistical output to calculate summaries of the uncertainty in terms of the expected value and standard deviation for the quantity of interest.

In the illustrative example only a single quantity of interest, namely C_p at say $x = \frac{1}{2}L_1$ and $y = H_2$, is considered so the output is technically a univariate quantity. The univariate output from the post-processed PDE solution would then have a statistical uncertainty that is modelled as a Gaussian PDF if symmetric, or alternately as a skew-normal distribution if asymmetries are present as discussed by Possolo et al. (2019). However, in this particular problem the quantity of interest could in principle actually be all C_p values along the bottom of the duct and the top of the duct, in which case the quantity of interest would be a multivariate output. Another possibility for modelling the uncertainty for this particular problem is to consider the terms L_2 and β as random variables ξ_{L_2} and ξ_β and the output C_p as a random variable output η_{C_p} in a equation $\mathbf{h}(\mathbf{Y}, \mathbf{X}) = \mathbf{0}$ so that the output uncertainty can be modelled as a joint PDF. As a result, it may be observed that there are technically a number of different possible choices of how to refine a PDE based model's uncertainty depending on the nature of the physical problem and how the PDE solution is post-processed.

Numerical Results

Whilst various possible approaches for solving PDEs are possible in the specified mathematical example, for mathematical efficiency a Boundary Element Method (BEM) using the Method of Fundamental Solutions (MFS) as discussed by Golberg (1995) may be preferable in the particular cases of Laplace's, Poisson's and Helmholtz's PDEs to reduce the dimension of the problem and hence the amount of numerical calculations. If a larger number of Monte Carlo simulations is possible through a reduction of computational complexity then it is possible to achieve refinements in the final results through for example higher accuracy discrete representations of statistical distribution functions.

A practical consideration that works against mathematical efficiency for particular classes of PDEs particularly for many real engineering problems, is that only general purpose FEM and FVM based PDE computer software like the commercial package ANSYS or the open source package OpenFOAM are usually available due to the geometrical complexity of real world problems which are not amenable to specialist techniques such as MFS and RBF numerical schemes.

Consequently, it is seldom practical to generate a very large number of Monte Carlo simulations for real world engineering PDEs without access to high performance computing (HPC) resources, and a judicious smaller number of sampled random values of relevant terms must be selected in order to at least generate reasonable estimates of expected values and variances of expected values. Due to

these considerations for illustrative purposes the mathematical example is solved with the C++ library Fenics by Loggs et al. (2012) using a Python 3 interface with $M = 50$ simulations by sampling from the probability density function distributions previously specified in Eqs. (16) and (17) and plotted in Fig. 4. The general approach is to sample $M = 50$ points from each of the PDFs and then use that as an input to

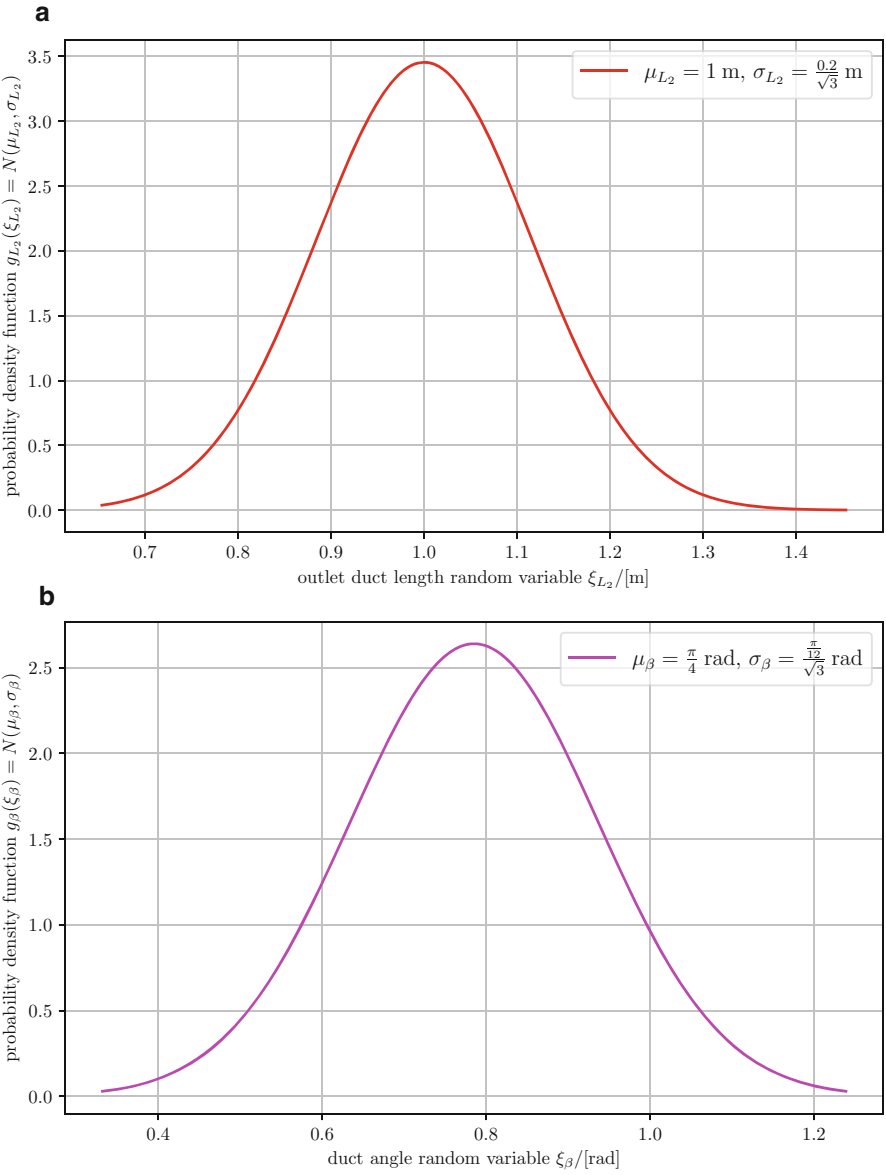

Fig. 4 Illustration of probability density function variations for model input random variables

solve the PDE so that there would be a total of $M = 50$ different solutions which can then be post-processed.

Final representative results for the PDE solution using two sampled values with two simulations are shown in Fig. 5 since it is not feasible to plot 50 different graphs. In these two simulations mesh A corresponds to a domain Ω_A constructed with $L_2 = 0.840$ m and $\beta = 51.886°$ whilst mesh B corresponds to a domain Ω_B constructed with $L_2 = 0.997$ m and $\beta = 48.352°$, both of which which the PDE $\nabla^2\psi = 0$ is solved for and then post-processed by computing the gradients $u = \frac{\partial\psi}{\partial y}$ and $v = -\frac{\partial\psi}{\partial x}$. This simulation process is repeated for each of the remaining 48 sampled values of L_2 and β input random variables so that a total of $M = 50$ simulations are performed i.e. 50 different meshes are re-generated for each Monte Carlo simulation event where a new mesh is constructed for the new varying geometry based on the sampled different values of L_2 and β, and in each Monte Carlo simulation event corresponding to a PDE solution the results are saved to file, so at the end there are $M = 50$ solution data sets for the solution $\nabla^2\psi = 0$ with the specified boundary conditions.

In principle the underlying PDE solution data may now be post-processed based on the relevant measurement model requirements. Since C_p only makes physical sense on the lower boundary and upper boundary of the domain it is natural to process the PDE results to calculate the pressure coefficient. Choosing for convenience the upper surface for the value of C_p as the position varies along the top length it may be seen in Fig. 6 that a sequence of $M = 50$ curves for C_p may be plotted. Having solved the PDE based model if the position along the length of the upper surface is considered as one output $Y_1 = x^{[\text{upper surf}]}$ and the corresponding value of $Y_2 = C_p(x^{[\text{upper surf}]}, y = H_2)$ is calculated as another output then the set of $M = 50$ curves could be considered as a multivariate output $\mathbf{Y} = [Y_1, Y_2]^\top$ based on the multivariate input $\mathbf{X} = [L_2, \beta]^\top$. Although just 5 curves are shown in the figure, when performing a Monte Carlo simulation for a practical engineering problem a very large number of simulation events is usually necessary. In this case if for example $M = 10000$ simulation events corresponding to sampled values of inputs for a PDE are solved, then if all the points from curves are considered as a scatter plot of x vs. $C_p(x, y)$, a covariance matrix $\mathbf{U}_{\tilde{\mathbf{Y}}}$ may be calculated with the multivariate GUM Supplement 2 to model the statistical uncertainty in the pressure coefficient.

Considering instead a simpler problem to demonstrate the general uncertainty approach for PDE based models, suppose that it is simply required to determine the pressure coefficient C_p at the mid-point of the top surface i.e. the value $C_p\left(x = \frac{1}{2}L_1, y = y_5\right)$ as per the previous diagram in Fig. 3. For this particular case step 1, step 2 and step 3 have already been performed, and step 4 now requires to calculate the value of C_p at the point of interest. This can be achieved by going through each of the $M = 50$ data sets and simply working out the value of $C_p\left(x = \frac{1}{2}L_1, y = y_5\right)$ which will yield a univariate data set of values $y_1, \ldots, y_M$. The univariate data may then be post-processed according to the GUM Supplement 1 to produce the cumulative distribution function $G(y)$ as shown in Fig. 7.

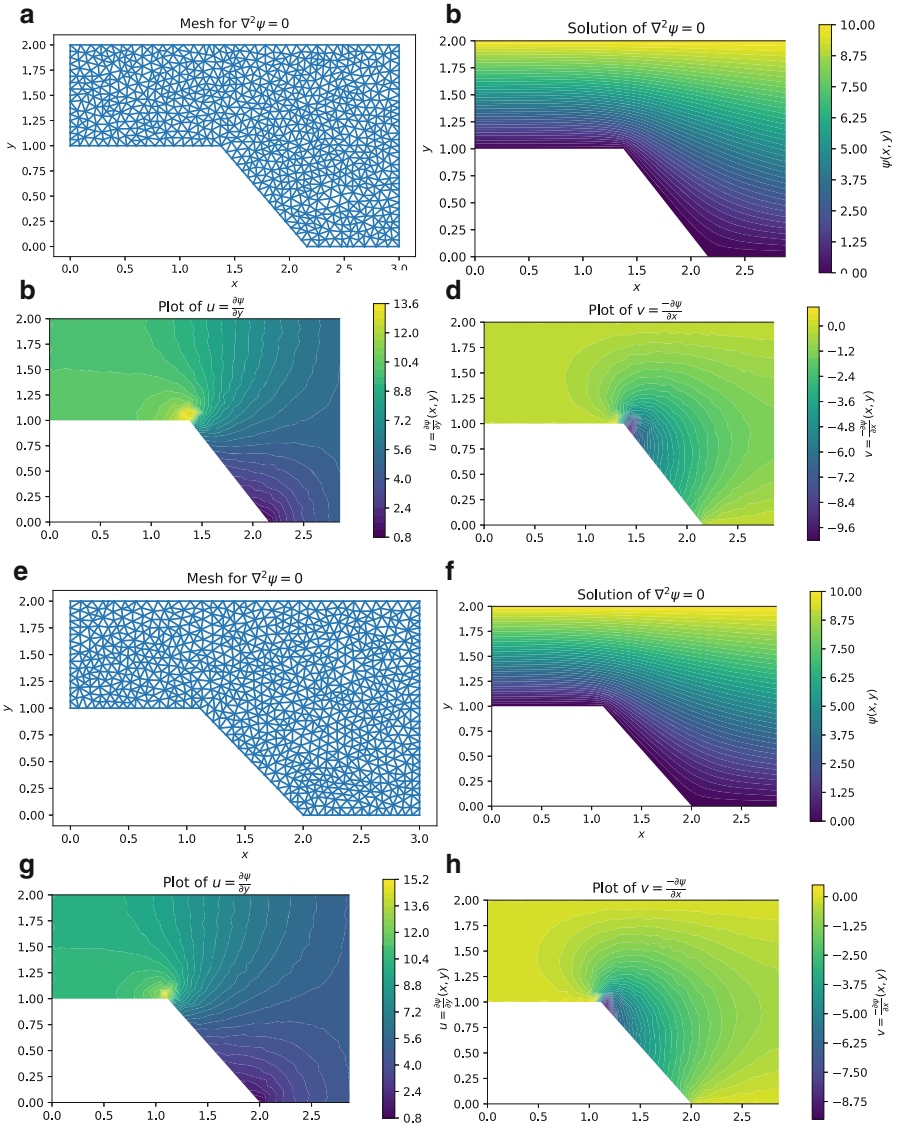

Fig. 5 Illustration of finite element method simulations for varying domain geometries and meshes based on the influence of the random variable inputs L_2 and β which are allowed to independently vary based on their respective statistical uncertainties. As L_2 and β vary they will change the underlying domain Ω for which the PDE $\nabla^2\psi = 0$ must be solved with the specified boundary conditions. For each Monte Carlo simulation event for $j = 1, \ldots, M$ where $M = 50$ is the number of simulations there will therefore be a slightly different domain $\Omega_j, j = 1, \ldots, M$ for which the PDE must be solved. Geometry for domain Ω_A corresponds to sampled values of $L_2 = 0.840$ m and $\beta = 51.886°$ whilst geometry for domain Ω_B corresponds to sampled values of $L_2 = 0.997$ m and $\beta = 48.352°$ which are are representative samples of how Ω_j varies

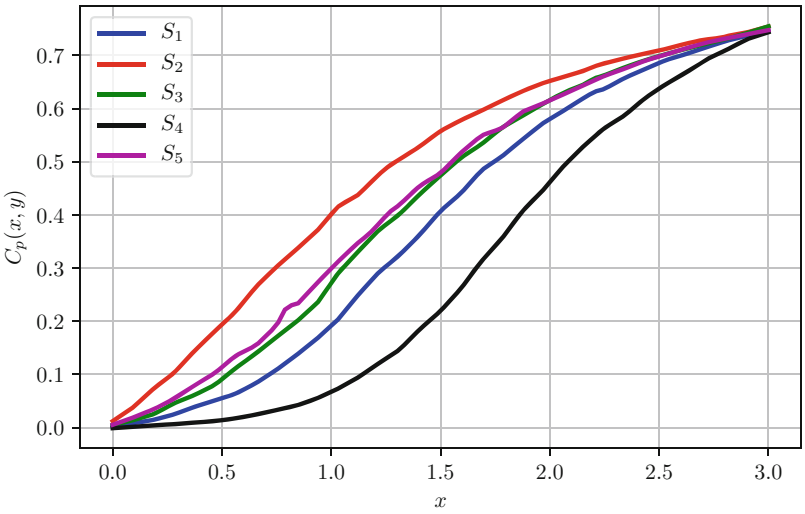

Fig. 6 Schematic illustration of pressure coefficient C_P obtained from post-processing of the PDE solution showing the variation on the upper surface of the channel based on the influence of different sampled random variables L_2 and β for simulation events $S_1, \ldots, S_5$

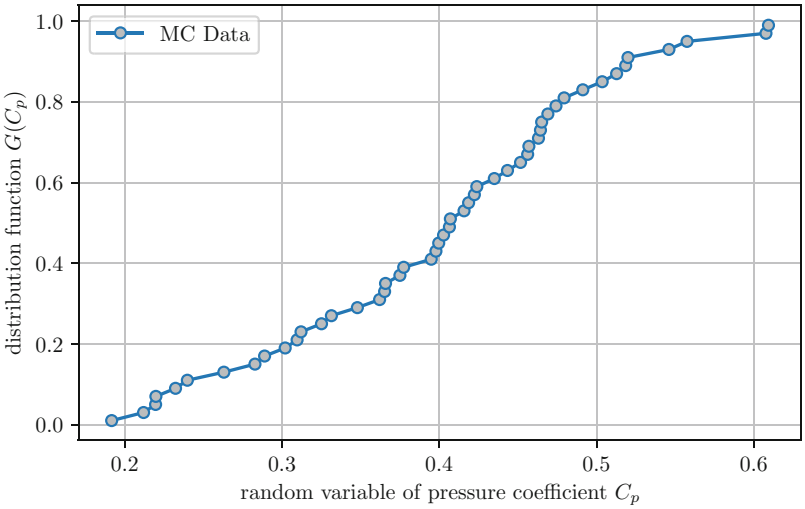

Fig. 7 Visualization of cumulative distribution function for pressure coefficient C_P evaluated at $x = \frac{1}{2}L_1$ and $y = y_5$

An important point to note in the uncertainty analysis of PDE models is that due to the general computational cost involved in numerically solving for multiple evaluations of PDEs, where each solution may take anywhere from 1 h to several hours to solve, that the total feasible number of Monte Carlo simulation events M based on available computational resources is generally quite small. As a result

usually only the expected value $\tilde{y}$ and standard deviation $u(\tilde{y})$ may be calculated with any reasonable degree of certainty. Consequently, using the substitutions $\rho = G(y)$ and $y = Q(\rho)$ where $Q(\rho)$ is the corresponding quantile function, it is generally inadvisable to directly apply the mathematical statistics definitions $\mathbb{E}(y) = \int_0^1 Q(\rho)\mathrm{d}\rho$ and $\mathbb{V}(y) = \int_0^1 [Q(\rho) - \mathbb{E}(y)]^2 \, \mathrm{d}\rho$ in order to calculate the expected value and standard deviation. For post-processing of Monte Carlo data, it is usually more accurate to simply estimate the expected value $\tilde{y}$ and standard deviation $u^2(\tilde{y})$ as

$$\tilde{y} = \frac{1}{M}{\sum_{r=1}^{M}}'' \, y_r \approx \frac{1}{M}\sum_{r=1}^{M} y_r \text{ for } M \text{ large} \tag{23}$$

$$\begin{aligned} u^2(\tilde{y}) &= \frac{1}{M}\left[{\sum_{r=1}^{M}}'' \, (y_r - \tilde{y})^2 - \frac{1}{6}\sum_{r=1}^{M-1}\left(y_{r+1} - y_r\right)^2\right] \\ &\approx \frac{1}{M-1}\sum_{r=1}^{M}(y_r - \tilde{y})^2 \text{ for } M \text{ large} \end{aligned} \tag{24}$$

In the above two equations the double prime on the summation as per Annex D in the GUM Supplement 1 means that the first and last terms in the sum are to be taken with a weight of one half. The usual more common formulae for $\tilde{y}$ and $u^2(\tilde{y})$ only formally apply in the limit of a very large number of Monte Carlo simulation events when M is sufficiently large.

A practical effect of these different formulae is that when an uncertainty analysis is performed for a measurement system modelled in terms of partial differential equation it is only usually feasible, particularly for very complicated models when numerically solved for on laptops in the absence of HPC resources, to perform say $M = 25$ or $M = 50$ Monte Carlo simulations corresponding to a PDE solution if each solution takes anywhere from 1 h to an afternoon to reach grid convergence. As a result the more common and simpler statistical formulae for an expected value and standard deviation, which is only accurate for a large number of data points e.g. $M = 10000$, would potentially introduce a statistical systematic bias in a model simulation in primary/apex measurement standards in national laboratories, and which may then subsequently negatively impact on the measurement traceability accuracy of commercial calibration laboratories.

Discussion and Conclusion

Based on the overview of the Monte Carlo approach for computing uncertainties in PDE based models as discussed in this chapter the following aspects may be noted:

- The Monte Carlo approach is conceptually straightforward to implement with "black-box" PDE solvers for both low-dimensional as well as high-dimensional models if the model inputs can be conveniently sampled and introduced into the solver/post-processor to generate discrete output statistical data
- The discrete output statistical data may be conveniently post-processed to easily produce expected values and standard uncertainties with standard formulae for real practical engineering problems
- If sensitivity analysis of uncertainties is necessary in the case of many competing random variable influences then more advanced techniques such as principal component analysis (PCA) may be considered (Fig. 8)

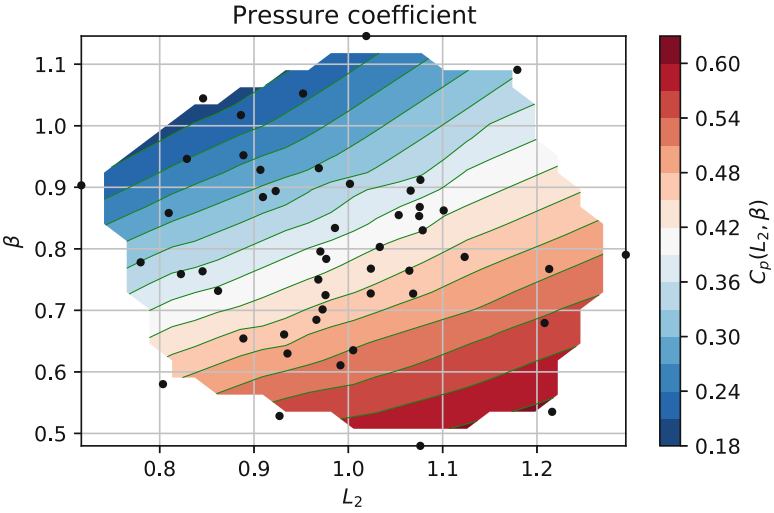

Fig. 8 Visualization of pressure coefficient $C_p(L_2, \beta)$ sensitivity variation evaluated at $x = \frac{1}{2}L_1$ and $y = y_5$ based on PDE input random variables. The results of the Monte Carlo simulation may be further post-processed if necessary to estimate the corresponding sensitivity coefficients $\frac{\partial C_P}{\partial L_2}$ and $\frac{\partial C_P}{\partial \beta}$ to calculate the uncertainty of C_P at any given point in the domain where a pressure coefficient is physically meaningful by using finite differences. As an example if the uncertainty at $L_2 = 1.0$ and $\beta = 0.8$ is required then the value of $C_P(L_2 = 1.0, \beta = 0.8) = C_P^{center}$ is read off the graph, slightly perturbed values are read of for say $C_P(L_2 = 0.99, \beta = 0.8) = C_P^{west}$ slightly to the left, $C_P(L_2 = 1.01, \beta = 0.8) = C_P^{east}$ slightly to the right, $C_P(L_2 = 1.0, \beta = 0.79) = C_P^{south}$ slightly to the bottom and $C_P(L_2 = 1.0, \beta = 0.81) = C_P^{north}$ slightly to the top, and then the partial derivatives for the sensitivity coefficients are approximated with finite differences as $\frac{\partial C_P}{\partial L_2} \approx \frac{1}{1.01-0.99} \times \left[C_P^{east} - C_P^{west}\right]$ and $\frac{\partial C_P}{\partial \beta} \approx \frac{1}{0.81-0.79}\left[C_P^{north} - C_P^{south}\right]$. In this manner the uncertainty for C_P could be approximately estimated as $u^2(C_P) = \left(\frac{\partial C_P}{\partial L_2}\right)^2 u^2(L_2) + \left(\frac{\partial C_P}{\partial \beta}\right)^2 u^2(\beta)$ at any given point in the domain that is physically meaningful. This sensitivity analysis approximation approach is sometimes desirable for metrology practitioners when performing an uncertainty analysis that does not require a full knowledge of the joint probability density function

Abstract

Metrology as the science about measurement is highly intertwined with statistical point estimation. Evaluating and controling uncertainty of measurements and analyzing them by means of exploratory data analysis (EDA) or predictive data

mining requires to exploit advanced tools of statistical estimation. The main focus of the chapter is devoted to nonstandard approaches to the analysis of measurements in two fundamental models, namely, the location model and linear regression. Robust regression methods, which are resistant to the presence of outlying (anomalous) measurements, are discussed here. An illustration of their performance over a real dataset related to thyroid disease and a Monte Carlo simulation reveal here the least weighted squares estimator, which has remained quite neglected so far, outperforms much more renowned robust regression estimators in terms of the variability. Further, Bayesian estimation in the location model is revealed here to have the ability to incorporate previous measurements in a very intuitive way. Finally, the chapter gives a warning that linear regression performed on data contaminated by measurement errors yields biased estimates and requires specific estimation tools for the so-called measurement error model.

Introduction

Measurements in all possible fields of applications are typically imprecise because of errors coming from various sources, which can be classified as instrumental errors, method errors, personal errors, errors caused by an unsuitable design, random errors, etc. (Crowder et al. 2020). Metrology as the science of measurement and its application is linked with information theory (Lesurf 2002; Kong et al. 2019), because measuring provides gathering of information about complex systems and reduces the uncertainty (information entropy). Metrology is at the same time linked with statistical methodology as it operates with fundamental statistical concepts such as variability, standard deviation, general law of error propagation, or confidence intervals. Statistical point estimation overviewed in Lehmann and Casella (1998) can be characterized as an essential approach for evaluating uncertainty. Estimates variability of the measurements is an important application formally described in the Guide to the Expression of Uncertainty in Measurement, which is known as the GUM methodology (JCGM 2012; Lira 2016). Other statistical methods further allow to control the quality of measurements (e.g., in Hynek et al. 2021) or to analyze the results of measurements (Hebra 2010), i.e., to obtain and interpret useful knowledge from the measured information.

This chapter starts with a brief historical overview of standard as well as robust statistical tools applicable to analyzing measurements. Two important statistical models, namely, the location model and the linear regression, are further recalled. The main focus of the chapter is devoted to advanced (nonstandard) approaches to the analysis of measurements. Various regression estimators suitable for the errors-in-variables model are recalled with a focus on the advanced procedures. Robust regression methods are discussed together with an illustration of their performance over a real dataset related to thyroid disease, and over a Monte Carlo simulation. Finally, the Bayesian estimation is explained to have the ability to incorporate previous measurements in a very intuitive way.

History of Statistical Methods for Analyzing Measurements

While the history of metrology has been thoroughly overviewed in specialized monographs (Robinson 2007) and the same is true for the history of commonly used statistical methods (Hald 2006), let us briefly comment here the historical development of the (quite narrow) connection between measurement science and statistics (Stigler 1973). This overview recalls that the need for advanced methods for analyzing measurements, i.e., the natural need for a robust (resistant) analysis of contamined data, has been known for a very long time, already from the very dawn of the regression methodology. The personalities mentioned here with a remarkable contribution to the development of statistics, who all were polymaths with strong mathematical skills, were namely heavily and passionately involved in their own practical measurements.

In a posthumously published paper by Thomas Bayes (1702–1761), the first version of the Bayes theorem appeared. This was later rediscovered by Pierre Simon de Laplace (1749–1827), who greatly contributed to the development of probability theory. Laplace perceived Bayesian probabilistic thinking as a natural extension of mathematical logic and common sense. Let us recall already now that the Bayesian statistics framework is currently the preferred theoretical approach for metrology and that future editions of the GUM can be expected to adopt its modelling framework more strongly. Going back to Laplace, he was also the author of the first rigorous work on robust estimation in 1818, which was devoted to the distribution of the median. Laplace was intensively interested in analyzing astronomic measurements by regression models and was aware of the harmful effect of measurement errors. Apart from the median, Laplace also propagated using the regression median in the linear regression model.

Carl Friedrich Gauss (1777–1855) belonged to the pioneers of a consistent usage of probability theory in the processing of measurements from various fields, mainly in astronomy, geodesy, and physics. By investigating properties of measurement errors and formulating the law or error propagation, he laid foundations of the theory of errors. He developed the maximum likelihood estimation, which became one of the pillars of mathematical statistics. Using the maximum likelihood method, Gauss derived the normal distribution denoted as "the law of errors" and considered it as a suitable model for measurement errors. Gauss also theoretically justified the least squares estimator by means of a Bayesian argument (Sheinin 1996).

The first mathematical approach to handling outlying measurements (outliers) was presented by Benjamin Peirce (1809–1880) in an 1852 paper in the *Astronomical Journal*, where he proposed a historically first formal rule for detecting outliers in measurements. He did not study properties of the trimmed mean, which he considered as the mean computed over the non-outlying measurements, but still was able to understand that the trimmed mean has more appealing properties compared to the arithmetic mean computed across all measurements (Wheeler 2020).

Simon Newcomb (1835–1909) performed a series of measurements of the speed of light in 1881. He realized that his measurements related to the orbits of Mercury have different levels of accuracy, so that the arithmetic mean would not be their suitable characteristic. Instead, he considered small weights assigned to unreliable measurements, which he called to be discordant values, and commonly used the weighted mean instead of arithmetic mean, however with subjectively chosen weights. He also realized the data to have heavy tails and attempted for a more robust estimation by deleting very severe outliers; he assumed the normal distribution to represent a suitable model for the remaining measurements (Stigler 1986).

Ronald A. Fisher (1890–1962), the father of modern statistics, developed the field of statistical point estimation by deriving properties of maximum likelihood estimators and also developed statistical principles of design of experiments. He predecessed ideas of information theory by understanding measurements to reduce uncertainty of a system; in this spirit, he proposed the Fisher information of an unknown parameter as a quantification of the information carried in a single measurement about this parameter.

The Location Model

The location model represents the simplest statistical model and at the same time a special case of the linear regression model. It considers independent measurements $X_1, \ldots, X_n$, where each X_i (i.e., for $i = 1, \ldots, n$) is assumed to come from the normal distribution $X_i \sim N(\mu, \sigma^2)$. The purpose of the measurements is typically to estimate μ. However, the most common estimate of μ based on the data, i.e., their arithmetic mean $\overline{X} = (1/n)\sum_{i=1}^{n} X_i$, is known to be vulnerable (non-robust) with respect to the presence of outliers (anomalous measurements) in the data. Also the standard deviation S, obtained as

$$S = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n}\left(X_i - \overline{X}\right)^2}, \tag{1}$$

may be heavily influenced by outliers. The GUM methodology considers the standard deviation to represent the most appropriate estimate (empirical counterpart) of σ for (not only) evaluating uncertainty of measurements. This is however not appropriate, because S is (just like the arithmetic mean) heavily vulnerable with respect to the presence of outliers in the data. It is for this reason that reliable outlier detection cannot be based on using S. Because robust estimators in the location model are often defined as special cases of robust estimators for regression, we will further discuss the location model only later after having described robust estimators for the regression model.

Linear Regression

The aim of regression modeling is to explain (predict) a given explanatory variable (dependent variable, response) by means of one or more predictors (regressors, independent variables). An overview of regression applications for the task of uncertainty evaluation in metrology was presented in Nielsen (2002). Regression analysis has become an important part of analyzing measurements by means of exploratory data analysis (EDA) or predictive data mining (Tin et al. 2021) with numerous applications not limited to calibration of measuring instruments, estimating missing values, or detecting mixtures of two or more populations or clusters of data (Kalina and Tichavský 2020). Linear measurement systems, which can be analyzed by linear regression, were discussed in Sect. 4 of Raghavendra and Krishnamurthy (2013). As an extension, a recent work of Peremans and Van Aelst (2018) considered multiple measurements characterized by several (seemingly uncorrelated) regression models. Regression models are also useful for denoising (reconstructing) images obtained, e.g., by 3D scanners within optical metrology (Papageorgiou et al. 2017).

Let us consider the standard linear regression model

$$Y_i = \beta_0 + \beta_1 X_{i1} + \ldots + \beta_p X_{ip} + e_i, i = 1, \ldots, n, \tag{2}$$

where $Y_1, \ldots, Y_n$ are values of a continuous response variable, $X_i = (X_{i1}, \ldots, X_{ip})^T$ is the regressor (predictor) for the ith measurement, and $e_1, \ldots, e_n$ are random errors (disturbances). The model (2) can be expressed in the matrix notation as $Y = \boldsymbol{X}\beta + e$; matrices will be denoted by bold face throughout the chapter. The most important possible methods for estimating the regression parameters $\beta = (\beta_0, \beta_1, \ldots, \beta_p)^T$ in the situation with measurement errors are the following:

- Least squares (aka ordinary least squares)
- A consistent modification of least squares
- Generalized least squares (GLS), including weighted least squares (WLS)
- Total least squares (TLS) and extensions, which include weighted total least squares (WTLS) or weighted total least squares with correlation (WTLSC)
- Nonparametric estimators (including rank-based estimators) for the errors-in-variables model
- Estimators based on robust optimization
- Robust estimators

The least squares estimator remains to be very often used in the errors-in-variables model, i.e., the model assuming not only the response but also the indpendent variables to be measured with errors. However, the least squares estimator is not consistent under the presence of measurement errors in the regressors. Only in the location model, the arithmetic mean remains to be consistent if the data contain symmetrically distributed measurement errors. In regression, however, metrologists should be aware of alternative approaches tailor-made for the measurement error models.

Weighted Least Squares

Let us recall the weighted least squares (WLS) with specified non-negative weights $w_1, \ldots, w_n$ fulfilling the natural requirement $\sum_{i=1}^{n} w_i = 1$. Let $u_i(b)$ denote the residual of the ith measurement based on a given estimate $b = (b_0, \ldots, b_p)^T$ of β, i.e.,

$$u_i(b) = Y_i - b_0 - b_1 X_{i1} - \ldots - b_p X_{ip}, i = 1, \ldots, n. \tag{3}$$

The WLS estimator, which is also known as Aitken estimator or generalized least squares (Greene 2018), is defined by minimizing a weighted estimate of σ^2 in the form

$$b_{WLS} = \arg\min_{b \in \mathbb{R}^{p+1}} \sum_{i=1}^{n} w_i u_i^2(b). \tag{4}$$

The WLS estimator has an explicit form; denoting by $\boldsymbol{W} = diag\,(w_1, \ldots, w_n)$ the diagonal matrix with the weights on the main diagonal, the WLS estimator is obtained as

$$b_{WLS} = \left(\boldsymbol{X}^T \boldsymbol{W} \boldsymbol{X}\right)^{-1} \boldsymbol{X}^T \boldsymbol{W} Y.$$

Errros-in-Variables Model

The errors-in-variables (EIV) model can be understood as the most basic additive measurement error (ME) model. Assuming Eq. (3), vectors

$$W_i = \left(W_{i1}, \ldots, W_{ip}\right)^T = \left(X_{i1} + u_{i1}, \ldots, X_{ip} + u_{ip}\right)^T, i = 1, \ldots, n, \tag{5}$$

instead of the true predictors X_i are observed; here $u_i = (u_{i1}, \ldots, u_{ip})^T$ is an (observed) measurement error. It seems natural to estimate β by the least squares in the model

$$Y_i = \beta_0 + \beta_1 W_{i1} + \ldots + \beta_p W_{ip} + e_i, i = 1, \ldots, n, \tag{6}$$

explaining the response by the imprecise predictors (Eq. 5). Let now $\widehat{\beta}$ denote the least squares estimate. In the ME model, the slopes in $\widehat{\beta}$ (but not the intercept) are not consistent and $\widehat{\beta}$ remains biased even for a large number of measurements, while the bias does not vanish if the number of measurements is assumed to increase to infinity. It is typical for the ME model that the least squares estimator underestimates the effects in the model and such phenomenon is known as the attenuation bias or regression dilution.

Consistent Modification of Least Squares in the EIV Model

A consistent estimator of the slopes $\beta_1, \ldots, \beta_p$ in Eq. (6) may be obtained as follows. Denoting now the least squares estimate as $\widehat{\beta} = \left(\widehat{\beta}_0, \widehat{\beta}_1, \ldots, \widehat{\beta}_p\right)^T$, we consider

$$\left(\boldsymbol{C}^2 + \boldsymbol{D}^2\right)^{-1} \boldsymbol{C}^2 \left(\widehat{\beta}_1, \ldots, \widehat{\beta}_p\right)^T, \tag{7}$$

where $\boldsymbol{C}^2$ is the covariance matrix obtained from the true but unobserved predictors, $\boldsymbol{D}^2$ is the covariance matrix obtained from the unobserved measurement errors, and $(\boldsymbol{C}^2 + \boldsymbol{D}^2)^{-1}\boldsymbol{C}^2$ represents the reliability matrix. Equation (7) is consistent under a specific set of assumptions, which naturally include the requirement that the distribution of the measurement errors is symmetric. Although Eq. (7) requires the knowledge of the variability of measurement errors, it may be possible to estimate this variability from prior measurements; such approach is commonly assumed in the literature on the subject (Buonaccorsi 2010).

General Discussion of Estimators in the EIV Model

The theory of various parametric estimates in the EIV model was overviewed in Buonaccorsi (2010), where a focus is given to GLS estimators. The book is also strongly focused on investigating the performance of standard statistical procedures (i.e., those not tailor-made for measurement error models) under the presence of measurement errors. Nonparametric estimators together with methods for regression calibration were overviewed in Carroll et al. (2006).

Particular types of (especially the advanced) estimation procedures for the EIV model will be discussed below. Let us already now stress that some of the approaches require specific assumptions and/or are suitable only in certain circumstances. The TLS estimator (and its extensions) does not require any assumptions on the magnitude of the measurement errors, which explains its popularity in metrology. The weighted approaches (WLS or WTLS) are naturally suitable in situations with known precision (uncertainty) assigned to individual measurements.

A nonparametric estimator of β that is based on ranks of residuals was proposed for the EIV model in Saleh et al. (2012). This estimator denoted as R-estimator is inspired by the consistent approach for the least squares. It is asymptotically highly efficient and admits a local asymptotic bias, which depends only on the precision of the measurements and surprisingly not on the distribution of the regression errors (Jurečková et al. 2016).

Estimators based on robust optimization assume the measurement error to be bounded in some interval and find the solution as the standard one (e.g., least squares) considered for the least favorable case, i.e., for the worst measurement

errors. Such procedures based on optimization under uncertainty have been thoroughly discussed in Ben-Tal et al. (2009).

The presence of measurement errors also causes standard statistical hypothesis testing in the regression model not to be valid. So far, hypothesis testing allowing for measurement errors was considered only rarely; the likelihood ratio test for a general ME model was constructed by means of robust optimization in Broniatowski et al. (2018), who proved it to be a minimax test, i.e., its maximal risk over all values of the parameters is the minimal among all possible tests.

Total Least Squares and Extensions

The TLS estimator, which is one of the popular regression procedures for the EIV model, represents an extension of the orthogonal regression estimators, where the latter consider residuals evaluated as perpendicular Euclidean distances from the fitted regression line (for $p = 1$). The TLS estimator is formally obtained by minimizing the Frobenius norm of the matrix of perturbations, which are considered for the response as well as for the regressors. Such estimator is a nonlinear function of the response and the regressors, and this causes some complications from the practical point of view. Particularly, Hnětynková et al. (2011) studied the computational difficulties of TLS and claimed that the solution of the common algorithm for TLS is not the true TLS estimator obtained by minimizing the Frobenius norm. Pešta (2013) warned that the asymptotic distribution of the TLS estimator might be useless as its assumptions cannot be verified in practice and that the asymptotic covariance matrix of the estimator is unwieldy.

If each measurement has a known and fixed weight corresponding to its precision, it is natural to consider WTLS as the weighted version of the TLS. Krystek and Anton (2007) proposed an algorithm for computing WTLS, and Klauenberg et al. (2022) discussed WTLS in the perspective of the GUM. Because WTLS ignores correlations between the response and the regressors, Krystek and Anton (2011) proposed the WTLSC method, which reduces the uncertainties about the parameters by taking the correlations into account. Particularly for $p = 1$, a single additional correlation parameter is considered in the model. The obtained WTLSC estimator allows to analytically quantify the covariance structure between the parameters, which is very useful in metrology. An interesting application of WTLSC was presented by Ramnath (2020) for the context of pressure balance models in physics of gases.

Robust Regression Estimators

Because the least squares (as well as the total least squares) estimator is too vulnerable to the presence of outliers in the data, various robust statistical methods have been proposed as more resistant alternatives. Many of the robust estimators do

not require to specify, which observations are outliers and which are not (Maronna et al. 2006). Robust estimators typically consider the model (3) without measurement errors, but are intended to be resistant to outliers (global robustness) and only some of them also to small (local) modifications of all measurements (local robustness). However, local robustness has not been sufficiently investigated for many common robust estimators (Sect. 4.9 of Jurečková et al. (2019)). Robust regression methods were applied in Ostojski et al. (2016) for calibration, verification, and validation of models of ecological measurements. They are suitable for multi-sensor positioning methods, especially if high precision and high reliability are needed (Liu et al. 2021). Robust methods also turned out to outperform standard (non-robust) tools in positioning techniques based on the global navigation satellite system (Medina et al. 2019).

Let us now mention some important robust estimators. M-estimators (Huber and Ronchetti 2009) represent a popular class of tools, which may be robust to outliers in the response variable, but none are robust with respect to leverage points, i.e., outliers in the regressors (Jurečková et al. 2019). This is true also for the regression median, which is based on minimizing the sum of absolute values of residuals. M-estimators are not robust in terms of the breakdown point, which represents a fundamental measure of robustness of a statistical estimator of an unknown parameter. The finite-sample breakdown point measures the minimal fraction of data that can drive an estimator beyond all bounds when set to arbitrary value. The first highly robust regression methods had a low efficiency, i.e., low performance for non-contaminated measurements (Rousseeuw and Leroy 1987). The same is true for S-estimators, which are based on minimizing a robust estimate of the scale of the residuals (Davies 1990). MM-estimators of Yohai (1987) can be described as two-stage procedures; their computation starts with performing an S-estimator and proceeds with computing an M-estimator with a particular (fixed) scale.

The least weighted squares (LWS) estimator is a robust regression estimator, which remains less known in spite of its appealing properties (Víšek 2011; Kalina 2015). The motivation is to assign small weights to less reliable observations; such idea of implicit weights assigned after a permutation, which is determined only during the computation, yields promising results in real-life applications (Kalina and Hlinka 2017). The LWS estimator is different from the very common weighted least squares (WLS) estimator, where the latter considers fixed (known) weights assigned to individual measurements. The LWS estimator assumes just like WLS that different measurements have a different accuracy (precision); the precisions of individual measurements correspond to the selected weight function, while it is not known before the computation of the LWS which precision value will correspond to which measurement. Thus, the user does not assign weights to individual measurements, but only chooses their magnitudes.

If suitable weights are used, the LWS estimator is highly robust in terms of the breakdown point. The LWS estimator is at the same time suitable for measurements with unequal variances. The computation of the LWS estimator may exploit an

adaptation of the approximate algorithm of Rousseeuw and Van Driessen (2006). Formally, the LWS estimator requires the user to specify a sequence of magnitudes of weights

$$w_1 \geq w_2 \geq \ldots \geq w_n, \tag{8}$$

where the magnitudes $w_1, \ldots, w_n$ are considered in the form

$$w_i = \frac{\psi\left(\frac{i-1/2}{n}\right)}{\sum_{j=1}^{n} \psi\left(\frac{j-1/2}{n}\right)}, i = 1, \ldots, n. \tag{9}$$

Here, the user has to specify a weight function ψ, which is defined as a function $\psi : [0, 1] \rightarrow [0, 1]$; it must be continuous on $[0, 1]$ with $\psi(0) = 1$ and $\psi(1) = 0$.

The weights are assigned to individual measurements only after some permutation. To define the LWS estimator formally, let us first denote the squared residuals corresponding to a given estimator b of β as

$$u^2_{(1)}(b) \leq u^2_{(2)}(b) \leq \ldots \leq u^2_{(n)}(b). \tag{10}$$

The LWS estimator b_{LWS} is then defined as

$$b_{LWS} = \arg\min_{\beta \in \mathbb{R}^{p+1}} \sum_{i=1}^{n} w_i u^2_{(i)}(b). \tag{11}$$

We propose to use the weight function

$$\psi(t) = exp\left\{-\frac{t^2}{3/2}\right\} \mathbb{1}[t \geq h], t \in (0, 1), \tag{12}$$

where $\mathbb{1}$ denotes indicator function. Such function corresponds to a trimmed version of the Gaussian density with h corresponding to the smallest integer greater than $3n/4$. Such choice ensures a high breakdown point. The LWS estimator remains consistent for weights generated by any weight function which is continuous and nonincreasing. If additionally the errors have a common value of variance $var\, e_1 = \ldots = var\, e_n = \sigma^2$, metrological applications may need to estimate this for the task of uncertainty evaluation (Nielsen 2002); an estimate of σ^2 related to the LWS estimator was proposed in Kalina and Tichavský (2020). An extension of the LWS to nonlinear regression was studied in Kalina (2014).

The quite popular least trimmed squares (LTS) estimator can be perceived as a special case of the LWS with weights equal only to 1 or 0. Defining the LTS requires to choose the trimming constant h between $n/2$ and n so that the minimization of squared residuals is performed only across the h measurements that have the smallest

squared residual. However, the LTS estimator retains vulnerable with respect to small changes of centrally located data (Jurečková et al. 2019).

Robust Estimation in the Location Model

In the location model, robust characteristics of location, i.e., robust estimates of μ, are more suitable than the arithmetic mean if the measurements contain outliers. It is advisable to use robust approaches also for variability estimation as robust counterparts of Eq. (1); let us recall that no approaches for outlier detection are currently described in the GUM methodology. The LWS estimator defined for regression is a promising robust estimator also in the location model (Kalina 2018). It is equal to the weighted mean of the data with such permutation of the weights, which yields the smallest weighted variance

$$S_w^2 = \frac{1}{\gamma} \sum_{i=1}^{n} w_i \left(X_i - \sum\nolimits_{j=1}^{n} w_j X_j \right)^2. \tag{13}$$

When the weights after the optimal permutation are denoted as $w_1^*, \ldots, w_n^*$, the LWS estimate of μ proposed in Kalina (2018) is computed as $\overline{X}_{LWS} = \sum_{i=1}^{n} w_i^* X_i$. A consistency factor γ is needed to be used, depending on the particular ψ; the values of γ were evaluated in Kalina and Tichavský (2020) by numerical simulations for different weight functions so that Eq. (13) becomes a consistent estimator of σ^2 for normally distributed measurements, i.e., S_w^2 converges to the true σ^2 if the number of measurements increases to infinity.

If the measurements in the location model are multivariate (say p-dimensional), robust estimates of the p-dimensional paramete μ can be typically formulated as special cases of robust regression procedures. Evaluating the measurement uncertainty of such measurements must take into account the whole covariance matrix of the measurements, i.e., requires evaluating correlations for pairs of coordinates of μ (Tellinghuisen 2001; Senin et al. 2021).

Robust Regression: A Real Data Example

The aim of this example is to compare the variances of several regression estimators. An important task of evaluating measurements by linear regression is namely an evaluation of uncertainty of the obtained result; for this task, it is important to evaluate the variability of the estimates of regression parameters. We analyze the thyroid disease dataset previously used for regression modeling in Kalina and Tichavský (2020), where however the variability of regression estimates was not considered. The dataset contains measurements obtained from blood tests performed for a sample of $n = 22$ patients with hypothyroidism. The data include continuous

values $Y_1, \ldots, Y_n$ of the level of a specific drug, which is known to be correlated with the excretion level of the C-reactive protein in the body; this protein represents an important sensitive inflammatory marker and a common biomarker for the disease. Measured continuous values of this protein represent the regressor $X_1, \ldots, X_n$. The linear model (3) with $p = 1$ is meaningful, because there is a hypothesis that the amount of the protein in the body is proportional to the level of the drug in the blood.

The computations are performed in R software (R Core Team 2021), version 4.1.2 for Microsoft Windows. The following estimates are used:

- Least squares
- S-estimator (with breakdown point 0.5)
- MM-estimator (with breakdown point 0.5 and efficiency 0.95)
- LTS with a specific h ($h = 0.55n$ or $h = 0.80n$)
- LWS with the weight function (12) with the choice $h = 0.75$, i.e., with breakdown point 0.75

Because explicit formulas for variances are not available for all of these estimators, we take resort to bootstrap estimates. Bootstrapping is commonly applied to approximate the variability of estimators by means of resampling the data (sampling from the measured data with replacement). The results of various estimators of β together with nonparametric bootstrap estimates of their standard deviations are presented in Table 1. Nonparametric bootstrap was also used to evaluate $\rho(b_0, b_1)$, which denotes the correlation coefficient between the slope and the intercept. The results bring an argument in favor of the LWS estimates, which give a reasonable regression fit and their standard deviations are at the same time smaller compared to all other estimators here, including renowned robust regression estimators.

Robust Regression: Simulation

Further, we present a Monte Carlo simulation study performed (again) with the aim to compare nonparametric bootstrap estimates of variances of various regression estimators. For the linear model (3) with $p = 1$, we consider $N = 100$ randomly simulated datasets with $n = 60$ measurements each. For each dataset, the regressor is

Table 1 Results for the thyroid disease dataset: estimates of regression parameters and nonparametric bootstrap estimates of their standard deviation and correlation

Estimator	b_0	b_1	$S.D.(b_0)$	$S.D.(b_1)$	$\rho(b_0, b_1)$
Least squares	−582	0.239	108.9	0.016	−0.98
S-estimator	−542	0.206	132.1	0.023	−0.81

LTS ($h = 0.55$)	−371	0.203	119.2	0.017	−0.87
LTS ($h = 0.80$)	−515	0.228	110.6	0.016	−0.87
LWS	−455	0.214	102.5	0.014	−0.85

randomly generated from uniform distribution $U(0, 10)$, i.e., over the interval $(0, 10)$. We always use $\beta = (2, 1)^T$ and $\sigma^2 = 1$. The random errors are generated from normal distribution as $e_i \sim N(0, \sigma^2)$ with $\sigma = 0.3$. We consider each of the N datasets itself, together with $R = 100$ contaminated versions. Each contamination considers $c\%$ of randomly selected measurements (using $c = 0$, $c = 10$, or $c = 30$). Then, a value denoted as m is generated from $U(0, 10)$. For each of the selected measurements, a specific value v is generated from $U(-0.5, 0.5)$ and the regressor is replaced by $m + v$; the response is replaced by a value obtained according to Eq. (3) with the error generated from $U(3, 6)$.

For each of the contaminated datasets, $S = 100$ bootstrap samples are created and evaluated. For each bootstrap sample, each of the six given estimators is computed, and the results are averaged over all the bootstrap samples. From the averaged results computed over the datasets in each situation, the covariance matrix is obtained. Table 2 presents the results; using the notation $b = (b_0, b_1)^T$ for a particular estimator under consideration, Table 2 also presents averaged values of $S.D.(b_0)$, $S.D.(b_1)$, and $\rho(b_0, b_1)$. This simulation reveals that the LWS estimates are close to true values of β and are able to outperform all other estimates (especially under a severe contamination) in terms of variability. It can be also seen in Table 2 how much is the least squares estimator biased for contaminated measurements. This is further

Table 2 Results of the simulation study: averaged estimates of regression parameters, and nonparametric bootstrap estimates of their standard deviation and correlation

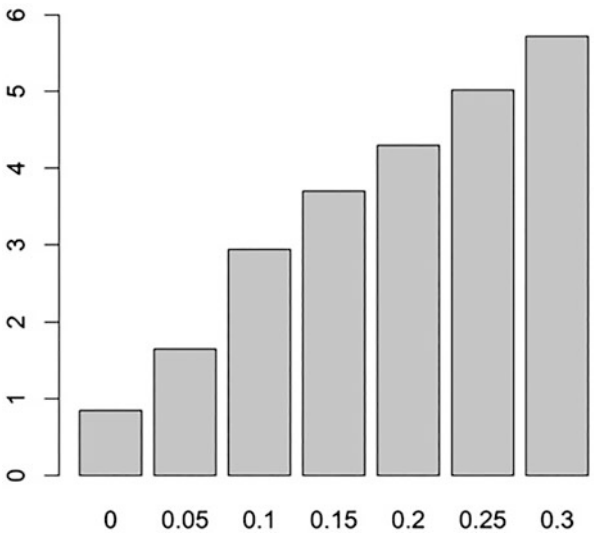

Fig. 1 Results of the simulation study: the averaged ratio $S.D.\left(b_1^{LS}\right)/S.D.\left(b_1^{LWS}\right)$ depending on the contamination level c

revealed in Fig. 1, which shows the ratio of $S.D.\left(b_1^{LS}\right)/S.D.\left(b_1^{LWS}\right)$ comparing the standard deviations of the LWS and the least squares, respectively. The figure clearly reveals the negative effect of outliers on the non-robust least squares estimator to be increasing together with an increasing contamination of the dataset.

Bayesian Estimation in the Location Model

Bayesian statistical methodology allows to naturally combine the results of given measurements with prior measurements, if the latter are available. Bayesian estimates of location or estimates of variability obtained as such combinations correspond to intuition. This section presents useful connections revealing how Bayesian estimates use prior measurements in a very natural way. It is rather surprising that the explanations presented here and the intuitive interpretation of formulas are missing in available monographs on Bayesian statistics (e.g., Ghosh 2019).

Bayesian reasoning as such represents an intuitive approach to considering conditional probabilities (Kahneman 2011). Bayesian methods are not presently formulated in the GUM methodology (Wübbeler et al. 2020), which does not provide state-of-the-art data analysis (Marschall et al. 2022). Bayesian methods are expected to be incorporated in later editions of the GUM in the next 5 years so that the GUM will finally be able to exploit the latest Bayesian statistical theoretical framework allowing to fully integrate prior measurements with actual measurements. Such combination of information has been denoted as the Bayesian information fusion (Cheng et al. 2018). Metrologists have always debated, whether the

frequentist or the Bayesian approach should be preferable for evaluating uncertainty. Arguments in favor of the Bayesian approach were summarized already, e.g., in Cox et al. (2004). While the Bayesian approach seems to be prevailing in current metrology (Ferrero et al. 2019), Bayesian approaches to uncertainty evaluation (Bayesian metrology approaches) are still under development for some specific measurement models, such as for mass spectrometry measurements in metabolomics (Banks et al. 2021).

In the following paragraphs, the Bayesian estimator is always obtained as the expectation (population mean) of the posterior distribution; such estimator is commonly denoted as MAP (maximum a posteriori) estimator. We focus on the situations when previous R measurements (for $R \geq 1$) are performed under the same conditions as the current (new) data. We also explain whether Bayesian estimation always requires to understand (e.g., physical) constants to be random variables. A deeper philosophical justification of Bayesian reasoning can be found in Jaynes (2003). This section is focused on simple fundamental problems and thus omits many advanced problems, such as a suitable choice of prior distribution, construction of Bayesian confidence areas, Bayesian approaches to linear regression (Saleh et al. 2022), or empirical Bayes estimation; technical proofs are also omitted.

Bayesian Estimation: Mean of One-Dimensional Gaussian Distribution

Let us consider independent measurements $X_1, \ldots, X_n$, where X_i is assumed to come from the normal distribution $X_i \sim N(\mu, \sigma^2)$ for $i = 1, \ldots, n$. These can be measurements of some physical constant (e.g., the speed of light), which is thus denoted here as μ. In some other situations, the normality of values X_i can be quite natural, if each individual (indirect) measurement X_i is obtained as the mean of several independent measurements and if the data do not contain outliers.

At any case, we use the notation $\overline{X}$ for the mean of the measurements, for which it naturally holds $var\,\overline{X} = \sigma^2/n$. This expression can also be justified from the Bayesian point of view under the assumption of a noninformative prior distribution.

Independently on the measurements, we assume that previous measurements were performed and the measured values are known. Estimates of μ obtained from these prior measurements will be denoted as $t_1, \ldots, t_R$. Let us assume that each of them was acquired as a realization of a normally distributed random variable. We denote $\overline{t} = \sum_{r=1}^{R} t_r/R$.

Let us now proceed very slowly. The knowledge of $t_1, \ldots, t_R$ reduces the uncertainty about the unknown value of μ. We expect the value of $\overline{t}$ to be close to the true (unknown) value of μ, because we consider it to be unlikely that the true value of μ is much different from the experimentally determined mean value $\overline{t}$. We do not know the reason for such difference (deviation), and therefore we consider it to be random. We may believe that if $\overline{t}$ exceeds μ by a certain constant, this is equally likely as if $\overline{t}$ remains below μ by the same constant. Considering the concepts of

randomness, likelihood, or probability means that the uncertainty about the value of μ may be expressed by the concept of a random variable. This does not state that μ is objectively a random variable, which would be a mere self-deception. Thanks to the same probability of deviating on both sides, we may consider the distribution corresponding to the uncertainty about the value of μ to be symmetric. Here, we consider it to be normally distributed according to $\mu \sim N(\bar{t}, \gamma^2)$, where $\gamma^2 = var\,\mu$ is obtained by means of the formula for the variance of the mean $\gamma^2 = \xi^2/R$. Here, the parameter ξ evaluates the accuracy (standard deviation) of the measurements $t_1, \ldots, t_R$.

In general, it is possible to interpret the Bayesian estimation by means of two ways, which have an equal mathematical expression:

1) The prior distribution corresponds to the uncertainty about the estimated parameter. This (in our opinion more realistic) approach was also considered by Laplace; as a propagator of Bayesian reasoning, he did not consider physical constants to be random but perceived the world and universe in a deterministic manner. In general, the uncertainty can be perceived either objectively from the point of view of information theory or objectively as a degree of belief (Abdellaoui et al. 2021).
2) The estimated parameter is a random variable, while the measurements $X_1, \ldots, X_n$ inform us about its distribution.

Both points of view lead to the conclusion that the mean of the posterior distribution, i.e., the Bayesian estimate of the parameter μ,has the form

$$\widehat{\mu} = \frac{\sigma^{-2}\sum_{i=1}^{n} X_i + \gamma^{-2}\bar{t}}{n\sigma^{-2} + \gamma^{-2}}. \tag{14}$$

We may easily express Eq. (14) as

$$\widehat{\mu} = (1-\delta)\overline{X} + \delta\bar{t}, \text{where } \delta = \frac{\gamma^{-2}}{n\sigma^{-2} + \gamma^{-2}}. \tag{15}$$

Let us now consider a special situation, when each of the measurements $t_1, \ldots, t_R$ (just like the value of $\overline{X}$ computed from these measurements) is obtained from the total number of n measurements with variance σ^2. Because it holds $var\, t_r = \sigma^2/n$ for $r = 1, \ldots, R$, we obtain $var\,\bar{t} = \sigma^2/(nR)$. The literature typically states only briefly that γ may be estimated from previous measurements; nevertheless, it is natural here to make the particular choice for $var\,\mu$ to obtain $\gamma^2 = \sigma^2/(nR)$. Thus, we obtain

$$\delta = \frac{R}{R+1} \text{ and } \widehat{\mu} = \frac{1}{R+1}\overline{X} + \frac{R}{R+1}\bar{t}. \tag{16}$$

The resulting estimate can be interpreted as the mean of all available measurements obtained by incorporating the prior (previous) measurements to the set of the

new measurements that were acquired later. It is an intuitively expected combination of previous and current measurements. In practice, however, it is common to have new measurements with a higher accuracy compared to the previous measurements. But also in the situation with a fixed ratio $\sigma^2/(n\gamma^2)$,i.e., when there were no prior measurements $t_1, \ldots, t_R$, a result analogous to Eq. (16) is valid.

Bayesian Estimation: Mean of Multivariate Gaussian Distribution

For multivariate location model under the assumption of multivariate normality, let us explain how the Bayesian estimator (again) allows to incorporate prior measurements in a natural way. Let us consider independent p-dimensional measurements $X_1, \ldots, X_n$, where X_i is explained by the multivariate normal distribution $X_i \sim N_p(\mu, \boldsymbol{\Sigma})$ for $i = 1, \ldots, n$. Let us proceed in the same way as above but in a much concise manner. We assume estimates of the parameter μ to be available from prior measurements; these estimates are denoted as $t_1, \ldots, t_R$. We denote the arithmetic means as

$$\overline{X} = \frac{1}{n}\sum_{i=1}^{n} X_i \text{ and } \bar{t} = \frac{1}{R}\sum_{r=1}^{R} t_r. \tag{17}$$

If the prior knowledge about the parameter μ is modeled by means of the p-variate normal distribution $\mu \sim N_p(\bar{t}, \boldsymbol{\eta})$, the expectation of the posterior distribution of μ may be expressed as

$$\widehat{\mu} = \left(n\boldsymbol{\Sigma}^{-1} + \boldsymbol{\eta}^{-1}\right)^{-1}\left(n\boldsymbol{\Sigma}^{-1}\overline{X} + \boldsymbol{\eta}^{-1}\bar{t}\right). \tag{18}$$

This result was proven in Evans (1965), who also derived a more complex result for data with an unknown $\boldsymbol{\Sigma}$. If some previous measurements are available and it is possible to estimate $\boldsymbol{\Sigma}$ from them, it may be replaced by the empirical covariance matrix, which gives a consistent estimate (thanks to the assumed normality).

Let us assume now a specific situation with a known $\boldsymbol{\Sigma}$ and let us assume $\boldsymbol{\Sigma} = \sigma^2\boldsymbol{I}$, where $\boldsymbol{I}$ denotes a unit matrix. We assume the accuracy of all coordinates of the vector μ to be the same and the prior knowledge of the parameter μ is modeled by a normal distribution

$$\mu \sim N_p\left(\bar{t}, diag\left(\gamma^2, \ldots, \gamma^2\right)\right). \tag{19}$$

The expectation (Eq. 18) of the posterior distribution of μ then corresponds to

$$\widehat{\mu} = \frac{n\gamma^2\overline{X} + \sigma^2\bar{t}}{n\gamma^2 + \sigma^2}, \tag{20}$$

which may be expressed as

$$\widehat{\mu} = (1-\delta)\overline{X} + \delta\bar{t}, \text{ where } \delta = \frac{\gamma^{-2}}{n\sigma^{-2}+\gamma^{-2}}. \quad (21)$$

More specifically, let us assume each of the vectors $t_1, \ldots, t_R$ obtained from the previous measurements to be obtained from the total number of n measurements with variance σ^2. It holds $var\,\overline{X} = \sigma^2 \boldsymbol{I}/n$, and it is natural to choose $\gamma^2 = \sigma^2/(nR)$. Then, we obtain Eq. (16). This multivariate estimator can be interpreted as a so-called shrinkage estimator of μ, i.e., an estimator which is shrunken towards the value $\bar{t}$.

Bayesian Estimation: Covariance Matrix of Multivariate Gaussian Distribution

We consider to have independent p-variate measurements $X_1, \ldots, X_n$ explained by the normal distribution $N_p(\mu, \boldsymbol{\Sigma})$ with a known μ and an unknown covariance matrix $\boldsymbol{\Sigma} \in PD(p)$, where $PD(p)$ denotes the set of all positively definite matrices of size pxp. It is natural to estimate $\boldsymbol{\Sigma}$ by means of the matrix $\boldsymbol{U}/n$,where

$$\boldsymbol{U} = \sum_{i=1}^{n} (X_i - \mu)(X_i - \mu)^T \quad (22)$$

exploits the known vector μ. In such a situation, the matrix $\boldsymbol{U}$ follows Wishart distribution $W_p(\boldsymbol{\Sigma}, n)$ and therefore we have $E(\boldsymbol{U}/n) = \boldsymbol{\Sigma}$. It is usual to model the uncertainty about $\boldsymbol{\Sigma}$ (in fact about $\boldsymbol{\Sigma}^{-1}$) by means of Wishart distribution $\boldsymbol{\Sigma}^{-1} \sim W_p(\nu + p - 1, \boldsymbol{\Omega}^{-1})$ for a certain $\nu > 0$ and for a certain $\boldsymbol{\Omega} \in PD(p)$. In such situation, $\boldsymbol{\Sigma}$ follows the inverse Wishart distribution $W_p^{-1}(\nu + p - 1, \boldsymbol{\Omega})$. It holds

$$E\boldsymbol{\Sigma}^{-1} = (\nu + p - 1)\boldsymbol{\Omega}^{-1} \text{ and } E\boldsymbol{\Sigma} = \boldsymbol{\Omega}/(\nu - 2). \quad (23)$$

The posterior expectation of $\boldsymbol{\Sigma}$ is then equal to

$$\widehat{\boldsymbol{\Sigma}} = \frac{\boldsymbol{U} + \boldsymbol{\Sigma}}{n + \nu - 2}. \quad (24)$$

Let us assume to have prior estimates of $\boldsymbol{\Sigma}$ denoted as $\boldsymbol{U}_1/n, \ldots, \boldsymbol{U}_R/n$, which are obtained from some previous measurements. In other words, the matrices $\boldsymbol{U}_1, \ldots, \boldsymbol{U}_R$ represent empirical counterparts of $\boldsymbol{U}$. Let us further assume that each of the previous experiments was performed across n measurements, and that each had the same accuracy (variability) as the current measurements. It is natural to choose $\boldsymbol{\Omega}$ and ν so that

$$\frac{1}{R}\sum_{r=1}^{R}\frac{\boldsymbol{U}_r}{n}=\frac{\boldsymbol{\Omega}}{\nu-2}, \tag{25}$$

i.e., to take $\boldsymbol{\Omega}=\sum_{r=1}^{R}\boldsymbol{U}_r$ and $\nu=Rn+2$. The estimate (Eq. 24) is then obtained as the intuitive combination of the measurements with results of the previous measurements in the form

$$\widehat{\boldsymbol{\Sigma}}=\frac{1}{n(R+1)}\left(\boldsymbol{U}+\sum_{r=1}^{R}\boldsymbol{U}_r\right). \tag{26}$$

Conclusion

This chapter describes and discusses selected nonstandard statistical techniques for analyzing measurements, or in fact selected classes of advanced available statistical tools. While each of the topics covered here deserves much more space, the chapter is focused on principles while keeping aside a vast number of other available methods potentially applicable to metrology. Current metrology intensively makes use of various forms of the measurement error models, and the Bayesian approach represents the prevailing approach nowadays, especially if prior knowledge related to the variability of the measurement errors is available. Robust statistical methods, which have established their place within mathematical statistics, have a potential for being used in metrology much more often than nowadays.

At any case, the authors recommend that an analysis of measurements is always accompanied by verifying that the available data are really raw; it is namely known that no analysis (not even by robust methods) can perform a reliable analysis of data after an inappropriate pre-processing (cf. Kalina 2018). In addition to the topics covered in this chapter, metrologists can nowadays experience an advent of data with a high dimensionality, which become available thanks to the increasing level of digitalization, availability of sensors in various fields, or automation of various processes of human activities (Chap. 14 of Hebra 2010). As we cannot expect the availability of various low cost measurement equipment to be decreasing, there will also remain an intensive need for robust statistical methods for metrological applications across diverse fields.

Acknowledgments The work of J. Kalina was supported by the project GA22-02067S (Approximate Neurocomputing) of the Czech Science Foundation. The authors would like to thank an anomymous reviewer for valuable suggestions.

Abstract

Despite the importance of measurement uncertainty, it is widely misunderstood, and it represents a vague subject for both industrial and scientific practitioners. In this chapter, it is aimed to introduce the subject of measurement uncertainty step-by-step starting from the basic principles to the actual uncertainty evaluation techniques. The text does not only present the theoretical aspects of uncertainty, but it also deals with its practical implementation. The chapter begins by introducing the concept of uncertainty and its importance, and then it discusses Type A

and Type B uncertainty evaluation methods. After that, the GUM uncertainty framework is presented as well as the Monte Carlo simulation technique and its programming details. Throughout the chapter, several examples are demonstrated to put the discussed concepts into action. The chapter is very useful for anyone whether an industrial practitioner, scientist, or student.

Introduction

Every measurement process must have some sorts of imperfections that reduce the trustworthiness of the measurement's result. In other words, there is always some doubt about any measurement result whatever the precautions taken to obtain that result. Depending on the application in which the measurement result will be used, different levels of doubt may be acceptable or not. To deal with that doubt, it is necessary to quantify it in terms of the unit of the measurand or as a percentage of the measurement result. This numerical quantification of the doubt about the measurement's result is what is called the measurement *uncertainty*. The uncertainty is a key term in reflecting the quality of the measurement process and the trustworthiness of its result and the decision taken upon it.

The uncertainty in measurement can be simply defined as the "quantified doubt about the result of a measurement" (Bell 2001). To clarify the concept of uncertainty, consider a measuring process aims to estimate the length of a steel bar using a classical micrometer, the length was measured five times, and the results were as follows: 50.00 mm, 49.98 mm, 49.98 mm, 50.03 mm, and 50.00 mm. Why different values are obtained? And where is the true value of the length? In fact, the true value may lie in between these values, i.e., in the interval [49.98 mm, 50.03 mm], but due to the *repeatability error* that arises from some sorts of imperfections in the measuring process, e.g., the ambient temperature and humidity, stiffness of the measured object, etc., the measured values spread around the true value resulting in some doubt (uncertainty) about the final result of the measurement (i.e., the estimated true value) and reducing its trustworthiness.

Practically, several sources of uncertainty – beside repeatability – depending on the nature of the measuring process can be present resulting in more dispersion around the measurement result thereby more extension in the interval in which the true value is expected to lie, which means more increase in the uncertainty. From a mathematical point of view, the uncertainty is a value that quantifies the dispersion of the values that have probabilities to be the true value around the measurement result. Accordingly another definition for the uncertainty was introduced by the *International Vocabulary of Metrology* (VIM) (BIPM 2012) as "non-negative parameter characterizing the dispersion of the quantity values being attributed to a measurand, based on the information used."

It should be clear that the uncertainty is different from *error*. The error is the deviation between the measurement result and the true value of the measurand. All known errors should be corrected while the errors with unknown values are considered sources of uncertainty (Bell 2001) which are uncorrectable.

The General Idea of Quantifying Uncertainty

Generally, the quantification of measurement uncertainty begins by identifying the uncertainty sources that can significantly affect the trustworthiness of the measurement result. Each uncertainty source is quantified by determining its expected range of doubt and then, that range is assigned a reasonable probability distribution. After that, various uncertainty sources are combined using an appropriate technique to obtain the total range of doubt and its probability distribution which is known as the output distribution.

Depending on the output distribution, the mean value is estimated and considered as the result of the measurement process. Also, the standard deviation of the output distribution is calculated and considered as the combined standard uncertainty of the measurement result. Here, the term "standard" means that the estimated combined uncertainty is obtained using the individual standard uncertainties of the uncertainty sources, i.e., the individual standard deviations of their respective distributions. As a common case in metrology, the output distribution is considered as normal (Gaussian). In that case, the combined standard uncertainty is $\pm$ *one standard deviation* around the mean value (Fig. 1).

Is the true value really lies within the uncertainty interval? This question is answered by determining the *level of confidence* provided by that uncertainty interval. Mathematically, the level of confidence is the probability/area under the output distribution over the uncertainty interval; this value tells us on what probability the true value lies within that uncertainty interval. In practice, the level of confidence provided by the combined standard uncertainty may not be satisfactory for some industrial and commercial applications (BIPM 2008a). As a result, the considered uncertainty interval is extended to encompass a larger fraction of the output distribution, this produces what is called *expanded uncertainty*. In fact, the expanded uncertainty increases the level of confidence in trade off increasing the range of doubt in which the true value is expected to lie. For a normal output distribution (Fig. 1), the combined standard uncertainty provides about 68% level of confidence, while if that range of uncertainty is doubled, the level of confidence reaches approximately 95%.

The reporting of the measurement result should be along with the uncertainty value and the level of confidence. For example, the result of measuring the length of a copper bar can be reported as follows:

69.88 mm $\pm$ 0.03 mm at a level of confidence 95%.

This means that we have 0.95 probability that the true length of the copper bar falls between 69.85 mm and 69.91 mm.

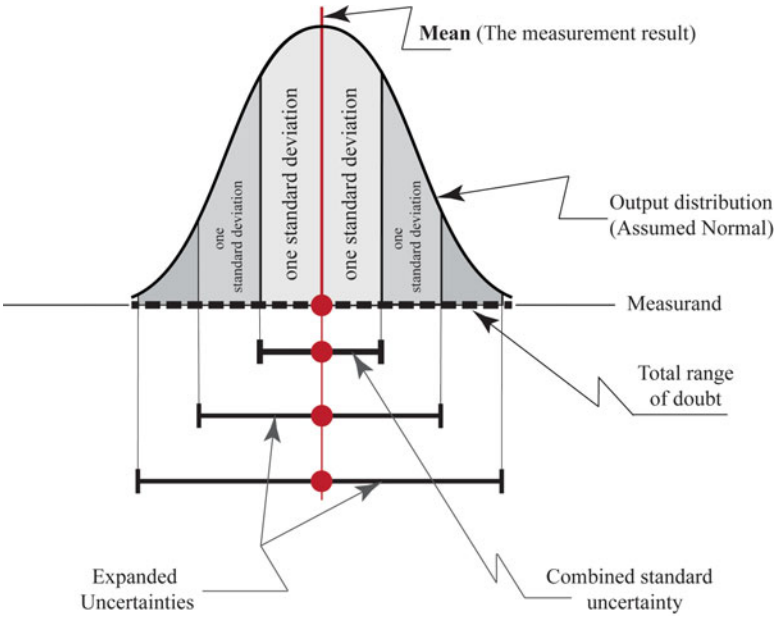

Fig. 1 The normal output distribution obtained from combining several uncertainties

Considering Uncertainty in Determining Conformance to Specifications

One of the major applications of measurement uncertainty is determining the conformance of products to their specifications. Consider a certain feature of a product that has a lower tolerance limit T_L and an upper tolerance limit T_U. The feature is measured using an appropriate measurement process that has an expanded uncertainty U. Unless the tolerance width $T_U - T_L$ is greater than the uncertainty interval 2 U, the result of the measuring process would be inconclusive in determining the conformance of the feature to its specified tolerance even if the measurement result falls within that tolerance. A common parameter that used to quantify the capability of the measuring process to provide conclusive results with respect to the tolerance width is the *measurement capability index* C_m where C_m is the ratio of the tolerance width to the uncertainty interval, $C_m = (T_U - T_L)/2U$ (ASME B89.7.4.1 2005).

Although C_m can have a relatively large value, the measurement result would still be inconclusive in case the uncertainty interval intersects with a tolerance limit. To clarify that, see Fig. 2, in that figure, the uncertainty interval in cases (c), (d), and (e) entirely lies inside the tolerance zone; this leads to the conclusion that the measured feature is acceptable. In cases (a) and (g), the uncertainty interval falls entirely outside the tolerance zone which leads to the conclusion that the measured

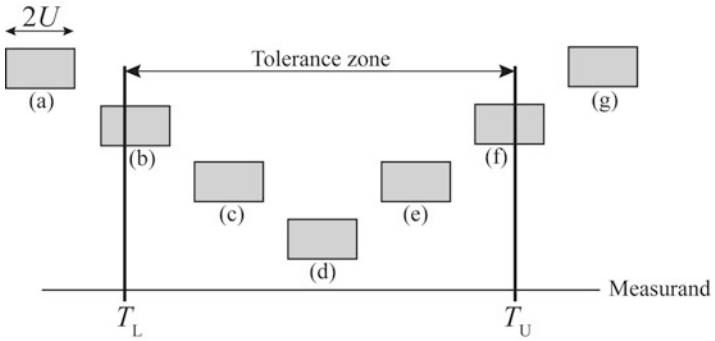

Fig. 2 The relative positions between the uncertainty interval and the specified tolerance

feature is unacceptable. In cases (b) and (f), the uncertainty interval intersects with a tolerance limit; this means that the measured feature may be acceptable or not at certain probabilities; these are inconclusive situations.

In practice, accepting or rejecting a certain feature is decisioned upon a *decision rule*; these decision rules consider the measurement uncertainty in taking accept/reject decisions even if the uncertainty interval is near the tolerance limits or intersect with them. The decision rules contain some risks of accepting a nonconforming product or vice versa; it is a business issue and subject to cost analysis. For detailed information about decision rules, how uncertainty is considered in determining the conformance to specifications, and risk analysis, refer to references (ASME B89.7.4.1 2005; ASME B89.7.3.1 2001; ISO 2017; Ribeiro et al. 2017).

Toward quantifying the uncertainty of a measurement result, the first step is identifying the individual uncertainty sources that expected to have significant contributions to the total uncertainty. In practice, the standard guidelines devoted to specific metrological tasks issued by standardization bodies are rich with useful information in determining the uncertainty sources that deserve consideration. Moreover, the experience with the measurement process and the special conditions of the laboratory should be paid attention in identifying those sources. Once, the uncertainty sources are identified, their contributions are quantified according to *Type A* method or *Type B* method depending on the nature of the available information about the uncertainty source. Through section "Type A Evaluation Method" and "Type B Evaluation Method," both quantification methods are discussed as well as the quantification of several examples of uncertainty sources that are common in metrological practices.

Type A Evaluation Method

Type A evaluation method is the statistical evaluation technique that is used to quantify uncertainty sources only when the available data about the source is in the form of repeated observations under the same conditions. In that method, a measured

quantity q is considered as a random variable and its available n observations q_1, q_2, …, q_n are independently captured from its respective distribution under the same conditions of measurement (BIPM 2008a; M3003 2012). Accordingly, the expectation μ_q of that distribution is the best representative of the true value of the quantity being measured, i.e., it represents the measurement result. Nevertheless, the expectation of that distribution needs a very large number of observations to be calculated accurately; this is not common in metrological practices in which only few observations are available. So, the arithmetic mean $\overline{q}$ of the available observations is taken as the best available estimate of the expectation μ_q of the distribution and is calculated as:

$$\overline{q} = \frac{1}{n}\sum_{i=1}^{n} q_i \tag{1}$$

As we ultimately seek for the value of μ_q, it is required to quantify how well the mean value available in hand $\overline{q}$ estimates μ_q; this can be achieved by calculating the *experimental standard deviation of the mean* $s(\overline{q})$ as follows:

$$s(\overline{q}) = \frac{s(q_i)}{\sqrt{n}} \tag{2}$$

where $s(q_i)$ is the *experimental standard deviation* which characterizes the dispersion of the observations about their mean $\overline{q}$ and is calculated as:

$$s(q_i) = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(q_i - \overline{q})^2} \tag{3}$$

Eventually, the mean value $\overline{q}$ is considered as the best estimate of q while the associated standard uncertainty $u(q)$ is taken equal to $s(\overline{q})$.

Type B Evaluation Method

Type B evaluation method is used for quantifying uncertainty sources whenever the available knowledge about the source is not in the form of repeated observations (BIPM 2008a). In Type B, scientific judgment is the key in determining the expected range of doubt and the assigned probability distribution. In practice, for an uncertainty source quantified according to Type B method, reasonable judgments must be issued by experts with respect to:

(a) The possible range of the doubt.
(b) An estimation for the likelihood of different values in the range of doubt, this may be achieved by answering some questions, e.g., What are the points that have more probability than others? What is the rate in which the probability is

decreased as the value gets farther from the most probable values? (ASME B89.7.3.2 2007), and so forth.

These judgments should be based on all the available knowledge about the uncertainty source; this knowledge may be found in a variety of sources such as but not limited to (a) previous measurements, (b) calibration certificates, (c) manufacturer's specifications, (d) engineering judgments, (e) handbook values, etc. (BIPM 2008a; ASME B89.7.3.2 2007; Boumans 2013).

In practice, the available knowledge about uncertainty sources is commonly limited to typical levels such as: (Kadis 2000).

Level 1: The limits of the possible values are only the knowns.
Level 2: A more likely mean value and the limits of permissible values which are usually symmetric about the mean.
Level 3: An interval that encompasses a certain probability percentage of the probability distribution, e.g., 95% or 99%.

For each level from the previous list, there is a certain probability distribution that best fit with the available level of knowledge. In the next sections, the characteristics of the most utilized probability distributions will be discussed.

The Uniform Distribution (Best Fit with Level 1)

The uniform distribution of a quantity q is fully defined by specifying its lower limit a and upper limit b; within that interval, the values are assigned equal probabilities (Fig. 3). The expected value $\overline{q}$ of the quantity q is calculated as:

$$\overline{q} = \frac{a+b}{2} \tag{4}$$

The standard uncertainty of the quantity q is taken equal to the standard deviation of q and calculated according to the characteristics of the Uniform distribution as follows:

$$u(q) = s(q) = \frac{b-a}{2\sqrt{3}} \tag{5}$$

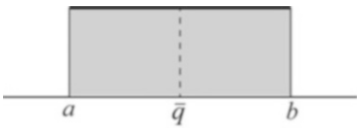

Fig. 3 The uniform distribution of a quantity q

A classical example of uncertainty sources that attributed to the uniform distribution is the resolution uncertainty of digital indications. Consider a digital instrument that indicates an indication X on its display; what is the actual value of the measurand that results in that indication? The prevailing point of view is that if the measurand value is within the limits $X - r/2$ and $X + r/2$ inclusive (r is the resolution of the digital display), the digital instrument would round it to X on its display (Hawam et al. 2018). Accordingly, and considering that there is no more knowledge available about the location of the measurand value, the uniform distribution is applied over the uncertainty interval $[X - r/2, \quad X + r/2]$. Therefore, the expected value of the measurand is X and the resolution standard uncertainty is $r/2\sqrt{3}$.

The Isosceles Triangular Distribution (Best Fit with Level 2)

The isosceles triangular distribution of a quantity q is fully defined by specifying its lower limit a and upper limit b while the mean value $\overline{q}$ falls exactly midway between a and b. Within that interval [a, b], the probability is increased gradually from *zero* at the lower limit a until it reaches its maximum at $\overline{q}$ and then it decreases gradually until it reaches *zero* again at the upper limit b (Fig. 4). The expected value $\overline{q}$ of the quantity q is calculated as:

$$\overline{q} = \frac{a+b}{2} \tag{6}$$

The standard uncertainty of the quantity q is taken equal to the standard deviation of q and calculated according to the characteristics of the isosceles triangular distribution as follows:

$$u(q) = s(q) = \frac{b-a}{2\sqrt{6}} \tag{7}$$

The resolution uncertainty of analogue indications may be attributed to the isosceles triangular distribution in case the pointer is in conjunction with a graduation mark on the analogue display. In that case, it is reasonable to assign the highest probability to the graduation value and decrease it gradually until it reaches *zero* at the limits of the uncertainty interval. For example, if the width of the resolution

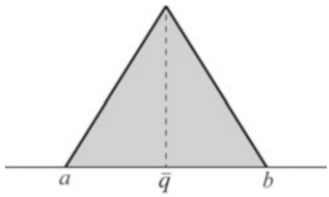

Fig. 4 The isosceles triangular distribution of a quantity q

uncertainty interval is r (r is the resolution of the analogue display) and the pointer is in conjunction with a certain graduation with value X, the expected value of the measurand would be X while the resolution standard uncertainty would be $r/2\sqrt{6}$. For detailed information about analogue indications and how its uncertainty is quantified, refer to Ref. (Hawam et al. 2021).

Note: For more information about the uniform, triangular, and other similar distributions, refer to Ref. (Raghu and James 2007).

It is noteworthy that the measuring devices, either analogue or digital, with limited resolution (i.e., with large r value) may result in identical observations. Accordingly, Type A uncertainty calculated as per Eq. 2 would equal *zero*. This does not mean that the measuring process is ideal; on the contrary, this indicates that the measuring instrument does not have the enough resolution necessary to detect the scattering in the observations. In such situation, the resolution uncertainty should be paid more attention as the resolution becomes the only source of knowledge about the possible repeatability error that can be encountered in the observations. For a mathematical analysis and an example that demonstrate this issue and how the resolution can affect the results, refer to Ref. (Ignacio and Wolfgang 1997).

The Normal Distribution (Best Fit with Level 3)

The normal distribution of a quantity q is fully defined by specifying its mean value $\overline{q}$ and standard deviation σ_q. The mean value $\overline{q}$ is assigned the highest probability and its neighborhood values are assigned higher probabilities than assigned to other far values.

Based on the level of knowledge provided by level 3, the center of the known interval $[a, b]$ can be considered as the expectation $\overline{q}$ of the normal distribution, i.e., $\overline{q} = (a + b)/2$; see Fig. 5. For obtaining the standard deviation σ_q, the equivalent z score (from the standard normal distribution) of the interval limit, say b, is extracted from the standard normal table (For ease of application, computer software packages such as Microsoft Excel can be used instead of statistical tables.) as the z score z_b corresponding to the probability encompassed by $[a, b]$ divided by *two* (assuming that the table provides the probability values starting from $z = 0$). Then, the standard deviation σ_q can be calculated as follows:

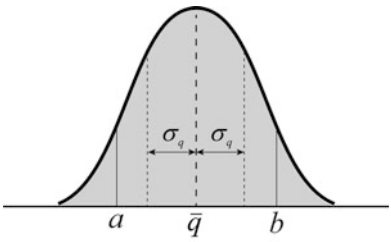

Fig. 5 The normal distribution of a quantity q

$$\sigma_q = \frac{b - \overline{q}}{z_b} \tag{8}$$

The standard uncertainty of the quantity q is taken equal to the calculated standard deviation, i.e., $u(q) = \sigma_q$.

Practically, the standard deviation of normal distribution can be calculated according to a simple rule if the intervals that encompass certain probabilities are known. According to this rule, if an interval $[a, b]$ centered about $\overline{q}$ and encompasses 0.68 probability, its length approximately equals $2\sigma_q$, i.e., $b - a \approx 2\sigma_q$; for 0.95 probability, $b - a \approx 4\sigma_q$; for 0.99 probability, $b - a \approx 6\sigma_q$.

One of the uncertainty sources that commonly attributed to the normal distribution is the calibration uncertainty. In calibration laboratories, the performance of the under-test instrument is evaluated, quantified, and combined to the *Calibration and Measurement Capability* (CMC) of the laboratory; the resultant is the calibration uncertainty of the under-test instrument and its usually reported at 95% level of confidence (ILAC 2013) assuming normal distribution.

Example 1 Consider that the length of a steel bar is measured using a Vernier caliper that has a calibration uncertainty 0.2% of the measured length at a confidence level 95% assuming a normal distribution. For calculating the calibration uncertainty, the measurement length is estimated at first, say 59.25 mm. Then the calibration uncertainty at 95% level of confidence (0.95 probability) is calculated as (0.2/100) × 59.25 mm = 0.1185 mm; this is the half width of the uncertainty interval that centered around the measurement result. For obtaining the calibration *standard* uncertainty, this half width is divided by *two* which results in 0.1185 mm /2 = 0.05925 mm; this means that the limits of the calibration standard uncertainty are 59.19075 mm and 59.30925 mm; this interval provides approximately 68% level of confidence, i.e., 0.68 probability under the normal distribution.

In practice, all uncertainty values attributed to different uncertainty sources are converted to standard uncertainties, i.e., the values of standard deviations of their distributions. This is a prior step before combining different standard uncertainties in order to obtain the combined standard uncertainty.

As obvious, the final objective of any measurement process is estimating the measurement result and its associated uncertainty. For achieving this objective, the uncertainty sources are identified and quantified as illustrated in the previous two sections, and then their individual estimates and associated uncertainties are combined depending on a relationship mathematical function that relates the measurand to its uncertainty sources; this function is what is called the *measurement model*. Mathematically, there are different combining techniques that may be used to estimate the desired results; however, the *GUM uncertainty framework* is the most used one in practice. Through sections "The Measurement Model" and "The GUM Uncertainty Framework," the definition of the measurement model and its

construction steps are discussed, the GUM uncertainty framework is illustrated, and simple solved examples are presented.

The Measurement Model

Usually, the measurement system does not determine the measurand value directly but depending on a number of other *input* quantities (The "input quantity" is that quantity which its value must be obtained in order to calculate the measurement result.) that affect the measurement result. The mathematical formula that relates the measurand with its input quantities is what is called the "measurement model." The measurement model is the essential relationship upon which the measurement result and its associated uncertainty are evaluated. Theoretically, all quantities that affect the measurement system can be included in the model for obtaining the maximum accuracy in evaluating the measurement result and its associated uncertainty. However, in practice, including each effect even trivial ones may result in a very complex mathematical model which probably would require an advanced uncertainty estimation technique in order to obtain accurate results. On the contrary, much simplifying the model by ignoring significant effects would lead to losing accuracy. As a rule, the degree of model details and complexity should meet the accuracy requirements imposed by the application in which the measurement result is employed.

In fact, modelling is not an easy task as it requires deep understanding of the input quantities, how they interact, and how they affect the measurement result. Therefore, it is not sufficient to know that a certain input quantity is significant to include it in the measurement model, but you should know how this quantity affects the measured value; this question is crucial for the mathematical formulation of its effect in the measurement model. In practice, there are two modelling routes namely "bottom-up" and "top-down" approaches (EUROLAB 2006). In the bottom-up approach, the model is constructed mathematically depending on the input quantities and the knowledge about their interaction and effects on the measured value. In the top-down approach, the uncertainty is evaluated depending on an empirical model which is constructed based on the performance data of the measurement system, e.g., the results of inter-laboratory and within-laboratory comparisons, quality control data, etc. The top-down approach can be considered as an indirect solution for modelling in case the bottom-up model is incomplete, or its input quantities have unknown effects on the measured value. In these cases, the top-down approach is feasible because the effects of its quantities are assessed experimentally without the need of a prescribed mathematical relation. Moreover, as the top-down approach depends on the whole performance of the measurement system, it can include the effects of minor or even unknown quantities that would be neglected in bottom-up modelling. For more information about how the uncertainty can be estimated depending on inter-laboratory or within-laboratory comparisons results, refer to Ref. (EUROLAB 2006).

The *guide to the expression of uncertainty in measurement* (GUM) (BIPM 2008a), the master uncertainty guide in metrology, adopt the bottom-up modelling

approach as the first choice in building the measurement model. The GUM assumes that the metrologist can define the measurand, is aware of the significant input quantities, and has the necessary knowledge about these quantities for formulating the measurement model. In case of experimental results reveal that the results of the measurement model lack accuracy, the GUM suggests including additional quantities in the model to eliminate the inadequacy.

Until soon, there was not a standard set of modelling guidelines; however, there was an attempt by *Sommer K D* et al. to systemize the modelling process. This attempt was presented in a series of publications (Sommer et al. 2003; Sommer et al. 2005; Sommer and Siebert 2006) that suggest a five-step modelling procedure as follows:

1. Describing the measurement system, i.e., the measurand, the input quantities, and the method of measurement.
2. Analyzing the measurement system and graphically constructing the cause-and-effect relationship considering the ideal measuring scenario.
3. Identifying all potential imperfections that lead to deviations from the ideal response of the measurement system. Then reconstructing the cause-and-effect diagram by incorporating the identified imperfections to represent the practical measurement system. Finally, the practical cause-and-effect is converted into a mathematical formula.
4. Identifying any potential correlations between the input quantities and including them in the mathematical formula.
5. Inversing the practical cause-and-effect mathematical formula (from the previous step) for obtaining the model equation that relates explicitly the measurand with the input quantities and imperfections.

Example 2 For demonstrating the practical implementation of Sommer's modelling procedure, consider the case of calibrating an industrial-class force measuring system (an industrial-class load cell connected to an industrial-class indicator) depending on a reference-class force measuring system (a reference-class load cell connected to a reference-class indicator) using a force comparator standard machine. Both load cells can measure only normal compressive loads while their designs resist side and bending loads. In this metrological exercise, both the under-calibration and reference load cells are aligned vertically so that they become have a common vertical axis in which the calibration force can be applied; see Fig. 6. Thereafter, the calibration force F_C is applied through the common vertical axis, and both readings indicated by the reference-class indicator (connected to the reference load cell) and the industrial-class indicator (connected to the under-calibration load cell) are recorded.

The application of Sommer's modelling procedure for modelling this calibration exercise and calculating the error induced by the under-calibration force measuring system can be as follows:

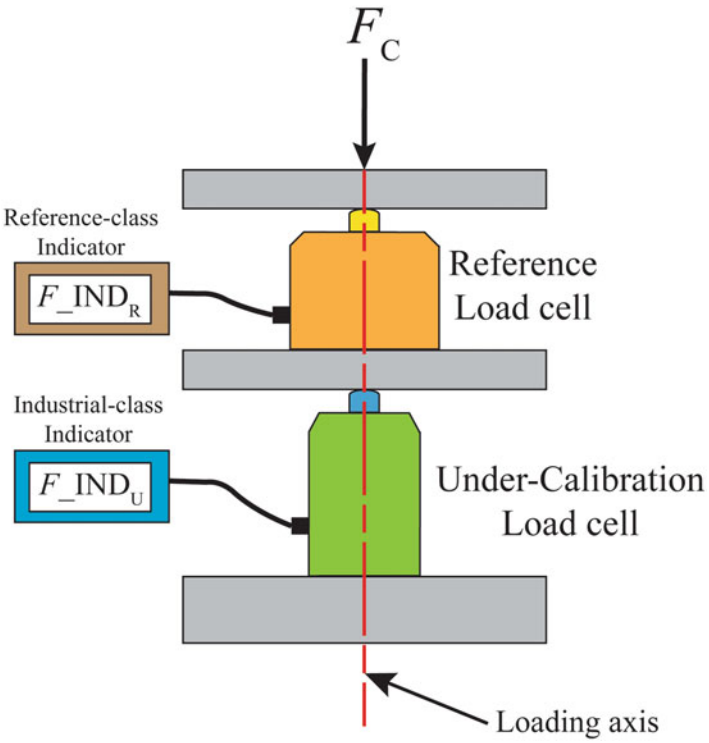

Fig. 6 The calibration of a load cell against a reference load cell using a standard force comparator machine

Step 1: Describing the Measurement System An industrial-class force measuring system is to be calibrated against a reference-class force measuring system using a force comparator standard machine. The under-calibration force measuring system consists of an industrial-class load cell connected to an industrial-class indicator. At the same time, the reference-class force measuring system consists of a reference-class load-cell connected to a reference-class indicator.

Measurand: Error ΔF_U in the indication value of the under-calibration force measuring system.
Measurement method: Direct comparison of the under-calibration force measuring system against the reference one.

Step 2: Graphical Construction of the Ideal Cause-and-Effect Block Relationship Figure 7 shows the block relationship of the calibration exercise considering the ideal scenario. As shown, the calibration force F_C generated by the standard machine acts simultaneously on both reference and under-calibration load cells. As a response, the reference measuring system indicates F_IND_R on its digital display; ideally the reference system is considered as error-free so F_IND_R should

equal F_C. The under-calibration system indicates F_IND_U on its digital display as a response to the acting force F_C. As the under-calibration system has an instrumental error ΔF_U, the value F_IND_U has a deviation from F_C.

Step 3: Including all Potential Imperfections In real implementation of this calibration exercise, there are some sorts of imperfections such as the inclination of the calibration force F_C by a small angle θ with respect to the common loading axis and the instrumental error ΔF_R of the reference system. Figure 8 shows the block relationship of the calibration exercise considering the real circumstances. As shown in that figure, the calibration force F_C is decremented by the value ΔF_C that arises from its inclination with respect to the loading axis. Accordingly, and as both reference and under-calibration load cells resist side loads, the value of force sensible by the load cells becomes F_N where $F_N = F_C - \Delta F_C$. Also, the instrumental error ΔF_R of the reference system is added so that it shifts the indication value F_IND_R of the reference system from F_N by the value ΔF_R.

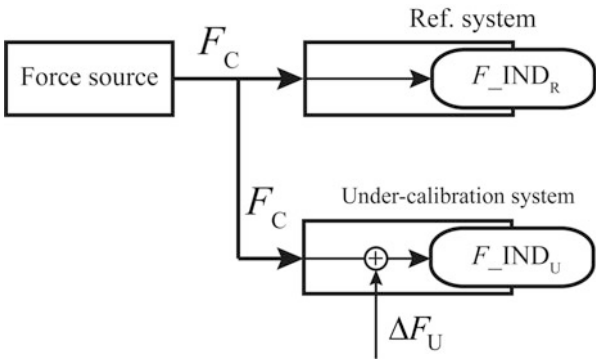

Fig. 7 The ideal cause-and-effect block relationship of the force-measuring-system calibration exercise

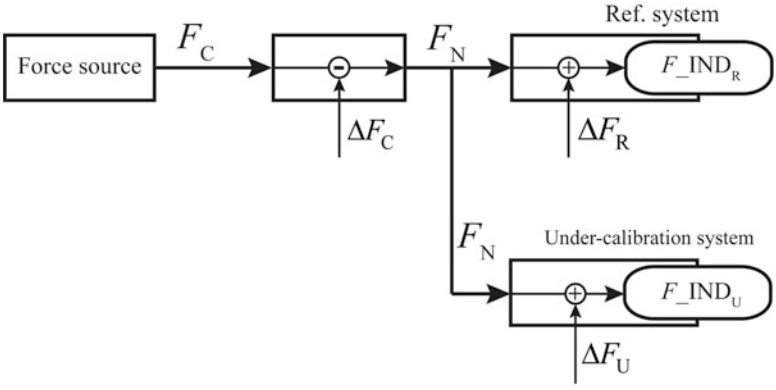

Fig. 8 The real cause-and-effect block relationship of the force-measuring-system calibration exercise

The real cause-and-effect block relationship can be translated into two mathematical equations:

Reference System Equation:

$$F_\mathrm{IND_R} = F_\mathrm{C} - \Delta F_\mathrm{C} + \Delta F_\mathrm{R} \tag{9}$$

Under-calibration system equation:

$$F_\mathrm{IND_U} = F_\mathrm{C} - \Delta F_\mathrm{C} + \Delta F_\mathrm{U} \tag{10}$$

Step 4: Identifying any Potential Correlations For simplicity, all affecting quantities and observations are assumed to be independent.

Step 5: Inversing the Practical Cause-and-Effect Mathematical Formula for Obtaining the Model Equation By subtracting Eq. 9 from Eq. 10, the following formula is obtained:

$$F_\mathrm{IND_U} - F_\mathrm{IND_R} = \Delta F_\mathrm{U} - \Delta F_\mathrm{R} \tag{11}$$

From the previous equation, the final model equation can be concluded as:

$$\Delta F_\mathrm{U} = F_\mathrm{IND_U} - F_\mathrm{IND_R} + \Delta F_\mathrm{R} \tag{12}$$

Finally, for quantifying the value of ΔF_U and its associated uncertainty depending on the final model equation, each term in the final model equation must be quantified using an appropriate technique depending on the nature of the available knowledge about that term. Typically, the values of the indications $F_\mathrm{IND_U}$ and $F_\mathrm{IND_R}$ and their associated uncertainties would be quantified from repeated observations using Type A evaluation method. The instrumental error ΔF_R of the reference system would be quantified depending on the available data found in its calibration certificate.

Recently, the first edition of the modelling guide (BIPM 2020) issued by the *Joint Committee for Guides in Metrology* (JCGM) was released. It is anticipated that this guide will generate discussions among metrologists and practitioners to figure out the weakness and strengths in its proposed guidelines.

The GUM Uncertainty Framework

The GUM uncertainty framework (Fig. 9) is the most popular technique used for estimating the measurement result and combining the uncertainty contributions of different input quantities for obtaining the overall uncertainty margin associated with the measurement result. The GUM uncertainty framework depends on three elements (BIPM 2009):

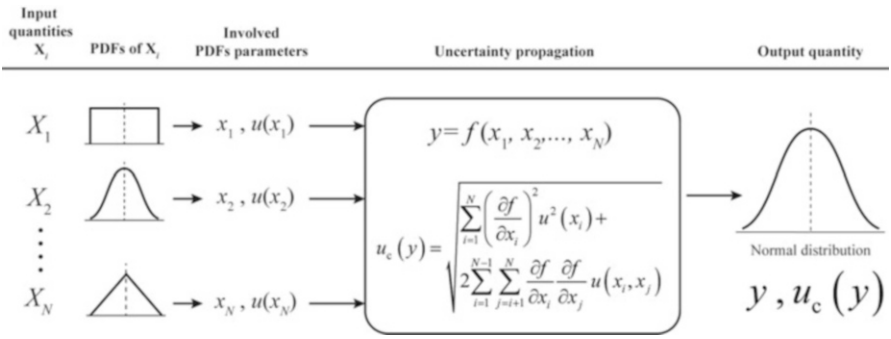

Fig. 9 The GUM uncertainty framework

(a) The best estimates of the input quantities.
(b) The standard uncertainties of the input quantities.
(c) The effect of changing the value of each input quantity on the estimate value of the measurand (usually known as sensitivity coefficients).

Consider a measurand Y which its value is determined upon N input quantities X_1, X_2, …, X_N; the measurement model can be written as:

$$Y = f(X_1, \ X_2, \ \ldots, \ X_N) \tag{13}$$

For obtaining the measurement result and its associated uncertainty, the GUM uncertainty framework employs the *law of propagation of uncertainties* (LPU). According to LPU, the measurement model (Eq. 13) is approximated using the first-order Taylor series expansion. Accordingly, the best estimate y of the measurand Y is calculated as:

$$y = f(x_1, \ x_2, \ \ldots, \ x_N) \tag{14}$$

where x_1, x_2, …, x_N are the best estimates of the input quantities X_1, X_2, …, X_N, respectively. Also, the combined standard uncertainty $u_c(y)$ associated with the best estimate y is taken equal to the positive square root of the estimated variance $u_c^2(y)$ that is obtained from the following formula:

$$u_c^2(y) = \sum_{i=1}^{N}\left(\frac{\partial f}{\partial x_i}\right)^2 u^2(x_i) + 2\sum_{i=1}^{N-1}\sum_{j=i+1}^{N}\frac{\partial f}{\partial x_i}\frac{\partial f}{\partial x_j}\ u(x_i, x_j) \tag{15}$$

where $u(x_i)$ is the standard uncertainty associated with the best estimate x_i of the input quantity X_i. $\partial f/\partial x_i$ is the partial derivative of the model equation $f(X_1, X_2, \ldots, X_N)$ with respect to X_i evaluated at $X_i = x_i$; these quantities are commonly known as the sensitivity coefficients, and they characterize how the best estimate y of the measurand Y varies in response to the change in the values of the best estimates x_1,

$x_2, \ldots, x_N$ of the input quantities. $u(x_i, x_j)$ where $i \neq j$ is the estimated covariance associated with x_i and x_j.

To simplify the process of evaluating uncertainty and make it easier to be implemented by practitioners in the industrial field, the uncertainty sources may be considered as uncorrelated as this is the most common case in regular metrological practices. Moreover, in case the uncertainty sources could be packed in input quantities that have the same unit as the measurand, the sensitivity coefficients can be eliminated as they would equal ones. Based on these simplifications, Eq. 15 can be simplified as follows:

$$u_c^2(y) = \sum_{i=1}^{N} u^2(x_i) \tag{16}$$

or

$$u_c(y) = \sqrt{u^2(x_1) + u^2(x_2) + \quad \ldots \quad + u^2(x_N)} \tag{17}$$

Such simplification can be found in GUM-based uncertainty evaluation standardized guidelines as ASME B89.7.3.2–2007 (ASME B89.7.3.2 2007) which is devoted to the evaluation of uncertainty in dimensional measurement.

The technique used for combining uncertainties in the GUM uncertainty framework is commonly known as the "propagation of uncertainties." In other words, this technique propagates the individual variances of the distributions of input quantities (their squared uncertainties) for obtaining the variance of the resulting distribution of the measurand, i.e., its squared combined standard uncertainty. According to the central limit theorem, when a number of distributions of any form are combined, the resulting distribution tends to the normal form, as long as there is not a non-Gaussian dominant contributor (M3003 2012). In practice, when combining three or more distributions of similar magnitude, a rational approximation to the normal distribution is obtained. Accordingly, when employing the GUM uncertainty framework, the distribution of the values that can be attributed to the measurand Y is usually considered as normal with the expectation y as estimated in Eq. 14 and variance $u_c^2(y)$ as estimated in Eq. 15.

The combined standard uncertainty $u_c(y)$ that is based on one standard deviation of the measurand output distribution is considered as the fundamental parameter that is used for quantitatively expressing the uncertainty associated with the measurement result y. Also, The *International Committee for Weights and Measures* (CIPM) has requested that the combined standard uncertainty is used – for expressing the uncertainty – by all participants in international comparisons and all work done under the umbrella of CIPM (BIPM 2008a). Nevertheless, it is common in commercial and industrial applications to enlarge the margin of uncertainty for giving more confidence that the true value of the measurand lie in that enlarged margin; the corresponding enlarged uncertainty value is what is called the *expanded uncertainty* U (refer to section "The General Idea of Quantifying Uncertainty").

The expanded uncertainty U is calculated by multiplying the combined standard uncertainty $u_c(y)$ by a positive, larger than unity factor k which is commonly known as the *coverage factor*. Depending on the nature of the distribution of the output quantity, a given coverage factor provides a certain *level of confidence* (i.e., probability) that the true value lies in the margin of the expanded uncertainty. When employing the GUM uncertainty framework, the output distribution is usually considered as Gaussian; accordingly, the combined standard uncertainty (i.e., at $k = 1$) provides about 68% level of confidence; for $k = 2$ and $k = 3$, the approximate level of confidence is 95% and 99%, respectively.

After evaluating the uncertainty for a certain metrological task, it may be required to summarize the details of the uncertainty calculations as well as its final results for reporting and analysis purposes; a common uncertainty reporting tool is what is called the *uncertainty budget*. The uncertainty budget is a statement of the measurement uncertainty that basically provides information about the uncertainty components, their calculations, and combinations (BIPM 2012). A proposed format of the uncertainty budget that is applicable for uncorrelated input quantities was presented by the *European Co-operation for Accreditation* in their uncertainty evaluation guidelines booklet (EA-4/02 2013). In this proposed arrangement (Table 1), each input quantity is listed besides its corresponding estimate, standard uncertainty, probability distribution, sensitivity coefficient, and contribution to the combined standard uncertainty. Moreover, the estimate y of the measured quantity Y and its associated combined standard uncertainty $u_c(y)$ are reported. This arrangement may be extended to include other pieces of information – as requested in the *International Vocabulary of Metrology* (VIM) (BIPM 2012) – such as the measurement model, the covariances (if exists), the expanded uncertainty, and the coverage factor (if applicable).

In practice, the uncertainty budget helps the metrologist to identify the dominant uncertainty components and improve it if necessary. Moreover, the uncertainty budget is an essential tool in assessing the reported combined standard uncertainty (Kacker et al. 2007), and solving the discrepancies that may arise between suppliers and customers regarding the uncertainty of measurements; refer to the standard ASME B89.7.3.3–2002 (ASME B89.7.3.3 2002) for such topic.

Table 1 A proposed arrangement of an uncertainty budget for uncorrelated input quantities

Input quantity X_i	Estimate x_i	Standard uncertainty $u(x_i)$	Probability distribution	Sensitivity coefficient $c_i = \partial f/\partial x_i$	Contribution to the standard uncertainty $u_i(y) = c_i \times u(x_i)$
X_1	x_1	$u(x_1)$		c_1	$u_1(y)$
X_2	x_2	$u(x_2)$		c_2	$u_2(y)$

Example 3 Consider that a metrologist wants to evaluate the volume of a cylinder that cut from a long cylindrical rod. The objective is to determine the volume V of the cylinder and its associated uncertainty depending on the measurement of its height H and the manufacturer specification about its diameter D. The measurement model can be written as follows:

$$V = \frac{\pi}{4} D^2 H \tag{18}$$

The height of the cylinder was measured experimentally and was found to have a mean value $h = 100.02$ mm with standard uncertainty $u(h) = 0.05$ mm assuming that the height values have a normal form. The manufacturer of the cylindrical rod certifies that the diameter D is between 49.75 mm and 50.35 mm.

Depending on the available knowledge about the input quantities, the best estimate of the height $h = 100.02$ mm with standard uncertainty $u(h) = 0.05$ mm assuming normal distribution. With respect to the diameter of the cylinder, the only knowns are the lower and upper limits of its value, so the uniform distribution best fit this situation. Accordingly, the best estimate of the diameter $d = (49.75 + 50.35)/2 = 50.05$ mm and the associated uncertainty $u(d) = (50.35 - 49.75)/2\sqrt{3} = 0.1732$ mm.

The best estimate of the volume is calculated as:

$$v = (\pi/4) \times 50.05^2 \times 100.02 = 196{,}781.785 \text{ mm}^3$$

The model equation (Eq. 18) is partially differentiated with respect to the input quantities for evaluating the sensitivity coefficients as follows:

$$\frac{\partial V}{\partial D} = \frac{\pi DH}{2} \rightarrow c_D = \frac{\pi \times 50.05 \times 100.02}{2} = 7{,}863.408$$

$$\frac{\partial V}{\partial H} = \frac{\pi \times D^2}{4} \rightarrow c_H = \frac{\pi \times 50.05^2}{4} = 1{,}967.424$$

The uncertainty due to the error in the diameter:

$$u_D(v) = c_D \times u(d) = 7863.408 \times 0.1732 = 1{,}361.9 \text{ mm}^3$$

The uncertainty due to the error in the height:

$$u_H(v) = c_H \times u(h) = 1967.424 \times 0.05 = 98.3712 \text{ mm}^3$$

The combined standard uncertainty $u_c(v)$ is calculated as follows considering uncorrelated inputs:

Table 2 The uncertainty budget of the cylinder volume example

Input quantity	Estimate	Standard uncertainty	Probability distribution	Sensitivity coefficient	Contribution to the standard uncertainty
π	3.1415926535898				
D	50.05 mm	0.1732 mm	Rectangular	7,863.408	1361.9 mm^3
H	100.02 mm	0.05 mm	Normal	1967.424	98.3712 mm^3
V	196,781.785 mm^3		Assumed Normal		1365.448 mm^3

$$u_c(v) = \sqrt{u_D^2(v) + u_H^2(v)} = \sqrt{1{,}361.9^2 + 98.3712^2} = 1{,}365.448 \ \text{mm}^3$$
$$\approx 1.36545 \ \text{cm}^3$$

The uncertainty budget can be summarized as follows in Table 2.

Considering that the distribution of the output quantity (i.e., the volume) is normal, the expanded uncertainty can be calculated as $2 \times 1365.448 = 2730.896\ mm^3 \approx 2.731\ cm^3$ with approximate level of confidence 95%.

Despite the popularity of the GUM uncertainty framework in both the scientific and industrial fields, it has a major limitation as it depends on a linearized version of the measurement model. This inherent approximation in the GUM method makes it give accurate results only in case of dealing with linear or approximate linear models (Martins et al. 2011). If major deviation from linearity in the measurement model is present, the GUM framework loses its accuracy, and other uncertainty combination techniques such as *Monte Carlo simulation* (MCS) is preferred. MCS is a numerical technique that depends on the original version of the measurement model (Bich et al. 2006); thereby it is not affected by the complexity of the model and does not lose its accuracy due to nonlinearity.

The Monte Carlo Simulation at a Glance

Monte Carlo simulation (MCS) is a stochastic technique that is used to mimic phenomena that have random components (Shonkwiler and Mendivil 2009). From a mathematical perspective, MCS provides an approximate solution to the mathematical model of the considered phenomenon through statistical sampling performed on a computer (Fishman 1996). The technique was originally developed in the 1940s by three scientists: *John von Neumann*, *Stanislaw Ulam*, and *Nicholas Metropolis*, while they were engaged on a nuclear weapon project in *Los Alamos National Laboratory* in the United States (Thomopoulos 2013). The name "Monte Carlo" was proposed for the technique by *Metropolis* as a joke about *Ulam*'s uncle who borrowed money to visit *Monte Carlo* (a neighborhood in Monaco) (Gobet 2016), and the name survived. In year 2000, the *Society for Industrial and Applied Mathematics* (SIAM) has selected Monte Carlo as

one of the top 10 algorithms that have the greatest influence on the development and practice of science and engineering in the twentieth century (Cipra 2000).

Simply, the idea of MCS is running the mathematical model of the considered phenomenon many times. In each run, random sample is drawn for each random input component of the model and the outcome is computed. As the inputs are random and mimic the stochastic nature of the model input components, the computed outcome is also random and mimics the stochastic nature of the outcome of the phenomenon. After running the model for a relatively large number of times, a set of outcome values is obtained; this set can be used to predict the outcome of interest and calculate its characteristics.

Using Monte Carlo in Evaluating Metrological Uncertainty

The *Supplement 1 to the Guide to the Expression of Uncertainty in Measurement* (GUM-S1) (BIPM 2008b) provides comprehensive guidelines for estimating metrological uncertainty using MCS. In practice, MCS is preferable as a tool for evaluating metrological uncertainty in case the measurement model has a great deviation from linearity.

For evaluating uncertainty using MCS, consider the measurement model equation (Eq. 13): $Y = f(X_1, X_2, \ldots, X_N)$. Once again, in this model, the measurand Y is determined upon N input quantities $X_1, X_2, \ldots, X_N$. Each input quantity of the measurement model must be assigned a *probability density function* (pdf) based on the available knowledge about that quantity. Thus, the pdfs $p(X_1), p(X_2), \ldots, p(X_N)$ corresponding to $X_1, X_2, \ldots, X_N$, respectively, must be known before the beginning. Thereafter, for each iteration j ($j = 1, 2, \ldots, M$) of the simulation, random samples $(x_1)_j, (x_2)_j, \ldots, (x_N)_j$, are drawn from the pdfs of the input quantities $X_1, X_2, \ldots, X_N$, respectively, and substituted into the model $Y = f(X_1, X_2, \ldots, X_N)$ for calculating the jth value of the outcome, i.e., y_j of the measurand Y. After running the simulation for M trials, a sample $\boldsymbol{y} = \{y_j\} = \{y_1, y_2, \ldots, y_M\}$ that contains M random draws from the pdf of the measurand Y is finally obtained. Depending on the sample $\boldsymbol{y}$, an empirical pdf can be constructed for the measurand Y, and upon it, the measurement result $\tilde{y}$ and its associated standard uncertainty $u(\tilde{y})$ can be calculated. Figure 10 shows the steps of MCS as it is employed in evaluating the measurement result and the associated standard uncertainty of the measurand Y; the technique is also known as *propagation of distributions*.

Programming MCS for Uncertainty Evaluation

Putting Monte Carlo Simulation into action needs writing a multifunction computer software that can (a) generate random samples, (b) calculate the outcome based on a mathematical model, (c) store output data in the form of an array, and (d) calculate

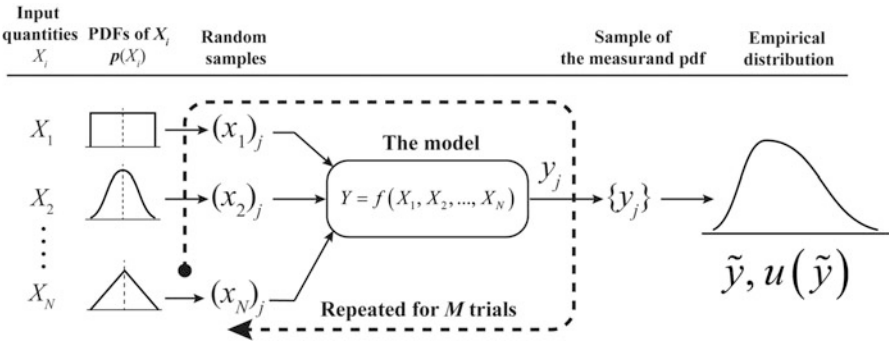

Fig. 10 The Monte Carlo simulation used for evaluating the estimate $\tilde{y}$ and the associated standard uncertainty $u(\tilde{y})$ of the measurand Y

the simulation results, i.e., the characteristics of the output data. Figure 11 shows a simple example of programming MCS for a measurand Y that has two input quantities X_1 and X_2 following a simple model, $Y = X_1 \times X_2$; the pdf of X_1, $p(X_1)$ is normal with mean value 5 and standard deviation 0.5, while the pdf of X_2, $p(X_2)$ is also normal with mean value 10 and standard deviation 2.

MCS can be programmed as a "While" or "For" loop with a number of trials equals M; the first step in the loop is generating random samples according to the assigned pdfs of the input quantities. In practice, most modern programming languages provide canned functions that can generate pseudo random numbers following several distributions such as uniform, normal, triangular, etc. These functions are powerful and usually are based on sophisticated algorithms that guarantee the quality of randomness of the generated numbers while minimizing the impact on the computer resources. The user may also resort to using the *inverse transform method* or the *accept-reject method* (Thomopoulos 2013) for generating pseudo random numbers following several distributions, e.g., triangular, trapezoidal, U, etc., depending on a uniform random generator that can be easily found as a canned function in most modern programming languages. In the example shown in Fig. 11, in each iteration j of the loop, random samples $(x_1)_j \sim N(5, 0.5^2)$ and $(x_2)_j \sim N(10, 2^2)$ are generated.

In each iteration j of the loop, the second step is substituting the random samples into the model equation to calculate the jth value of the outcome. In this stage, the program uses the original version of the measurement model whatever its degree of complexity or nonlinearity; this is what makes MCS superior in dealing with nonlinear models. In the example shown in Fig. 11, just the random sample $(x_1)_j$ is multiplied by the random sample $(x_2)_j$ for obtaining the outcome y_j.

The third step in each iteration j of the loop is sending the calculated outcome y_j for storing in the output array. This array begins empty, and its size is incremented by one after each iteration as the calculated outcome is appended to it. At the end of the

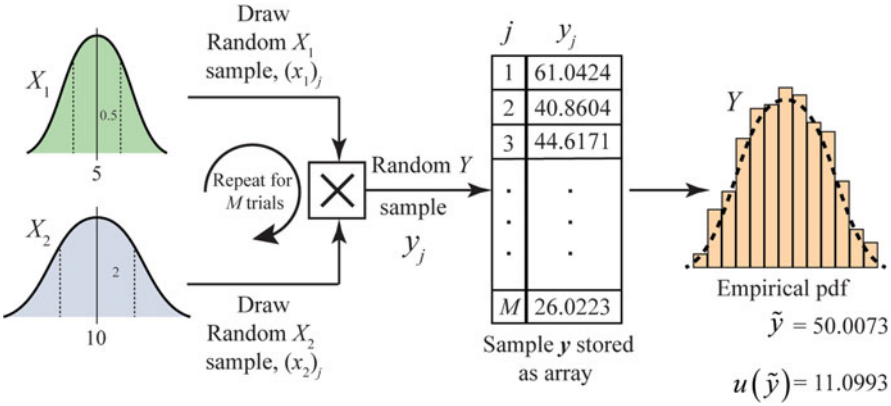

Fig. 11 An example to programming MCS for evaluating the measurement result $\tilde{y}$ and its associated standard uncertainty $u(\tilde{y})$

simulation, when the loop terminates, this array become includes the M elements of the sample set $\boldsymbol{y}$. In the example shown in Fig. 11, the storage array is shown as a table that relates each outcome to its corresponding index j.

The final step of MCS program is calculating the simulation results from the elements stored in the output array. The main results are the best estimate of the output quantity (i.e., the value of the measurement result) and its associated standard uncertainty. The best estimate of the output quantity is taken as the arithmetic average $\tilde{y}$ of the elements of the sample $\boldsymbol{y}$ and can be calculated as follows:

$$\tilde{y} = \frac{1}{M}\sum_{j=1}^{M} y_j \tag{19}$$

The standard uncertainty $u(\tilde{y})$ associated with the measurement result $\tilde{y}$ is taken as the standard deviation of the elements of the sample $\boldsymbol{y}$ that is calculated according to the following formula:

$$u(\tilde{y}) = \sqrt{\frac{1}{M-1}\sum_{j=1}^{M}\left(y_j - \tilde{y}\right)^2} \tag{20}$$

In the example shown in Fig. 11, the measurement result and its associated standard uncertainty were calculated as per the two previous equations using the data stored in the output array. This data may be used also for constructing a frequency histogram for the sample $\boldsymbol{y}$ which can give – if the bin width is set properly – an idea about the shape of the empirical distribution of the output quantity, i.e., measurand Y.

Coverage Interval for MCS Output Distribution

Once again, the MCS is useful when the measurement model is highly nonlinear. In this case, the output empirical distribution probably would be asymmetric and difficult to be defined analytically. Accordingly, the calculation of the bounds of a coverage interval that encompass certain probability $100p$ % (say $p = 0.95$, 0.99, etc.) that the true value of the measurand lies in that interval (This is analogue to calculating the expanded uncertainty in the GUM uncertainty framework.) is not as straightforward as it can be followed in the GUM framework via multiplying the combined standard uncertainty by a coverage factor. In fact, for an empirical distribution given by M discrete values, there is $(1\text{-}p)M$ intervals that contain $100p$ % of the values (Coleman and Steele 2009), each one of them represents a potential solution for our problem. However, in practice, the GUM-S1 (BIPM 2008b) provides only two solutions: (a) the probabilistically symmetric $100p$ % coverage interval and (b) the shortest $100p$ % coverage interval.

The probabilistically symmetric $100p$ % coverage interval (Fig. 12) is the unique interval that contains $100p$ % of the results while the probability on its right and left is symmetric and equals $100((1 - p)/2)\%$. For calculating the lower bound y_{low} of that interval and its upper bound y_{high} depending on the M elements of the sample $\boldsymbol{y}$ that resulted from MCS, follow the following steps (Coleman and Steele 2009):

1. Sort the M elements of the sample $\boldsymbol{y}$ into non-decreasing order $y_{(r)}$ where $r = 1, 2, \ldots, M$.
2. Take $r_{\text{low}} = (1 - p)M/2$; if r_{low} is not an integer, take r_{low} equal to the integer part of $[1/2 + ((1 - p)M/2)]$.
3. Take $r_{\text{high}} = (1 + p)M/2$; if r_{high} is not an integer, take r_{high} equal to the integer part of $[1/2 + ((1 + p)M/2)]$.
4. Take $y_{\text{low}} = y_{(r=r_{\text{low}})}$.
5. Take $y_{\text{high}} = y_{(r=r_{\text{high}})}$.

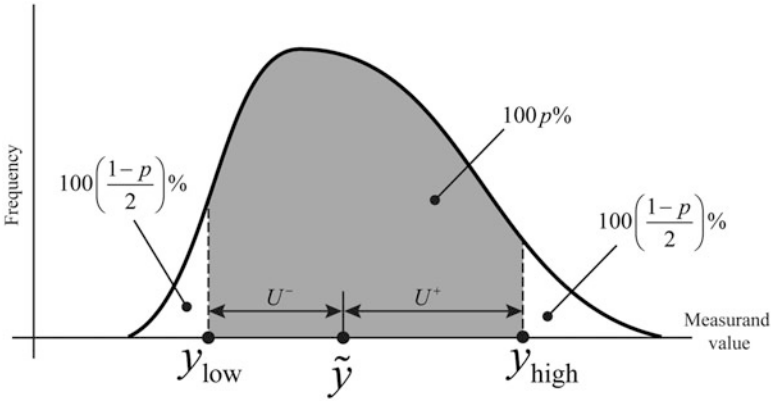

Fig. 12 The probabilistically symmetric $100p$ % coverage interval

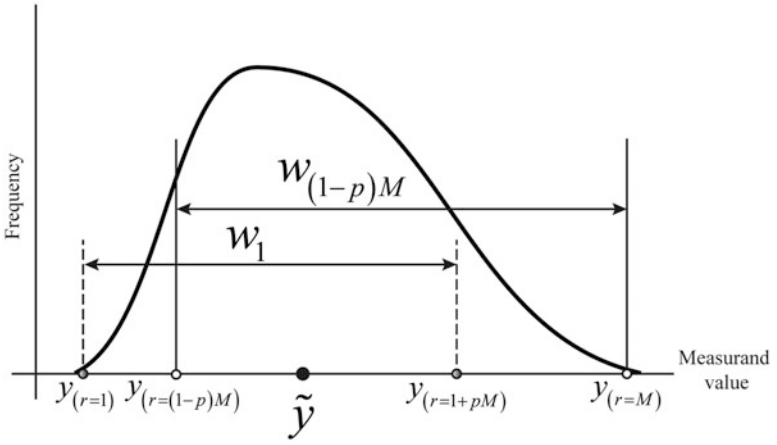

Fig. 13 The first and the last intervals that contain 100p % of the results

As shown in Fig. 12, due to the asymmetry of the distribution, the width of the probabilistically symmetric 100p % coverage interval is not symmetric about the mean value $\tilde{y}$, so the uncertainty cannot be written in the form $\tilde{y} \pm U$. Instead, it can be reported as the true value y_{true} of the measurand Y would lie in the interval $\tilde{y} - U^- \le y_{\text{true}} \le \tilde{y} + U^+$ with a level of confidence 100p %, where $U^- = \tilde{y} - y_{\text{low}}$ and $U^+ = y_{\text{high}} - \tilde{y}$.

The shortest 100p % coverage interval is an alternative to the probabilistically symmetric one. Once again, for a MCS output distribution given by a sample $\boldsymbol{y}$ that contain M discrete values, there is (1-p)M intervals that contain 100p % of the values. The width w of these intervals (i.e., $y_{\text{high}} - y_{\text{low}}$) differs from one interval to another. For instance, the width of the first interval $w_1 = y_{(r\,=\,1\,+\,pM)} - y_{(r\,=\,1)}$, the width of the second interval $w_2 = y_{(r\,=\,2\,+\,pM)} - y_{(r\,=\,2)}$, and the width of the last interval $w_{(1\,-\,p)M} = y_{(r\,=\,M)} - y_{(r\,=\,(1\,-\,p)M)}$; see Fig. 13. Generally, the width of the kth interval is $w_k = y_{(r\,=\,k\,+\,pM)} - y_{(r\,=\,k)}$ where $k = 1, 2, \ldots, (1\text{-}p)M$; if the value of the index r is not an integer, approximate it to the nearest integer by adding 0.5 and taking the integer part of the result; also, treat the non-integer values of the index k similarly. Finally, the interval with the smallest width w is the shortest coverage interval that contains 100p % of the results.

The GUM-S1 states that, for a *unimodal* (single-peaked) distribution, the shortest 100p % coverage interval would contain the mode, the most probable value of the measurand Y. Moreover, in case of symmetric distributions (e.g., Gaussian), the probabilistically symmetric 100p % coverage interval and the shortest 100p % coverage interval would be identical.

Number of Monte Carlo Trials, *M*

As a rule, the greater the number of model evaluations M, the more reliability of the results and the more stability of them. In practice, the number of Monte Carlo trials M can be chosen a priori before starting the simulation and provided as an input to

the simulation loop. In this case, the loop would continue to evaluate the model repeatedly until the number of evaluations reaches the prechosen number of trials; this is the conventional procedure of Monte Carlo simulation. As a drawback, this conventional procedure that depends on a prechosen number of trials does not monitor the stability of the numerical results provided by the simulation and does not guarantee its conformance to a certain numerical tolerance value. The reason is simply that the necessary number of MCS trials needed to provide the results stable within a prescribed numerical tolerance depends on the shape of the output distribution and the required coverage probability p. In practice, the coverage probability p can be determined according to the accuracy imposed by the application in which the results will be employed. On the contrary, the shape of the output distribution may not be known a priori before the simulation, and this would represent a stumbling block toward determining the necessary number of trials before the simulation. As a compromise, the GUM-S1 recommends that the number of trials M of conventional MCS should be large compared to the value $1/(1-p)$, e.g., $M \geq 10^4(1/(1-p))$ as it is expected – if this condition is met – that the simulation would provide reasonable discrete representation of the output distribution in the regions near the endpoints of the $100p$ % coverage interval.

Adaptive Monte Carlo Procedure

The adaptive Monte Carlo procedure is a modified version of conventional Monte Carlo in which the number of trials is not chosen in advance. Unlike in the case of conventional Monte Carlo, the adaptive procedure increases the number of trials progressively in batches until the simulation results of interest become statistically stable within a certain numerical tolerance value. Specifically, when applying Monte Carlo adaptively in uncertainty evaluation, any of the simulation results of interest ($\tilde{y}$, $u(\tilde{y})$, y_{low}, or y_{high}) is considered as stabilized if twice the standard deviation of the result that calculated from different simulation batches is less than the numerical tolerance δ associated with the standard uncertainty $u(\tilde{y})$.

For calculating the numerical tolerance δ associated with a standard uncertainty $u(\tilde{y})$, first, the number of significant decimal digits n_{dig} that is considered as meaningful in the value of $u(\tilde{y})$ is specified; usually it is chosen to be 1 or 2. Then the standard uncertainty $u(\tilde{y})$ is expressed in the form $u(\tilde{y}) = c \times 10^{\ell}$ where c is an n_{dig} decimal digit integer and ℓ is an integer. Finally, the numerical tolerance δ is taken as $\delta = (1/2) \times 10^{\ell}$.

Example 4 Consider that $u(\tilde{y}) = 0.0026$ mm and n_{dig} are chosen to be 2. Thus, $u(\tilde{y})$ can be expressed as $u(\tilde{y}) = 26 \times 10^{-4}$ mm, and so $c = 26$ and $\ell = -4$; thus take $\delta = (1/2) \times 10^{-4}$ mm $= 0.00005$ mm. However, if n_{dig} was chosen to be 1, $u(\tilde{y})$ would be expressed as $u(\tilde{y}) = 0.003$ mm $= 3 \times 10^{-3}$ mm, and so $c = 3$ and $\ell = -3$; thus take $\delta = (1/2) \times 10^{-3}$ mm $= 0.0005$ mm.

The adaptive Monte Carlo scheme can be programmed as a nested while loop in which the inner loop (simulation loop) is dedicated to running the simulation batch that have a prespecified number of trials exactly as the case of conventional Monte Carlo; the outer loop (stability-check loop) checks – starting after the second batch – for the stability criterion and terminates if it met or forced the simulation loop to run another batch otherwise; and so on until the statistical stability is achieved. At the end, the simulation final results are calculated based on the whole output values obtained from all batches.

Figure 14 demonstrates the adaptive Monte Carlo simulation using the same problem used for demonstrating the conventional simulation in Fig. 11. Before starting, the number of significant decimal digits n_{dig} that is considered as meaningful in the value of $u(\tilde{y})$ is chosen (usually $n_{\text{dig}}= 1$ or 2) and entered as an input to the simulation software. Also, the number of trials Q of the simulation batch is chosen as $Q = \max(G, 10^4)$, where G is the smallest integer greater than or equal to $100/(1-p)$ while p is the required coverage probability (BIPM 2008b).

The simulation starts with the first batch ($h = 1$) with Q number of trials. After the first batch, the stability-check loop forces the simulation loop to run the second batch without a stability check because that check requires at least two entries of the statistic being checked for stability. While a batch h is running, its output values are stored in the form of an array. At the end of the batch h, its own results are calculated

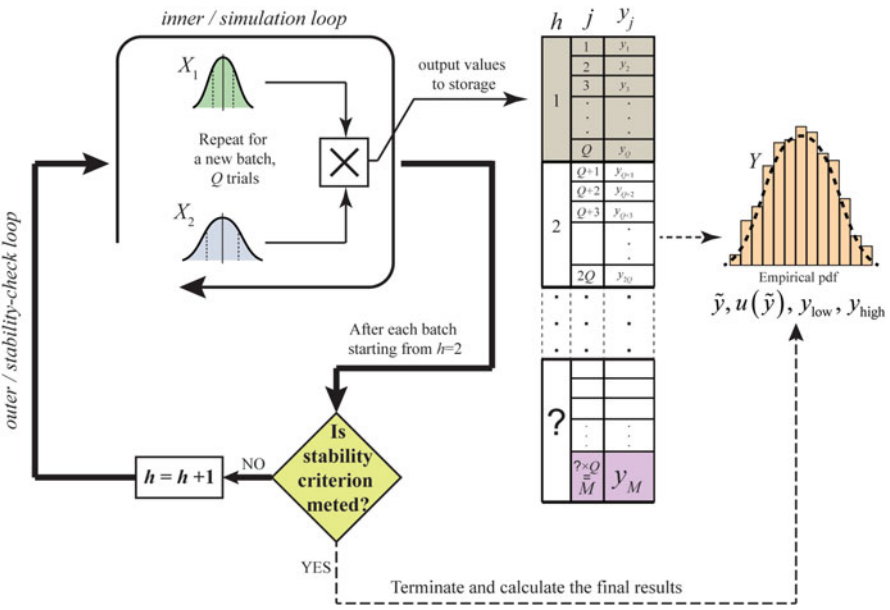

Fig. 14 An example to programming adaptive MCS

based on its own output values similarly as followed in the case of conventional simulation; the calculated results for the hth batch are:

(a) The estimate $\tilde{y}^{(h)}$.
(b) The standard uncertainty $u\left(\tilde{y}^{(h)}\right)$.
(c) The lower bound $y_{\text{low}}^{(h)}$ of the $100p$ % coverage interval.
(d) The upper bound $y_{\text{high}}^{(h)}$ of the $100p$ % coverage interval.

For each of the previous statistics, a separate array is required for storing the calculated values of different batches.

At the end of each batch, starting after the second one, the stability check is performed as follows (BIPM 2008b):

1. The standard deviation $s_{\bar{y}}$ associated with the average $\bar{y}$ of the estimates $\tilde{y}^{(1)}$, $\tilde{y}^{(2)}$, ..., $\tilde{y}^{(m)}$ of the m batches available so far is calculated as:

$$s_{\bar{y}} = \sqrt{\frac{1}{m(m-1)} \sum_{h=1}^{m} \left(\tilde{y}^{(h)} - \bar{y}\right)^2} \tag{21}$$

where

$$\bar{y} = \frac{1}{m} \sum_{h=1}^{m} \tilde{y}^{(h)} \tag{22}$$

2. The counterpart of the statistic $s_{\bar{y}}$ is calculated for $u(\tilde{y})$, y_{low}, and y_{high} in the same way followed in case of $\tilde{y}$. Thus, we obtain $s_{\bar{u}(\tilde{y})}$, $s_{\bar{y}_{\text{low}}}$, and $s_{\bar{y}_{\text{high}}}$ associated with the averages $\bar{u}(\tilde{y})$, $\bar{y}_{\text{low}}$, and $\bar{y}_{\text{high}}$ of the statistics $u(\tilde{y})$, y_{low}, and y_{high}, respectively.
3. The standard uncertainty $u(\tilde{y})$ is calculated using all $m \times Q$ output values available so far.
4. The numerical tolerance δ is calculated for $u(\tilde{y})$ using the specified n_{dig}.
5. If any of $2s_{\bar{y}}$, $2s_{\bar{u}(\tilde{y})}$, $2s_{\bar{y}_{\text{low}}}$, and $2s_{\bar{y}_{\text{high}}}$ exceeds δ, a new batch is executed. Otherwise, the stability criterion is considered to be met and the simulation is terminated.

Finally after all results get stabilized, the final results of the simulation $\tilde{y}$, $u(\tilde{y})$, y_{low}, and y_{high} are calculated using all output values obtained from all simulation batches.

In fact, the estimate $\tilde{y}$ and its associated standard uncertainty $u(\tilde{y})$ converge considerably faster than y_{low} and y_{high} with respect to the number of trials. So, when the coverage probability is not required, the stability check can be based only on $2s_{\bar{y}}$ and $2s_{\bar{u}(\tilde{y})}$ (BIPM 2008b).

Concluding Remarks

By the end of this chapter, the reader should have been understood the general framework and methodology of uncertainty quantification in metrology. To sum up the procedure, the uncertainty evaluation begins by identifying the significant uncertainty sources then they are quantified according to Type A or Type B evaluation methods based on the nature of the information available about the uncertainty source. It is noteworthy here that there are three sources of uncertainty usually applicable to every measurement: the repeatability of the measurement, the resolution of the measuring device, and its calibration uncertainty. The first can be quantified from repeated observations using Type A method, while the two others are quantified according to Type B method based on the available information. Other uncertainty sources may be applicable subject to the measuring method and its circumstances. The next step is combining individual uncertainties using an appropriate technique to estimate the measurement result and the total margin of uncertainty about that result. Here, it is remarkable that the GUM uncertainty framework is the most popular as it is simple, straightforward, and easy to implement in both the industrial and scientific fields. On the contrary, the Monte Carlo simulation is much more complex and cannot be implemented by hand; however, it has become a necessity if the measurement model has a great deviation from linearity to the extent that the GUM framework becomes inaccurate due to its inherent linear approximation. Probably, the GUM framework would still be the dominant until the ability of metrologists to develop complex measurement models is evolved to the extent that the GUM framework become inefficient.

As obvious, the ultimate benefit of quantifying the uncertainty is aiding in decision-making using the result of the measurement process. In this context, the decision maker should realize that the uncertainty interval provides a certain level of confidence (probability) that the true value lies in that interval. Accordingly, the decision itself is liable to be incorrect at a certain probability. In practice, improving the uncertainty to the extent that the error probability in decision-making become trivial may be inefficient from an economic point of view. So, a cost analysis is very useful in determining the appropriate balance between the level of investment in measurement and the cost of incorrect decision that keeps the total cost minimum.

Abstract

This introduction to measurement uncertainty is designed for metrology experts working in calibration laboratories and metrology institutions, as well as students in science and engineering programs at the university level. The topic is covered with a focus on creating models of the physical measuring process. Since the release of the Guide to the Expression of Uncertainty in Measurement, there has been an increase in the use of models for uncertainty analysis. However, there is no direction on how to do so. That issue is addressed in this booklet. The mathematics and statistics employed here are elementary and are normally studied in high school. Modeling, on the other hand, is a method of describing an abstraction of a measuring process using mathematical language. Some readers may be unfamiliar with this. This publication was made possible by the contributions of many people.

Measurement · Uncertainty · Errors · Probability distributions · Samples

Introduction

We get knowledge about amounts of interest from measurements. Measurements frequently provide solutions to questions such as what is the speed of the train and what are the glucose levels in a blood sample? The results of measurements are frequently required because a decision must be made: will I be late for the college, is the train moving too quickly, or is the patient's blood sugar level beyond the legal limit? Unfortunately, no measurement result can be guaranteed to be exact. As a result, bad decision-making outcomes are possible. Measurements are used to inform crucial decisions in modern society, such as industry, safety, public health, the environment, trade, and finance.

Measurement error is the discrepancy between a measurement result and the actual value of a quantity of interest. The presence of measurement mistakes, as well as the fact that they are unpredictable, causes doubt about decision accuracy. Uncertainty analysis is the exploration of measurement errors. This method detects and evaluates elements that can cause measurement error. An uncertainty analysis generates a model that characterizes the measurement's fundamentally unexpected behavior and gives statistical data on the accuracy of the results that can be utilized to make judgments. We will show you how to construct measurement models and how to use them to assess measurement uncertainty. We next apply these concepts to measurement and calibration case studies.

Main Text

Mathematical Notations and Symbols

This booklet employs mathematical expressions and symbols to provide clear and succinct representations of the quantities involved in a measurement process. The symbols, on the other hand, are merely symbols for things that can be explained in other ways; mathematical language is not strictly required. If you are having trouble understanding the mathematical equations, try thinking about the meaning of each sign in language.

For example, in the equation

$$\widehat{y} = y - Ey$$

here

$\widehat{y}$ represents measurand
y represents measured value
Ey error in calculating measurements.

Notations
To distinguish between known and unknown amounts, a simple notation is used: upper-case letters represent unknown quantities, whereas lower-case letters represent objects with a known value. Subscripts are also added to symbols to aid in quantity labeling. For example, the voltage might be represented by upper-case letter V (the exact voltage is not known), while lower-case letter represents v_{meter} (the meter reading from a volt meter is a known number).

$V_{meter}[i]$ Indicates i^{th} volt meter reading

Measurement Errors and Models

Because nuisance factors always affect the output of a measurement, we can never precisely establish the value of a number. As a result, a measured value can never be exactly equal to the amount of interest.

The relation between measurand, measurement value, and measurement error is given by

$$\widehat{y} = y - Ey \tag{1}$$

where Ey is measurement error. We can correct the measurement result y if we know the measurement error Ey

Equation (1) is an example of a measurement model. Models describe the link between the amount of interest and other variables that may affect the measurement result. They are essential to uncertainty analysis because they may be used to assess both the quantities to be measured and the measurement uncertainty. Uncertainty regarding the value of the error Ey leads to uncertainty in the value y as $\widehat{y}$ estimate in equation (1).

Defining the Concepts of Unpredictability and Probability

When something's behavior is unpredictable, we call it random. Because many minor factors influence the results in unpredictable ways, measurement outputs are random. Nonetheless, the quantities we want to measure are not random (we would like to know velocity, the voltage, the concentration of blood sample, and so on). We uncover the elements that can cause a measurement result to be skewed when we conduct an uncertainty analysis. Then, we try to use probability concepts to describe

each factor's behavior. The concepts of probability that are needed to define influencing factors and measurement mistakes are introduced in this chapter.

Probability: It is a number that indicates the chance or likelihood that a particular event will occur.
Mathematical definition: Probability is the ratio of the number of favorable cases to the number of total outcomes.

The behavior of uncertain outcomes is described by probability statements. When rolling a dice, for example, we cannot anticipate the outcome, but we can say there is a 3/6 chance of getting an even number. We made our 3/6 assessment based on our experience and other relevant information; we did not measure it. Nonetheless, measurement might be used to test the assumption that each of the six events is equally likely. We could roll the die several times to ensure that the relative frequency of sixes does not depart from 3/6 by more than is reasonable given the number of throws. Although dice are not used in real measurements, the ability to double-check assumptions is crucial. It should always be easy to check the correctness of any probability statement that describes uncertain behavior, at least in theory.

When there are a finite number of alternative outcomes, such as when rolling a die, each one can be assigned a probability value. When a measurement result can have any value, the likelihood of an outcome occurring within a range of values is what is important. In such instances, probability distributions are applied. As shown in Fig. 2, a probability distribution can be represented as a curve over a horizontal axis reflecting the various possibilities. The higher the curve is above the axis, the more likely it is that the values under that part of the curve will be observed.

Probability Distribution Curves We have three types of probability distribution curves:

1. Gaussian distribution
2. Rectangular distribution (Uniform distribution)
3. Triangular distribution

Gaussian Distribution

Because it is commonly assumed to characterize the unanticipated error in a measurement result, the Gaussian distribution (Fig. 1) is of particular importance in test and measurement. A Gaussian distribution is also commonly used to represent the mistake that occurs when statistical approaches are employed to determine influencing variables. Values are more likely to be found in the center of a Gaussian distribution when random behavior follows it (near the mean). Nonetheless, because the range is potentially unbounded, values far from the mean will occasionally be seen.

Uniform Distribution

The continuous uniform distribution, often known as the rectangle distribution, is a family of symmetric probability distribution in probability theory and statistics. An

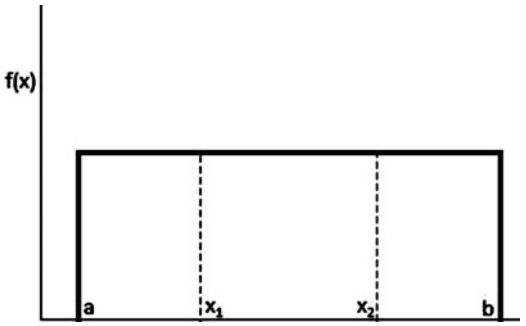

Fig. 1 A Uniform distribution. Center of the distribution is the mean of x_1 and x_2

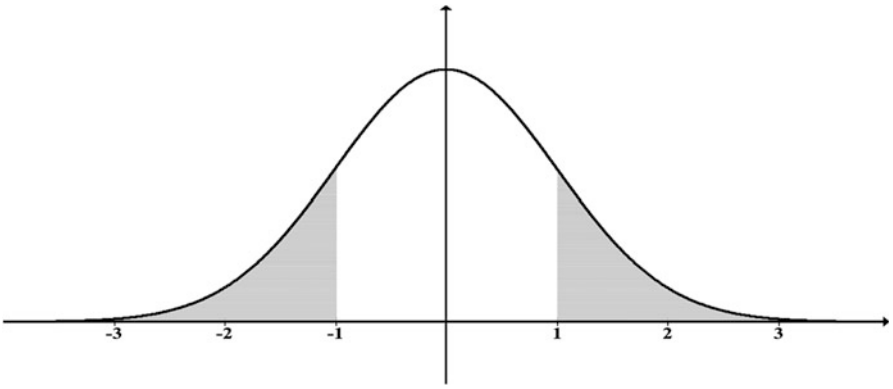

Fig. 2 Normal distribution. Center of the distribution is the mean, and the white band region represents the standard deviation

experiment with an arbitrary outcome that falls within defined limitations is described by a distribution.

It will be easier to express a uniform distribution's scale in terms of its width. However, this information must always be transformed into a standard deviation when determining the uncertainty.

When a number is displayed with a fixed number of digits, the inaccuracy is typically referred to as a uniform distribution. That is, a quantity Y is measured, and the result is rounded to

$$x = X + \mathrm{E}x \tag{2}$$

with Ex denoting the rounding error. Although neither Y nor Ex is known, we can say that x is a guess at X. (x is approximately equal to X). When a large number of different Y values are rounded, the resulting distribution of Ex values looks like a uniform distribution with a mean of zero and a range equal to the magnitude of the least significant digit (Fig. 2).

Triangular Distribution

A triangular distribution is a continuous probability distribution with a triangle-shaped probability density function. The minimum value a, the highest value *b*, and the peak value c are the three values that define it. This is extremely useful because, even if we do not know the mean or standard deviation, we can often predict the highest and lowest values, as well as the most likely outcome, in a real-life situation. We avoid undesirable extreme values by using the triangle distribution, which has a defined upper and lower limit. In addition, for skewed distributions, the triangular distribution is a reasonable model.

When values are more likely to occur around the center of a range than near the limits, the triangle distribution can be utilized. This is the situation, for example, when the difference between two uniformly dispersed values has the same width uniform distributions.

Example for the discrete triangular distribution is tossing two dice getting a minimum of 2, a maximum of 12, and a peak at 7 (Fig. 3).

Error Versus Uncertainty

It is crucial to distinguish between the terms "error" and "uncertainty."

Error: The discrepancy between the measured and the "actual value" of the thing being measured is called error.

Uncertainty: It is a metric that expresses the doubt about measurement's outcome.

We endeavor to remedy any known inaccuracies as much as feasible, for as by applying corrections from calibration certifications. Any inaccuracy whose value we do not know is, on the other hand, a cause of uncertainty.

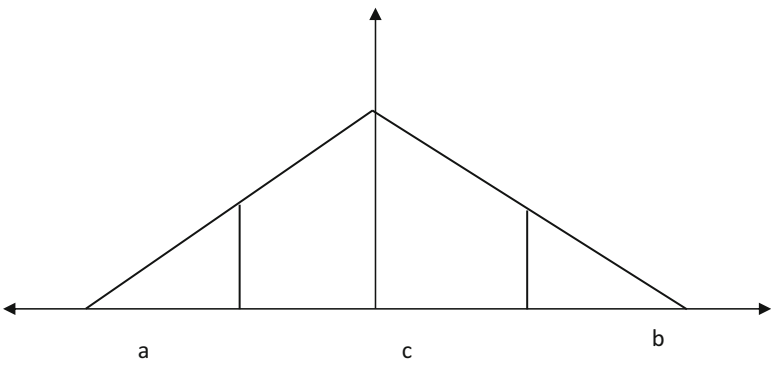

Fig. 3 Center of the distribution is the mean, and region between the two vertical lines is the standard deviation

Absolute Error of a Quantity of X

The units of an absolute error are the same as the units of the physical quantity. It is denoted by the letter k_x.

Relative Error of a Quantity X

Relative error is defined as the ratio of the error to the best value of the quantity. Denoted by K_{rx}, the letter r indicates "relative."

Types of Errors

Errors and their types depending on how the measurement was taken: Measurement mistakes might be characterized as random or systematic (an instrument could cause a random error in one situation and a systematic error in another).

Random errors are stochastic fluctuations (in either direction) in measured data caused by the measuring device's precision limitations. Random mistakes can be assessed using statistical methods and decreased by averaging over a large number of data (see standard error).

Systematic Errors: Systematic errors are reproducible inaccuracies that consistently go in the same direction. These errors are difficult to detect and cannot be statistically analyzed. If a bias is detected when you calibrate against the standard, you can reduce the bias by applying a correction or correction factor to correct the effect. Unlike random errors, increasing the number of observations cannot detect or reduce systematic errors.

Common Source of Errors in Physical Laboratory Experiments

Incomplete Definition (which can be systematic or random): One of the reasons why accurate measurements cannot be made is that measurements are not always well defined. For example, if two different people measure the same rope length, you will probably get different results because each person can stretch the rope with different tensions. The best way to minimize definition errors is to carefully consider and specify the conditions that may affect your measurement.

Failure to Account for a Factor (usually systematic): The hardest part of designing an experiment is trying to control or account for all possible factors except a single independent variable in the process. analyzer. For example, you may inadvertently ignore air resistance when measuring the free-fall acceleration, or you may ignore the effect of the earth's magnetic field when measuring the field of a small magnet. The best way to interpret these sources of error is to discuss with your colleagues all the factors that may affect your results. This brainstorming should be done before starting the test so that confounding factors can be sorted out before data collection. Sometimes error correction can be applied to a result after retrieving data to account for an undetected error.

i) *Instrument resolution* (random): All instruments have finite precision which limits their ability to resolve small measurement differences. For example, a gauge cannot distinguish distances with much better accuracy than about half of its smallest scale line (0.5 mm in this case). One of the best ways to get more accurate measurements is to use the zero difference method instead of measuring a quantity directly. The equal or empty method involves the use of instruments to measure the difference between two similar quantities, one of which is known to be very precise and can be adjusted. The adjustable reference quantity is varied until the difference is reduced to zero. The two quantities are then balanced
ii) *Environmental factors* (systemic or random): Be aware of errors introduced by your immediate work environment. You may need to consider or protect your experience from vibrations, drafts, temperature changes, electronic noise, or other effects from nearby devices.
iii) *Physical variations* (random): It is always wise to obtain several measurements over the entire range being studied. This often reveals variations that might go unnoticed. These variations may require further investigation or they may be combined to find the mean.
iv) *Lack of calibration or check zero of instrument* (systematic): Whenever possible, instrument calibration should be verified prior to data collection. If no calibration standard is available, the accuracy of the instrument should be checked by comparison with another at least the most accurate or by referring to the technical data provided by the manufacturer. Whenever making measurements with micrometers, digital scales, or power meters, always check zero first, zero instrumentation if possible, or measure the displacement of the zero reading from the true zero and correct all measurements accordingly. You should check for zero during the test.
v) *Parallax error* (systematic or random): This error can occur whenever there is a certain distance between the scale and the indicator used to obtain the measurement result. If the observer's eye is not perfectly aligned with the pointer and scale, the reading may be too high or too low (some analog meters have mirrors to help with this alignment).
vi) *Lag time and hysteresis* (Systematic): Some instruments take time to reach equilibrium, and reading before the instrument stabilizes will result in readings that are often too low. The most common example is measuring temperature with a thermometer that has not yet reached thermal equilibrium with its environment. A similar effect is latency where device reads are delayed, and there appears to be a "memory" effect as the data is retrieved sequentially moving up or down a range of values. Hysteresis is usually related to materials becoming magnetized when a changing magnetic field is applied.
vii) *Drift devices* (systematic): Most electronic devices have readings that drift over time. The amount of drift is usually not an issue, but sometimes the source of this error can be significant and should be considered.

viii) *Personal error arising from negligence*: Poor technique, or bias of the tester. The tester may measure inaccurately, may use the wrong technique to perform the measurement, or may introduce bias into the measurement by expecting (and unintentionally forcing) the result to agree, with expected results.

ix) *Aggregate individual errors*: Sometimes referred to as errors or omissions, should be avoided and corrected if discovered. As a general rule, gross individual errors are excluded from the error analysis discussion because it is generally assumed that test results are obtained by following correct procedures. The term human error should also be avoided in discussions of error analysis because it is too general to be useful.

Identifying Influence Quantities in Measuring Simple Length by Using a Calibrated Steel Ruler

A 1 m long steel ruler with 1 mm divisions is used to measure 60 cm length object.

(i) Errors are introduced by the ruler's curvature.

From Fig. 4, $l = \frac{L}{\cos\theta}$.

(ii) Errors are introduced by angle of observation (Fig. 5).

When taking readings, the observer should be perpendicular to the ruler scale and the feature edge. A reading error (also known as a parallax error) will occur if this is not done. If the work piece has a different thickness than the ruler and they are both sitting on a flat surface, a parallax mistake will occur if the observer is not looking directly down at the scale.

(iii) Rounding Error

The value of the scale marker closest to the feature edge is taken as a ruler reading. As a result, a measured value is rounded to the ruler scale's resolution, introducing an inaccuracy. If one end of the ruler is used to locate one edge, an error may be introduced due to the difficulty in aligning the ruler's end with the feature, as well as mechanical wear at the ruler's end (Fig. 6).

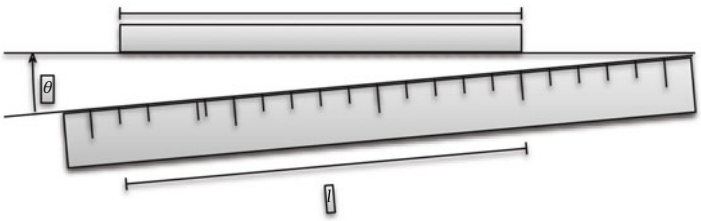

Fig. 4 A cosine error will make the length appear longer

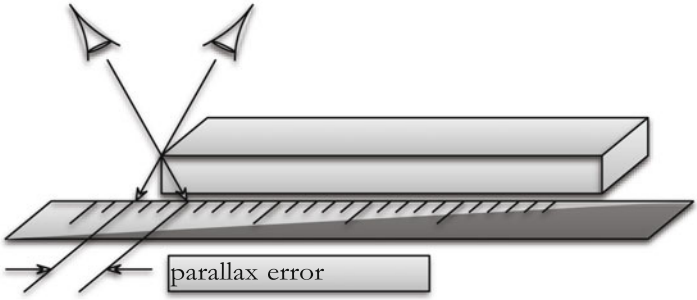

Fig. 5 Parallax error

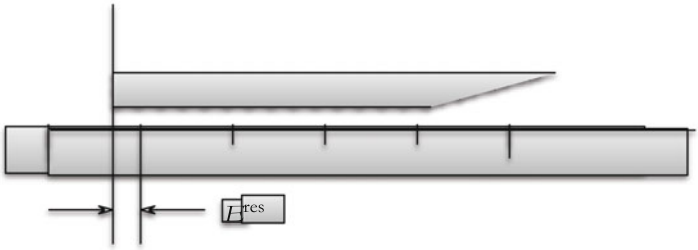

Fig. 6 Rounding error

Table 1 Errors

Factor	Typical magnitude
Cosine error	0.02 mm
Parallax error	0.06 mm
Ruler scale error	0.04 mm
Resolution error	0.25 mm
Thermal expansion	0.04 mm

Resolution error (E_{res}): The reading is taken from the number on the scale that is closest to a feature end-point. This brings the nearest scale division up to date.

Using Table 1, this can be converted to a standard deviation

$$E_{\text{res}} = \frac{1.0}{\sqrt{12}} = 0.29 \text{ mm}$$

Calibrating a Thermometer

Calibration is a process designed to verify that an instrument is suitable for use. Uncertainty Analysis of the calibration process must evaluate the accuracy of the calibration process The reference quantities are known, and so is the behavior of the model instrument calibration. In some cases, such as in the case of thermometers

discussed in this chapter, calibration determines correction works with raw instrument data and uncertainty correction value.

Temperature-controlled bathtubs are used to provide the environment. It has a precisely defined temperature. Two thermometers immersed in the bathtub next to each other: one is a glass thermometer calibrated and the other is a platinum resistance thermometer. Resistance thermometers are used to measure difference between bath temperature and reading glass thermometer and resistance thermometer readings for calibrating glass thermometers. Mercury-in-glass thermometer readings may vary. There are several reasons for the actual temperature. Roughly speaking, the effects are divided into two groups:

a) Random factors that may change in the short term
b) Systematic factors, which do not change over long periods

The effect of systematic factors is to introduce a fixed offset error to the thermometer reading. Random factors cause variability reading. Thermometer calibration determines offset values error and gathers information about the dispersion of measurements. This enables reliable temperature measurement with calibrated glass thermometer.

Measurand during Calibration

Glass thermometer readings can be described by a simple equation of observation

$$W_g[k] = T + D_g + E_{gr}[k] \tag{3}$$

where T is the actual temperature in the vicinity. For thermometers, D_g is a fixed offset error and $E_{gr}[k]$ is random errors. We use a different sign here for the fixed offset because this term is at the heart of the calibration process. Thermometers can be improved by applying corrections reading. So the metrics during calibration are D_g and A; calibration process is used to measure this offset. One way to think about D_g is to imagine a situation. There is no change in the thermometer reading (i.e., when $E_{gr}[k] = 0$). In this case, D_g will be the difference between the thermometer reading and the actual temperature T of the nearby area near the thermometer. There are many factors that affect thermometer calibration. Columns of mercury can separate, or high mercury droplets in capillaries, manufacturing quality may be unsatisfactory – e.g., tick marks may have incorrect format; otherwise, the thermometer may be very unstable.

Influencing Factors

There are many factors that affect thermometer calibration. Some are fatal because measurements should be aborted unless remedial action is taken. Major faults may be mercury column shedding, or high mercury droplets in capillary; build quality may be unsatisfactory — for example, dial markings may be poorly formed; otherwise, the thermometer may be extremely unstable due to improper annealing.

Unintended Effects: Operator errors in reading glass thermometers (e.g., parallax errors), reaction time between readings, etc.; irregularities in scale markings and apertures and stiction (sticking) of the mercury in the bore; randomness in the PRT display and instrumentation noise; and short-term instability of the bath temperature, etc.

Glass thermometers: Factors causing inaccurate thermometer readings are improper immersion of the thermometer and wrong orientation of the thermometer. Reference Thermometer: The accuracy of a platinum resistance thermometer (PRT) used as a reference is characterized by calibration. However, the thermometer must be used correctly, e.g., proper immersion should be taken care of. Bath Temperature Uniformity: A stirred bath produces a volume that is nearly uniform in temperature. Spatial uniformity of temperature can be assessed by periodic measurements at different locations and temperature ranges. This should be done as part of ongoing maintenance of the calibration equipment.

Control of Influencing Factors

Many influencing factors can be effectively managed through well-designed measurement procedures.

Make sure the operator waits enough time for the calibration bath to reach operating temperature before reading the thermometer:

(i) Note the correct immersion of the two thermometers and the orientation of the glass thermometer, which should be vertical.
(ii) The glass body of the thermometer can be tapped lightly before reading to avoid shrinkage.
(iii) Readings should be at right angles to the thermometer to avoid parallax errors.
(iv) Ensure that PRT readings are less random than glass thermometer readings (PRT reading variability should be $<$ one third of glass thermometer readings).

Modeling the Calibration Procedure

The measurand is determined as the offset term D Glass in equation (3). So we can start our model by rearranging the glass 44 Introduction to Measurement Uncertainty Thermometer observation equation for

$$D_g = W_g - E_{gr}[k] - T \tag{4}$$

This actually presents a calibration method. If the thermometer can be placed in an environment with a known temperature T, the average difference between the thermometer reading and T provides an estimate of Dglass. Our measurement method uses a heating bath to maintain a nearly uniform temperature in a volume of liquid. An electronic platinum resistance thermometer immersed in the bath was used to measure the temperature. Like glass thermometers, resistance thermometer readings fluctuate due to random influences and are also subject to a small fixed offset, which we attribute to residual calibration error $E_{\text{prt.cl}}$.

Observation equation for resistance thermometer readings: Reference thermometer is given by

$$W_{\text{prt}}[k] = T_{\text{prt}} + E_{\text{prt.r}}[k] + E_{\text{prt.cl}} \tag{5}$$

Note that T_{prt} is the temperature measured by a resistance thermometer. The temperature T near the glass thermometer is not necessarily equal to T_{prt}.

To account for this, we introduce an error term E_b representing a small temperature difference between the thermometer locations in the bath, so that

$$T_{\text{prt}} = T + E_b \tag{6}$$

From (5) and (6),
we get

$$W_{\text{prt}}[k] = T + E_b + E_{\text{prt.r}}[k] + E_{\text{prt.cl}}$$

$$\Rightarrow T = W_{\text{prt}}[k] - E_b - E_{\text{prt.r}}[k] - E_{\text{prt.cl}} \tag{7}$$

Equation (7) shows the reading of the resistance temperature detector. In this way, we get a model of how the glass thermometer deviates. Errors are readings from each thermometer and other thermometers.

Solving equation (4) and (7) for eliminating temperature T, we get

$$D_g = W_g[k] - W_{\text{prt}}[k] + E_{\text{prt.r}}[k] - E_{gr}[k] + E_{\text{prt..cl}} + E_{\text{b}} \tag{8}$$

We can simplify equation (8) by applying difference formulas

$$d[k] = W_g[k] - W_{\text{prt}}[k]$$

$$E_{d.r}[k] = E_{g.r}[k] - E_{\text{prt.r}}[k]$$

$$D_g = d[k] - E_{d.r}[k] + E_{\text{prt..cl}} + \text{E}_{\text{b}} \tag{9}$$

After calculating the average of sample differences

$$\overline{d} = \frac{1}{N}\sum_{k=1}^{N} d[k]$$

our final measurement model of the calibration is

$$D_g = \overline{d}[k] - E_{\overline{d}.r}[k] + E_{\text{prt..cl}} + E_{\text{b}} \tag{10}$$

$$u\left(E_{\text{prt..cl}}\right) = 0.0078$$

Example:
A sample thermometer readings and the differences are given as follows:

k	$w_g[k](Celcius)$	$w_{prt}[k](Celcius)$	$d[k](Celcius)$
1	79.850	79.847	0.003
2	79.840	79.840	0.000
3	79.830	79.830	0.000
4	80.060	80.050	0.010
5	80.130	80.124	0.006
6	80.130	80.125	0.005

The statistics of the sample differences are as follows:

$$\text{Sample mean} = 0.004$$

$$\text{Sample standard deviation} = 0.0038$$

$$\text{Sample standard error of mean} = 0.0016$$

Here $\overline{d} = 0.004\ ^\circ\text{C}$

In equation (10) , $E_{\overline{d}.r}$ is the error associated with our value of the sample mean due to variability in the readings.

$$E_{\overline{d}.r} = 0.000\ ^\circ\text{C}$$

Standard uncertainty associated with $E_{\overline{d}.r}$ is

$$u\left(E_{\overline{d}.r}\right) = 0.0016\ ^\circ\text{C}$$

Other Influence Factor Assessments
Residual error representing the difference between actual PRT and the ideal one

$$e_{\text{prt..cl}} = 0.000\ ^\circ\text{C}$$

PRT calibration certificate reports a standard uncertainty

$$u\left(e_{\text{prt..cl}}\right) = 0.0078\ ^\circ\text{C}$$

The maximum temperature difference between any two points within 100 mm of one other, in the bath's center, 0.0010 °C, according to routine bath observations. If we assume that each temperature variation is equally likely, we can correlate this range with a uniform distribution. The bath non-uniformity is connected with a standard uncertainty of

$$(e_b) = \frac{0.001}{\sqrt{12}} = 0.0029\ ^\circ\text{C}$$

Sample mean $\overline{d} = 0.004\ ^\circ\text{C}$

Three other influences, their estimates, and uncertainties are mentioned as follows:

Influence	Estimate	Uncertainty
$E_{\overline{d}.r}$	$e_{\overline{d}.r} = 0.000\ ^\circ\text{C}$	$u(e_{\overline{d}.r}) = 0.0016\ ^\circ\text{C}$
$E_{\text{prt..cl}}$	$e_{\text{prt.cl}} = 0.000\ ^\circ\text{C}$	$u(e_{\text{prt.cl}}) = 0.0078\ ^\circ\text{C}$
E_b	$e_b = 0.000\ ^\circ\text{C}$	$u(e_b) = 0.0029\ ^\circ\text{C}$

Evaluation of Result and Measurement Uncertainty

From the equation (10),

$$d_g = \overline{d}[k] - e_{\overline{d}.r}[k] + e_{\text{prt..cl}} + e_{\text{b}}$$

$$\Rightarrow d_g = 0.004\ ^\circ\text{C} - 0.000\ ^\circ\text{C} + 0.000\ ^\circ\text{C} + 0.000\ ^\circ\text{C}$$

$$d_g = 0.004\ ^\circ\text{C}$$

The combined standard uncertainty d_g as an estimate of D_g is

$$u(d_g) = \sqrt{u(e_{\overline{d}.r})^2 + u(e_{\text{prt.cl}})^2 + u(e_b)^2} \tag{11}$$

$$u(d_g) = \sqrt{0.0016^2 + 0.0078^2 + 0.0029^2} = 0.0084\ ^\circ\text{C}$$

Using the Glass Thermometer

It is the temperature T in the immediate region of the thermometer that is of interest when using a calibrated glass thermometer. Rearranging the observation equation (3)

$$T = W_g[k] - E_{\text{gr}}[k] - D_g \tag{12}$$

$$d_g = 0.004\ ^\circ\text{C}$$

with $u(d_g) = 0.0084\ ^\circ\text{C}$

Because positive and negative variations are expected to be equally likely, and there will be no tendency for one to occur more than the other; the estimate is $e_{g.\ r} = 0.00\ ^\circ\text{C}$. The sample standard deviation (estimated earlier, see 11.6.1) should be utilized to characterize the width of the Gaussian distribution representing $e_{g.\ r}$, because individual thermometer readings are now used to measure the temperature. As a result, $u(e_{g.\ r}) = 0.0038\ ^\circ\text{C}$ is the standard uncertainty.

$$t = w_g[k] - 0.000\ ^\circ\mathrm{C} - 0.0084\ ^\circ\mathrm{C}$$

with standard uncertainty

$$u(t) = \sqrt{u\left(d_g\right)^2 + u\left(e_{g.r}\right)^2} \tag{13}$$

$$\Rightarrow u(t) = \sqrt{0.0084^2 + 0.0038^2}$$

$$\Rightarrow u(t) = 0.0092$$

The value of d_g, which can be used to compensate for the thermometer offset error, and the uncertainty in a single corrected reading $u(t)$, from equation, are most likely to be of relevance to the thermometer's end-user (13).

It is important to note that one is not the same as the other's uncertainty!

Because the corrected reading uncertainty is more relevant to the client, a calibration laboratory may choose to report d_g and the uncertainty $u(t)$ rather than $u(d_g)$ from equation (11). When this is completed, the calibration report should clearly state the difference.

Relation Between the Width and Standard Deviation

When determining measurement uncertainty, the standard deviation of a distribution is always required. Formulas for converting a distribution's range into a standard deviation are as follows:

If width of the distribution is d, then

$$\text{Standard deviation of the uniform distribution} = \frac{d}{\sqrt{12}}$$

$$\text{Standard deviation of the triangular distribution} = \frac{d}{\sqrt{24}}$$

Observations of Variability

The effect of an influence factor can be seen directly as data variability. In such instances, a sample of data can be used to calculate the standard deviation of a distribution that explains the behavior. Gaussian distributions are frequently used to describe the variability encountered in test and measurement circumstances. Observations are considered to vary in this chapter due to the influence of a random error with a Gaussian distribution.

Samples and Estimates

Assume that the indicators in a measurement system change, but the quantity of interest Y remains constant.

The i^{th} indication is written as

$$V[i] = Y + E_r[i] \tag{14}$$

where $E_r[i]$ that give rise to variability have a Gaussian distribution with a mean of zero.

We will look at two methods for calculating Y: taking a single number or taking a sample of values and calculating the mean. E_r affects the outcome in both cases; the value y produced as an estimate of Y will always have an unpredictable error. In general, equation (1), which is repeated above, describes this circumstance.

In both circumstances, a Gaussian distribution with a mean of zero best describes the behavior of the error E_r. The standard deviation that scales the distribution width, on the other hand, will be determined by how y is collected. To evaluate this parameter, a sample of n observations $V[1]$, $V[2]$, …. $V[n]$ is required.

A Single Observation and the Sample Standard Deviation

We can write simply that when a single indication is used as an estimate of Y (the index i is no longer required), we can write simply $y = V$

The standard deviation of the distribution

$$S_n = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n}\left(\widehat{V} - V[i]\right)^2}$$

where sample mean $\widehat{V} = \frac{1}{n}\sum_{i=1}^{n} V[i]$

Example 1: Variable Current Readings

The following are 10 current readings measured from an ammeter:

2.998 mA, 3.001 mA, 3.002 mA, 2.999 mA, 3.003 mA
2.998 mA, 3.001 mA, 3.000 mA, 2.999 mA, 3.002 mA

Sample mean

$$\widehat{V} = \frac{1}{n}\sum\nolimits_{i=1}^{n} V[i]$$

$$\widehat{V} = \frac{1}{10}[30.003]$$

$$\widehat{V} = 3.0003$$

$$S_n = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n}\left(\widehat{V} - V[i]\right)^2}$$

$$S = 0.00176$$

Sample Mean and the Standard Deviation of the Mean

The sample mean yields a more accurate estimate of Y than a single indicator.

If $\widehat{V} = \frac{1}{n}\sum_{i=1}^{n} V[i]$ then the standard deviation of the distribution describing E_y is

$$SE_{\widehat{V}} = \frac{S_n}{\sqrt{n}}$$

The statistic value $SE_{\widehat{V}}$ is called standard error of the mean. S_n is standard deviation.

Example 2: Variable Current Readings

Below are the sample means of ten samples, each with ten observations:

2.99978 mA, 3.00027 mA, 3.00032 mA, 2.99953 mA, 3.00043 mA
2.99968 mA, 3.00041 mA, 3.00029 mA, 2.99951 mA, 3.00026 mA

The standard error of the 10 samples from Example 1 is

Is $\frac{S_n}{\sqrt{n}} = \frac{0.00176}{\sqrt{10}} = 0.00056$ mA

This value is closed to the standard deviation of the above 10 values 0.00046 mA.

Variability and Offset

A pair of impact factors can often be used to mimic the indications of a basic measuring instrument: one, E_{random}, changes with each indication, while the other, E_{offset}, remains constant. The ith indicator in this example can be written as

$$V[i] = Y + E_o + E_r[i] \tag{15}$$

where $E_o = E_{\text{offset}}$ and $E_r = E_{\text{random}}$

When this happens, the methods provided in sections "Identifying Influence Quantities in Measuring Simple Length by Using a Calibrated Steel Ruler" and "Calibrating a Thermometer" for measuring Y are no longer appropriate: they would estimate the value of $Y + E_o$, not Y. A new method of measuring the offset must be devised. One popular method is to compare the instrument's indications with those from a more accurate one. For example, the fixed offset of a thermometer being calibrated is determined by comparing thermometer readings to readings from a more accurate reference thermometer.

Sampling Theory

It is critical to gather a representative sample of the variability of an influence quantity when collecting observations. The effect of mechanical flaws in the bore of a thermometer is an influencing factor that requires careful planning to ensure that a suitable range of circumstances is covered when observations are gathered. By taking readings across an acceptable temperature range, a representative sample of data impacted by this factor can be acquired, with the changing height of the liquid column in the bore sampling the irregularities that affect measurements.

The Theory of Uncertainty

Lord Kelvin, the famed scientist, observed in 1889 "You know something about it when you can measure it and describe it in numbers; else, your knowledge is of a limited and unsatisfying kind." This well-known quote emphasizes the significance of measurement and measurement science. The term measurement refers to both the procedure for obtaining the number described by Lord Kelvin and the number itself. This figure, which is nothing more than the measurement's outcome, is extremely important. Consider what we do on a daily basis. Everything in our knowledge has a number linked with it: the weights of apples, the height of a tree, the length of a table, etc.

The theory of error was replaced by the theory of uncertainty at the end of the twentieth century. The uncertainty is a property of the measurement result that shows the lack of perfect knowledge about the value of the measurand, as reported in [ISO93]. The publication of the IEC-ISO "Guide to the Expression of Uncertainty in Measurement" (GUM) [ISO93] in 1992 marked the official transition from error to uncertainty. The traditional concept of mistake vanishes.

The question now is how to estimate such a probability density function in order to estimate the standard uncertainty as well. The most direct method is to try it out: The technique is done numerous times, and the standard deviation of the acquired measurement data is calculated. However, due to practical and financial constraints, this approach takes time and cannot always be followed. On the other hand, it is widely acknowledged that the probability density function associated with measurement findings can frequently be assumed based on a priori knowledge, such as a calibration certificate or the operator's experience. Both of these methods for estimating the probability density function and the associated standard deviation are equally accurate, according to the GUM, which classifies them as type A and type B uncertainty evaluations.

Type A evaluation of the standard uncertainty is obtained by means of statistical analysis of series of observations. Suppose n different measurements $x_1, x_2, \ldots x_n$ are obtained under the same conditions of measurement. We know that the arithmetic of n observations $\widehat{x}$ is the best estimate of the expected value of the quantity x.

The best estimate of the variance of the mean

$$S^2(\widehat{x}) = \frac{1}{n(n-1)} \sum_{i=1}^{n} (x_n - \widehat{x})^2$$

Standard deviation of the mean $= S(\widehat{x})$

The standard uncertainty is calculated in type B by making a judgment based on all relevant information about the likely variability of quantity x. Previous measurement data, experience or general knowledge, manufacturer's specifications, data provided in calibration certifications, and so on are examples of available information.

The available information leads to the conclusion that the measurement result distributes according to a rectangular distribution with base $2b = b_+ - b_-$; then the expected value of

$$x = \frac{(b_+ - b_-)}{2}$$

Standard uncertainty is $s(\widehat{x}) = \frac{b}{\sqrt{3}}$

If it is known that the measurement result is distributed according to a symmetric trapezoidal distribution with a base of width $2b = b_+ - b_-$ and a top of width $2b\ \beta$, where $0 \leq \beta \leq 1$ is the standard uncertainty, the standard uncertainty becomes

$$s(\widehat{x}) = \sqrt{\frac{b^2\left(1+\beta^2\right)}{6}}$$

When $\beta = 1$, the trapezoidal distribution transforms into a rectangle distribution $s(\widehat{x}) = \frac{b}{\sqrt{3}}$.

When $\beta = 0$, the trapezoidal distribution transforms into a triangular distribution $s(\widehat{x}) = \frac{b}{\sqrt{6}}$.

The definitions above apply to uncertainty estimates in direct measurements, or measurement processes where the measurand may be directly measured. Several quantities, on the other hand, are measured indirectly by appropriately processing the findings of previous measurements. It is crucial that, like the error idea, the uncertainty concept is applied to these indirect measurements and that the uncertainty associated with the final measurement result is calculated using the uncertainty values associated with each processed measured value. When the standard uncertainty is taken into account, the final measurement result can be connected with a combined standard uncertainty as shown further.

Let Y be the measurand, and $X_1, X_2, \ldots X_n$ be the measurable values on which the measurand is dependent, and $Y = f(X_1, X_2, \ldots X_n)$ be the mathematical relationship between them. The expectations $e_1, e, \ldots e_n$ of quantities $X_1, X_2, \ldots X_n$ determine the expected value y of quantity Y.

Furthermore, assuming f is a linear function, the measurement result y's combined standard uncertainty $U_c(y)$ can be calculated as follows:

$$U_c(y) = \sqrt{\sum_{i=1}^{n}\left(\frac{\partial f}{\partial e_i}\right)^2 U^2(e_i) + 2\sum_{i=1}^{n-1}\sum_{j=i+1}^{n}\frac{\partial f}{\partial e_i}\frac{\partial f}{\partial e_j}U\left(e_i, e_j\right)} \qquad (16)$$

where $\frac{\partial f}{\partial e_i}$ is a partial derivative of f with respect to e_i that is called sensitivity coefficient, $U(e_i)$ is called standard uncertainty, and $U(e_i, e_j)$ is called estimated covariance of e_i, e_j that can be calculated from the formula $U(e_i, e_j) = U(e_i)\ U(e_j)\ \emptyset\ (e_i, e_j)$.

Here $U(e_i)$, $U(e_j)$ are called standard uncertainty with respect to e_i, e_j, respectively, and $r(e_i, e_j)$ is a correlation coefficient between e_i and e_j .

We know that the correlation coefficient satisfies the following properties:

$$-1 \leq r\left(e_i, e_j\right) \leq 1$$

and

$$r\left(e_i, e_j\right) = r\left(e_j, e_i\right).$$

Note: If $r(e_i, e_j) = 0$, then the quantities are uncorrelated.

Equation (16) is the first-order Taylor-series approximation of $Y = f$ if $f(X_1, X_2, \ldots X_n)$ is not a linear function in the most practical cases; however, it can still be taken into account while evaluating$U_c(y)$. In truth, the measurement uncertainty is often minimal in relation to the observed value in measurement practice, resulting in small fluctuations in the measurand. This indicates that the linearity condition of f is usually verified locally, close to the measurement location, and Eq. (16) remains true. Higher-order terms in the Taylor series must be included in Eq. (16) when the nonlinearity of f is considerable.

It is now widely accepted that the standard uncertainty (and the combined standard uncertainty when indirect measurements are taken into account) achieves the primary goal of characterizing "the dispersion of the values that could reasonably be attributed to the measurand without any need to refer to the unknown and unknowable true value of the measurand, provided that the sole causes for this dispersion are random."

However, there is one remaining issue for which there is no obvious answer in terms of standard uncertainty. "In many industrial and commercial applications, as well as in the areas of health and safety, it is frequently necessary to provide an interval about the measurement result within which the values that can reasonably be attributed to the quantity subject to measurement can be expected to lie with a high level of confidence," according to the GUM. As a result, the ideal approach for evaluating and expressing measurement uncertainty should be capable of quickly generating such a confidence interval, preferably one that matches to the desired level of confidence in a realistic manner.

The confidence interval of a measurement result Y is usually expressed as an interval centered on the result $(y \pm U)$ and can only be determined if the probability distribution of the result is known and the desired level of confidence is set. In fact, if $p(y)$ is Y's probability distribution, its mean and standard deviation are given by

$$\overline{y} = \int_{-\infty}^{+\infty} yp(y)dy \tag{17}$$

$$\sigma_{p(y)} = \sqrt{\int_{-\infty}^{+\infty} (y - \overline{y})^2 p(y) dy} \tag{18}$$

Now c is the required level of confidence, the associated confidence can be found by using solution of the integral

$$c = \int_{\overline{y}-U}^{\overline{y}+U} p(y) dy \tag{19}$$

The confidence interval's semi-width U, also known as enlarged uncertainty, is usually expressed as a multiple of the standard uncertainty:

$$U = k_c \, u(y)$$

This indicates that the difficulty in obtaining k_c determines the challenge of determining a confidence interval. The multiplying factor k_c, also known as the coverage factor, is, of course, strictly dependent on the probability distribution p (y) and the level of confidence c. If p(y) is a normal distribution, the coverage factors correspond to the most typically used confidence intervals as follows:

$k_c = 1$ for $c = 68.27\%$
$k_c = 1.645$ for $c = 90\%$
$k_c = 1.96$ for $c = 95\%$
$k_c = 2$ for $c = 95.45\%$
$k_c = 2.576$ for $c = 99\%$
$k_c = 3$ for $c = 99.73\%$

If the measured quantity Y can be measured directly, a type A or type B assessment can be used to determine the probability distribution of the result. This endeavour can be challenging at times, but it usually results in a solution. When the measured quantity Y, on the other hand, can only be measured indirectly, determining the probability distribution of the result becomes more complex.

If the probability distributions of the input variables $X_1, X_2, \ldots X_n$ are known, and the relationship between Y and its input quantities is a linear function, the probability distribution of Y may be easily calculated via a sequence of convolutions, on the other hand, relationship f is nonlinear and a first-order Taylor expansion is not a good approximation. In these situations, we need numerical methods such as Monte Carlo one.

However, convolution of probability distributions is difficult, and Monte Carlo simulation is time-consuming. However, it is not always essential to deal with all probability distributions, and knowing the standard deviations is sufficient to estimate the proper coverage factor for a given level of confidence. This occurs whenever the Central Limit Theorem's assumptions are met, which is one of probability theory's most astounding results.

Central Limit Theorem

Theorem 1: Let independent random variables X_1, X_2, ... X_n share the same probability distribution. Assume that the expected value μ and the standard deviation σ exist and are finite. Consider the sum $S_n = X_1 + X_2 + \ldots + X_n$. Then, the expected value S_n is $n\mu$ and the standard deviation is $\sigma\sqrt{n}$. Furthermore as n approaches to ∞, the distribution of $N(n\mu, n\sigma^2)$. It is known that the outcome of the indirect measurement follows a certain normal distribution under the assumptions of this theorem; so, no computations are required, and the coverage factors may be found on tables.

Furthermore, it can be shown that the Central Limit Theorem's thesis is still valid when the hypotheses are less tight. In reality, there is a generalization of the Central Limit Theorem that does not need the initial random variables to have similar distributions. Of course, this modified form of the Central Limit Theorem necessitates certain extra criteria, such as ensuring that no single variable has a significantly greater impact than the rest.

The Central Limit Theorem guarantees that the random variable representing the ultimate result $Y = f(X_1, X_2, \ldots X_n)$ approximates a normal distribution under this condition. The standard deviation and mean value of this normal distribution are given by $y = f(x_1, x_2, \ldots x_n)$.

Furthermore, as the number of input rises, the approximation improves; convergence is faster as the variance values go closer to each other; and the closer the distributions X_i are to normal ones, the fewer X_i are needed to generate a normal distribution for S_n. The following example is provided to demonstrate how this concept holds true in practice.

Let us have a look at the sum of rectangular distributions, which is an important non-normal distribution. The probability density function of the sum is generated theoretically by convoluting the starting distributions, as indicated. Figure 7 depicts the convolution (dot line) of four rectangular distributions with an expected value of $\mu = 10$ and a width of 0.2, corresponding to a standard deviation of $\sigma = \frac{0.1}{\sqrt{3}}$ (given width $2b = 0.2$). Because this convolution is almost normal (solid line), the validity of the Central Limit Theorem is easily demonstrated. As a result, the convolution of only four equal-width rectangular distributions is essentially normal.

Figure 8 depicts the convolution (dot line) of four rectangular distributions with the same expected value of 10 but varying widths (0.14, 0.06, 0.4, and 0.6). It should be emphasized that four rectangular distributions are insufficient to approximate a normal distribution in this circumstance (solid line).

On the other hand, as shown in Fig. 9, seven rectangular distributions may be sufficient. In this scenario, the distributions have an expected value of 10 and widths of 0.14, 0.06, 0.4, 0.6, 0.1, 0.03, and 0.2, which are all one order of magnitude apart.

This example illustrates, intuitively, that the values attributed to the measured, when obtained through an indirect measurement method, distribute according to a pretty normal distribution, given that the Central Limit Theorem premise is satisfied (at least at a first approximation). As a result, the standard deviation of such a distribution is equal to the combined standard uncertainty provided by Eq. (16),

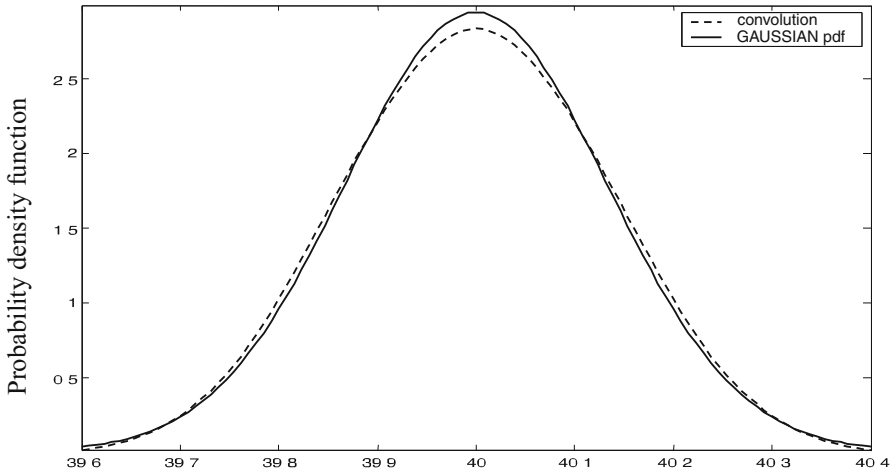

Fig. 7 Convolution of four rectangular distributions having the same mean and variance

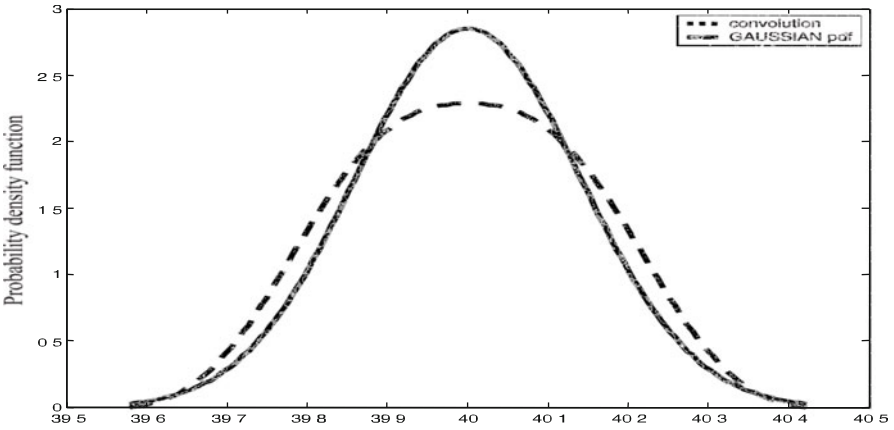

Fig. 8 Convolution of four rectangular distributions having different widths

and any required confidence interval with assigned confidence level can be easily obtained by multiplying this standard deviation by a coverage factor typical for the normal distribution.

Fuzzy Variables and Measurement Uncertainty

Section "The Theory of Uncertainty" provided an overview of the basic concepts of measurement theory. In particular, the results of the measurements represent incomplete knowledge of what is being measured, and this knowledge has been shown to be meaningful only if that "imperfections" can be estimated and quantified in some

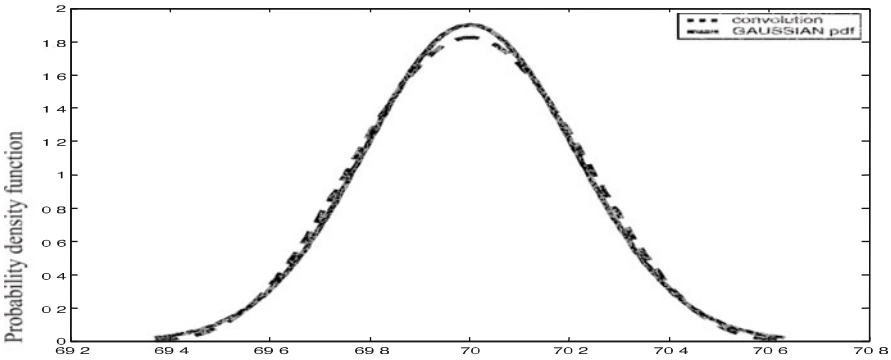

Fig. 9 Convolution of seven rectangular distributions having different widths

way. This approach also shows that proper mathematics is needed to deal with incomplete knowledge from a quantitative point of view. Current practice is primarily related to probability theory as it is the most well-known and most valuable mathematical theory dealing with incomplete knowledge. However, probability theory deals only with this particular kind of incomplete knowledge that results from random effects. As we saw in the previous chapter, this means that all other recognized and significant effects, including systematic effects, are fully compensated. Systematic effects always affect the measurement process with the same value and sign. If this value is known accurately, it will be treated as an error, and the correction may correct the measurement result during the measurement process. Of course, this situation generally does not occur.

Under normal circumstances, the presence of a systematic contribution is detected, but even if it is possible to find it within a closed interval of $\mathfrak{R}$, its exact value is unknown. By definition, the systematic contribution is unknown, but it always takes the same value within this estimated interval. This means that not all values of the interval have the same probability of occurrence, but without further evidence, there is no better value than the other values, so the probability of occurrence is the same. This situation can also be used to represent a more general case. In many real-world situations, there are signs that unknown effects affect measurement results. The only information available shows that the contribution to this unknown effect is at a certain level of confidence and within a certain interval, but it is unclear where it is.

Furthermore, nothing else can be assumed, even if the effect is systematic or random. This situation is called complete ignorance. Although the two types of contributions are represented the same way – confidence intervals – they should not be confused. In fact, when utter ignorance is considered, there is no other information; conversely, when looking at a systematic contribution, important information is available, i.e., the systematic behavior of the contribution itself. This additional information should be carefully considered when modeling the measurement process.

Consider the following simple example. Let w_1 and w_2 be two measurement results for the same quantity, such as the weight of an object obtained by the method of double balancing using a balance bridge. The final result of the measurement is said to be obtained as the average of w_1 and w_2. Assume that there is no random contribution, but only a contribution of a different nature, whose possible values are within $\pm$ 100 g. Two cases can be considered:

Case I: No additional information is available for this contribution to the uncertainty, so it must be considered completely ignorant. In this case, the following applies: and the uncertainty associated with the result is the same as the original uncertainty.

$$w = \frac{w_1 \pm 100g + w_2 \pm 100g}{2}$$

$$\Rightarrow w = \frac{w_1 + w_2}{2} \pm 100g$$

Case II: The additional information available suggests that the cause of the uncertainty is the different lengths of the two weighbridge beams. In this case, given the available information about this contribution to the uncertainty, we know that it affects w_1 and w_2 of the same absolute value. Contribution can therefore be described as systematic, as following:

$$w = \frac{w_1 \pm 100g + w_2 \pm 100g}{2}$$

$$\Rightarrow w = \frac{w_1 + w_2}{2}$$

and the final result of the measurement has an associated uncertainty of zero because, in the arithmetic mean, the contribution under consideration is offset.

This simple example demonstrates the importance of using all available information when modeling a measurement process. Indeed, if additional information about the reason for the system behavior is not taken into account, the measurement uncertainty of the final result will be overestimated.

Fuzzy variable: Thus, it can be said, also from a mathematical point of view, that a systematic contribution is a special case of complete ignorance, where additional information is added. If this additional information is provided, together with the reasons for the presence of the system contribution itself, this information can sometimes be used to convey the appropriateness and accuracy of the information. Measurement is not guaranteed through the measuring process, as in the case of a dual balance with a weighbridge. The goal of this chapter is to find a mathematical object capable of representing complete ignorance and its specific cases.

When probability theory is considered to solve the problem of incomplete knowledge, the total ignorance is represented by a random variable with a uniform probability distribution within the estimated confidence interval. However, this assumption is incompatible with the concept of complete ignorance. In fact, let us first consider the general case of complete ignorance. In this case, by definition, no assumptions can be made about the actual probability distribution, and all probability distributions are, in theory, possible. Therefore, assuming a uniform probability distribution means arbitrarily adding information that is not available. Let us now consider the special case of a systemic effect. In this case, by definition, a single unknown value has a 100% probability of occurring, while all other values have a zero probability. Therefore, assuming a uniform probability, which implies that all values in a given interval have the same probability of occurring, leads to misinterpretation of the available information. Of course, assuming any other probability distribution leads to similar considerations. It can therefore be concluded that probability theory and random variables cannot represent incomplete knowledge, whenever this is due to uncertain effects that are not explicitly random. Therefore, different mathematical variables must be considered for this purpose. In the second half of the twentieth century, fuzzy variables were introduced to represent incomplete knowledge. This approach is less well known than the statistical approach, and it is not included in current standards; therefore, an entire chapter is devoted to this approach.

Definition of Fuzzy Variables

Fuzzy variables and fuzzy units were extensively used, within the remaining decades, specifically within the field of automated controls, after Zadeh brought the fundamental concepts of fuzzy common sense and approximate reasoning [Z65]-[Z73]-[Z75]-[Z78]. In the conventional mathematical approach, a variable might also additionally best belong or now no longer belong to the set into which it is miles defined. The characteristic describing the club of this sort of crisp variable to its appertaining set can consequently take best the price 1, if the variable belongs to the set, or zero, if the variable does now no longer belong to the set.

When fuzzy variables and fuzzy units are taken into consideration, the characteristic describing the club of a variable to its appertaining set is permitted to take all values within the $0 - 1$ interval. This method shows that the referential set $\mathcal{R}$ of the actual numbers, a fuzzy variable X is defined with the aid of using its club characteristic $\mu X(x)$, in which $x \in \mathcal{R}$. The club characteristic of a fuzzy variable satisfies the subsequent properties:

$$0 \leq \mu X(x) \leq 1$$

(i) $\mu X(x)$ is convex.
(ii) $\mu X(x)$ is normal (this means that at the least one detail x usually exists for which $\mu X(x) = 1$).

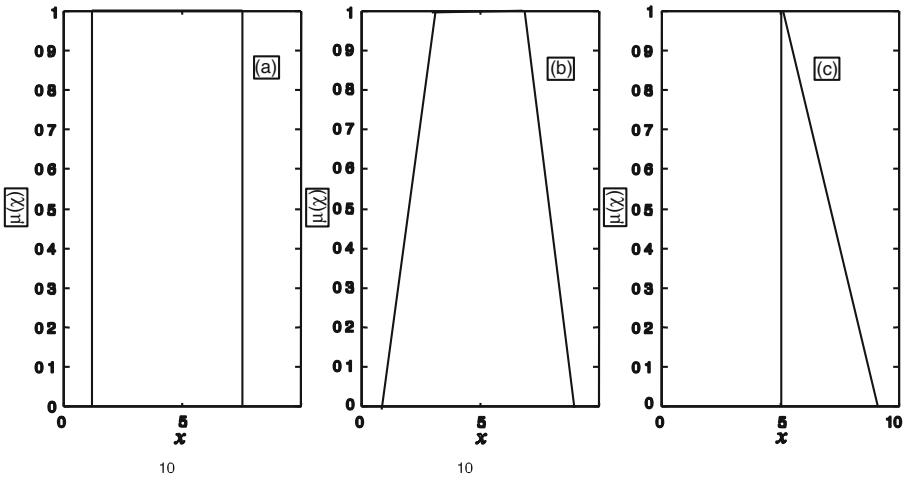

Fig. 10 Example of membership functions: (**a**) rectangular, (**b**) trapezoidal, and (**c**) triangular

Figure 10 indicates a few examples of club capabilities: the square one, the trapezoidal one, and the triangular one. Of course, different shapes are allowed, which do now no longer want to be symmetric. Moreover, club capabilities, that is, best growth or best lower, qualify as fuzzy variables and are used to symbolize the idea of "huge number" or "small number" within the context of every specific application. An instance of this sort of club characteristic is given in Fig. 11.

The club characteristic $\mu X(x)$ of a fuzzy variable may be additionally defined in phrases of α-cuts at different vertical degrees α. As the club characteristic of a fuzzy variable ranges, with the aid of using definition, among zero and 1, its α-cuts are defined for values of α among 0 and 1.

Each α-cut at generic level α is defined as

$$X_\alpha = \{x/\mu X(x) \geq \alpha\} \tag{20}$$

According to Equation (20), every α-cut defines in an interval $[x_1{}^\alpha, x_2{}^\alpha]$, in which it is far usually $x_1{}^\alpha \leq x_2{}^\alpha$. The equality of $x_1{}^\alpha$ and $x_2{}^\alpha$ may be reached simplest for $\alpha = 1$ and simplest if the club feature has a unmarried height cost, for instance, within the case of the triangular club feature stated in Figure 10 (iii). Generally, $x_1{}^\alpha$ and $x_2{}^\alpha$ take finite values; however, in a few cases, as shown in

Figure 11, it may be $x_1{}^\alpha \rightarrow -\infty$ and/or $x_1{}^\alpha \rightarrow +\infty$. If, for any value of α, i t is $x_1{}^\alpha = x_2{}^\alpha$, then the bushy variable degenerates right into a crisp variable. An instance of α-cut, for stage $\alpha = 0.3$, is given in Figure 12.

The significance of representing a fuzzy variable in phrases of its α-cuts is that the α-cuts of a fuzzy variable and the corresponding degrees α may be taken into consideration as a fixed of periods of confidence and related degrees of certitude. The stage of certitude consists of data approximately how sure someone is ready its expertise. If someone, for instance, recollects precisely the birthday of a friend, his

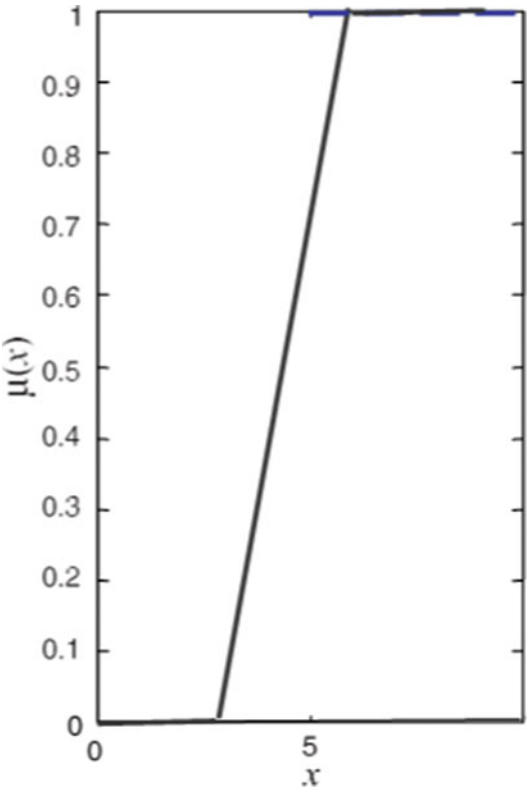

Fig. 11 Membership function describing the fuzzy statement 'more than 5

expertise is sure; however, if he simply recollects the month, however now no longer the day, the knowledge of his expertise is lower. In the first case, the available expertise may be represented through a crisp cost, that is, the precise day of the year (March, 16th); within the 2d case, the available expertise may be represented through a fixed, which includes the 30 days of March. Hence, as the extent of certitude increases, the width of the corresponding confidence c language decreases. As truly proven through the preceding instance, the hyperlink among the extent α of certitude and the confidence c language on the identical stage corresponds to the natural, regularly implicit, mechanism of human wondering within the subjective estimation of a cost for a measurement. The following instance suggests how a fuzzy variable may be built, beginning from the data, or private idea, of one, or greater human beings. Let us take into account once more the birthday of a friend, who is Shyam. Ram is positive that Shyam's birthday is March 16th; John is not so positive approximately about the date, despite the fact that he recollects nicely that the birthday falls in April. From a mathematical factor of view, the c language of confidence envisioned through Ram is [March 16, March 16], while the c language of confidence envisioned through Kesav is [March1, March 30]. The degrees of certitude related to the two periods are 1 and 0, respectively.

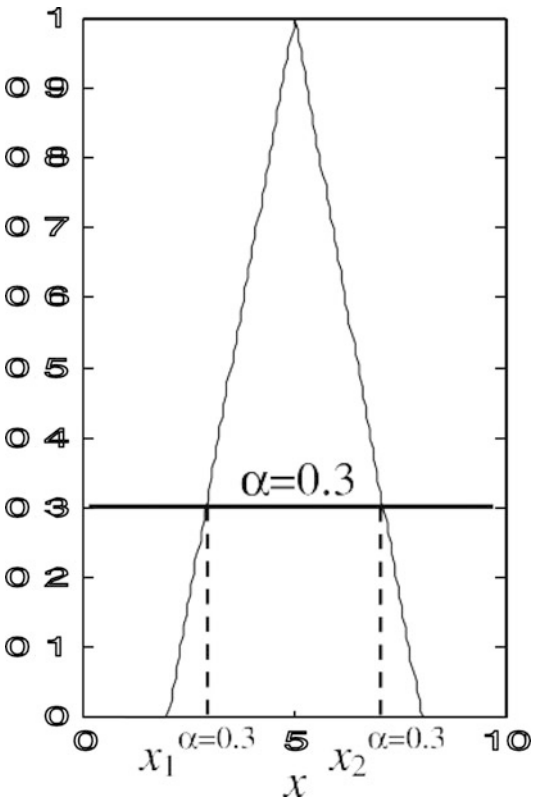

Fig. 12 α-Cut of a triangular membership function for level $\alpha = 0.3$

If now a fuzzy variable needs to be related to the available data, the subsequent applies. Let us think the simplest available data is from Ram. In this case, the available data may be represented through a crisp cost. In fact, on this case, complete actuality is given.

The following instance indicates how a fuzzy variable may be built, beginning from the statistics, or private idea, of one, or extra human beings. Let us recollect once more the birthday of a friend, who is Sharan. Tarun is certain that Sharan's birthday is May 12th; Jagan is not always so certain approximately about the date, even supposing he recollects nicely that the birthday falls in May. From a mathematical factor of view, the c programming language of self-belief expected with the aid of using Tarun is [May 12, May 12], while the c programming language of self-belief expected with the aid of using Jagan is [May2, May 24]. The degrees of certitude related to the two periods are 1 and 0, respectively. If now a fuzzy variable needs to be related to the available statistics, the subsequent applies. Let us think the hardiest available statistics is from Tarun. In this case, the available statistics may be represented with the aid of using a crisp value. In fact, on this case, complete fact is given. Let us now think the hardiest available statistics is from John. In this case, the

available statistics may be represented with the aid of using a square fuzzy variable, just like the one in Fig. 10a. However, it is also viable to mix the statistics given with the aid of using Tom and Jagan. As the extent of certitude related to Jagan's c programming language is 0 and people related to Tarun's c programming language is 1, those periods may be taken into consideration because of the α-cuts of the bushy variable, which represents Sharan's birthday, at degrees of α 0 and 1, respectively. Since, as the extent of certitude will increase, the c programming language of self-belief turns narrower, the bushy variable may want to be, for instance, triangular, just like the one in Fig. 10c. This easy instance additionally indicates, in an intuitive way, a courting between the extent of certitude and the extent of self-belief, which, in accordance to the theory of uncertainty, ought to continually be related to a c programming language of self-belief. The degree of certitude suggests how an awful lot someone is certain approximately a positive event. If, for instance, the instance of Sharan's birthday is considered once more, because of this the surer someone is set the birthday's date, the smaller is the estimated variety of days. On the opposite hand, the extent of self-belief suggests the possibility of a positive event. Therefore, considering the identical instance of Sam's birthday, the smaller the given variety of days, the smaller the possibility that Sam's birthday falls inside the ones dates. If the hardiest one date is given, the possibility that it is precisely Sharan's birthday is 0, as additionally proven with the aid of using Eq. (19). In different words, despite the fact that the extent of certitude will increase because the width of the self-belief c programming language decreases, the alternative applies to the degrees of self-belief. Hence, the degrees of self-belief identical to at least 1 and 0 are assigned to periods [May 2, May 24] and [May 12, May12], respectively. Moreover, intuitively, it is able to additionally be assessed that, given the self-belief c programming language at degree α, the related degree of self-belief is 1. α1[FS03, FGS04, FS04, FS05a, FS05b, FS05c].

The use of fuzzy variables within the context of size uncertainty is mainly interesting, if we do not forget that the maximum beneficial manner to specific end result of a size is in phrases of self-assurance periods, and "the precise approach for comparing and expressing size uncertainty has to be capable of conveniently supplying the sort of self-assurance interval" [ISO93]. Therefore, it could be said that a fuzzy variable may be correctly hired to symbolize the result of a size, as it affords all available statistics approximately the end result itself: the self-assurance periods and the related degrees of self-assurance. The true size exercise additionally calls for that the uncertainty of a size end result is immediately usable as an element in comparing the un-actuality of some other size wherein the primary end result is used [ISO93]; that is, size uncertainties should be composed among every other. Thus, mathematics operations among fuzzy variables need to be defined that allows you to make sure that fuzzy variables are capable of propagating size consequences and associated uncertainties.

Conclusion

This chapter gives an overview of measurement uncertainty analysis, with a focus on modeling. It is observed how the measurement modeling is vital for data processing and uncertainty calculations. It is also observed how these models are valuable in other ways. Both describe the measurement process and can be used as a tool for understanding, refining, and implementing it. They can provide insight into the strengths and weaknesses of a measurement process and suggest ways to improve it. Measurement models must be documented, and the documentation must be kept up to date. Words must be specified properly, and assumptions about influence quantities must be recorded. All too frequently, these subtleties are glossed over or completely ignored. The validity of a measurement model will frequently be scrutinized in accredited quality assurance environments, and adequate evidence to support a model will be necessary. Model documentation should be written in a way that other metrology professionals who are not necessarily experts in the field may understand it.

Abstract

Reliability of measurement data is particularly important in today's world of globalization and trading across international borders. The acceptable and meaningful way of expressing the measurement result is to give the average value along with a range called measurement uncertainty at a confidence level within which the true value shall lie. Measurement uncertainty has specifically gained more importance with emphasis on decision rule as the decision-making criteria

Introduction

Measurement is an important activity when talking about problem-solving, quality, monitoring, or safety and in design and assembly to make something fit. Reliability of measurement data becomes even more important in today's world of globalization and trading across international borders. Manufacturers seeking an international market would like their product parameters to be acceptable everywhere around the globe. This is where testing and calibration results play an important role. The way these results are expressed shows confidence in the measurement (Aswal 2020; Grabe 2018; Leach and Smith 2018; Magas 2019; Chrysochoos and Surrel 2013).

It is a general practice to take multiple readings for a given measurement, and in almost all cases, it would be found that each reading is not identical. It is known that a measurand has a unique true value. Choosing one of the multiple values as the correct one becomes the next question since each value has been measured under generally the same circumstances of environmental conditions, test method, equipment, and personnel skills. The average (mean) value is generally an acceptable answer to the value of measurand among the multiple readings found. It is assumed that the true value is spread around this average value since the true value itself cannot be determined. The acceptable, meaningful way of expressing the measurement result is to then give the average value with a range that hovers around this value within which the true value shall lie. This range is called measurement uncertainty which has a stated confidence level based on a scientific data management system of statistical analysis (White 2008; Tosello and De Chiffre 2004; Rab and Yadav 2022). The details of the measurement uncertainty and different approach for its quantification are discussed in the subsequent sections.

Uncertainty of Measurement

In metrology (measurement science), uncertainty of measurement (UoM) plays an important role in the area of testing and calibration since it shows the limits around the average value where the true value will lie and also the confidence level of these limits. These limits can be a deciding factor for accepting or rejecting a given sample for its measurement value reported. This has specifically gained more importance with emphasis on decision rule as decision-making criteria for this purpose in ISO 17025: 2017 (Bell 2001; Rab et al. 2019; Yadav 2007). The measurement result is expressed as the following:

$X \pm MU$ at y% of confidence level

where X is the measurement value and MU is the measurement uncertainty value associated with the measurement value at a confidence level of y (%). The confidence level gives the probability with which the true value will lie in the given interval.

For example, the value of the initial setting time of a cement sample determined using test method IS 4031 (Part 5) is 125 min, and measurement uncertainty of 5 min is associated with this measured value at a 95% confidence level. Hence, the measurement result will be expressed as follows:

125 min $\pm$ 5 min at 95% confidence level

Law of propagation of uncertainty (LPU) takes into account the propagation of uncertainties of various variables involved in determining a measurand into its measurement uncertainty. Different observers, instruments, samples, laboratories, and times at which observations are made, say different days are sources of variation or uncertainty in the value of measurand.

Although determining measurement uncertainty is based on systematic statistical analysis, it also involves sound scientific, technical knowledge, and judgment of the product under consideration. Such knowledge is important to decide which factors related to the test/calibration method would contribute to the measurement uncertainty of the reported value. Any mistake in the evaluation of MU would mean wrong decisions and interpretations and may lead to acceptable items getting rejected or rejected items getting accepted. Hence, it is important for laboratory personnel to have knowledge in statistics apart from expertise in their field of testing and calibration. Correct understanding and implementation of UoM is important for down-to-earth decision-making rather than just using the concept in a blindfolded stereotype routine manner.

Internationally, there are three basic approaches for evaluating UoM, namely, GUM Method, Monte Carlo simulation, and Bayesian Method. The GUM Method known as the Classical Method is the most popular but is based on many simplistic assumptions for its basic formulation. But it has limitations when talking about advanced measurement techniques (Rab et al. 2019; Kirkup and Frenkel 2006; Elster

2014). In this study, we shall be discussing the traditional GUM Method and other advanced techniques such as Monte Carlo and Bayesian methods.

GUM Method Based on LPU Approach

In 1980, the CIPM Recommendation INC-1 suggested that measurement uncertainty components should be grouped into two categories: type A and type B. This categorization has also been adopted in the GUM publication (Bich et al. 2006).

Type A uncertainty is evaluated using statistical methods on a number of repeated observations. This type of uncertainty is based on the central limit theorem which states that the distribution of an average tends to be normal, even when the distribution from which the average is computed is decidedly not normal. The concept is applied to the evaluation of type A uncertainty by calculating the mean value of a given set of repeated readings and its standard deviation. Now, this standard deviation represents the scatter of data around that mean value which is the measurement uncertainty. Type B uncertainty is evaluated for those factors where repetitive data is not available, but a full-width range of maximum and minimum values is available. Generally, three types of data distributions are considered for type B uncertainty: rectangular, triangular, and u-shaped. The details of all these distributions are further discussed in this section. Measurement uncertainty for type B is calculated by dividing the range with divisor typical of the type of distribution attributed to the factor under consideration (Forbes 2012; Cox et al. 2003; Singh et al. 2020).

The section will further focus on the systematic evaluation of the divisors of type B measurement uncertainty using the integration method (section "Integration Method for the Evaluation of Type B Measurement Uncertainty") and numerical statistical data analysis method (section "Numerical Statistical Data Analysis for the Evaluation of Type B Measurement Uncertainty").

Integration Method for the Evaluation of Type B Measurement Uncertainty

Testing or calibration involves the generation of measurement data using methods wherein uncertainty is introduced due to various factors such as the skill of the personnel involved, instruments used, etc. Since the contribution of some factors varies each time the test is performed, the procedure is kind of random.

A random variable is linked to observations in the real world, where uncertainty is involved. Its numerical value is determined by a procedure that is random. Unlike the general variables we see in everyday mathematics like a quadratic equation, we cannot say what the observed value of the random variable is until we carry out the random procedure. Random variables have distributions defining the possible outcomes of the variable from the random procedure. The mathematical function used

to describe the probability of the occurrence of each value of the discrete random variable is called its probability distribution function (pdf). There are about 19 types of data distributions in statistics. The probability distributions used for estimating measurement uncertainty are the following:

1. Normal
2. Rectangular
3. Triangular
4. U-shaped

The mean can be considered as a measure of the central location of the random variable in the distribution. It is the weighted average of the values that the variable can take, with weights provided by the probability distribution. The mean is also called the expected value since we would like the long-run average of the random variable to approach the mean value. Along with the mean, another important aspect to consider is the spread of the distribution which defines the concentration of the values of the random variable around the mean. The closer the values to the mean, the smaller would be the spread, whereas the spread would be larger if there are more chances of observing the values of the variable away from the mean. This is called the variance which is a way of determining the degree to which the values of the random variable differ from the expected value.

For a discrete random variable, the variance is calculated by summing the product of the square of the difference between the value of the random variable and the expected value along with the associated probability distribution function, taking over all the values of the random variable which implies integration over the infinity range. This can mathematically be expressed as Eq. (1):

$$\sigma^2 = \int_{-\infty}^{\infty} f(\varepsilon)(\varepsilon - \mu)^2 \, d\varepsilon \tag{1}$$

where σ^2 is the variance for the random variable ε having mean μ and $f(\varepsilon)$ as the probability distribution function (pdf).

In other words, the variance is the weighted average of the squared deviations from the mean, where the weights are given by the probability density function.

When considering error distribution, the mean is taken as zero and Eq. (1) reduces to Eq. (2).

$$\sigma^2 = \int_{-\infty}^{\infty} f(\varepsilon)\varepsilon^2 \, d\varepsilon \tag{2}$$

Standard deviation is another closely related measure to the variance and is calculated as its square root. Now, we will determine the measurement uncertainty for some commonly used distribution patterns which are typical to type B measurement uncertainty.

Uniform Distribution

Continuous uniform distribution or rectangular distribution is a family of symmetric probability distributions. The distribution describes an experiment where there is an arbitrary outcome that lies between certain bounds and has constant probability. The rectangular distribution is the most commonly used probability distribution in uncertainty analysis since it covers the majority of uncertainty factors when it is unsure how the data is distributed. In such a scenario, it is best to evaluate it conservatively as uniform distribution.

This type of distribution is typical for the error in instruments. Since the same value of error can go in both the positive (+) and the negative (−) range, it can be depicted as Fig. 1.

The variance for uniform distribution having lower limit as "$-a$" and upper limit as "a" can be determined as follows using Eq. (2). The pdf is $1/[a-(-a)]$ within these limits and 0 otherwise:

$$\sigma^2 = \int_{-a}^{a} f(\varepsilon)\varepsilon^2 \, d\varepsilon = \frac{1}{2a}\int_{-a}^{a} \varepsilon^2 \, d\varepsilon = \frac{1}{2a}\frac{\varepsilon^3}{3}\Big|_{-a}^{a} = \frac{a^2}{3}$$

$$\text{Standard deviation,} \quad \sigma = \frac{a}{\sqrt{3}} \tag{3}$$

Eq. (3) is the measurement uncertainty for the measurement data having rectangular distribution.

Triangular Distribution

The triangle distribution is a probability distribution with known minimum, maximum, and estimated central value. It is generally used where relationship between variables is known but data is scarce and is called lack of knowledge distribution. The distribution is also used where the data collection is difficult or expensive.

This type of distribution can be attributed as an example to the temperature of a laboratory where thermostat and PID controller are installed, and the temperature value is always trying to achieve a set target. The value would float around this set target and rarely reach the threshold limits (Elster 2014). So, we know the limits and

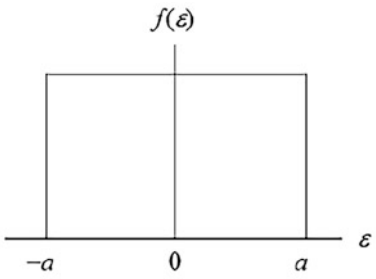

Fig. 1 pdf $f(\varepsilon)$ of uniform distribution of random variable ε having bounding limits $\pm a$ and mean as 0

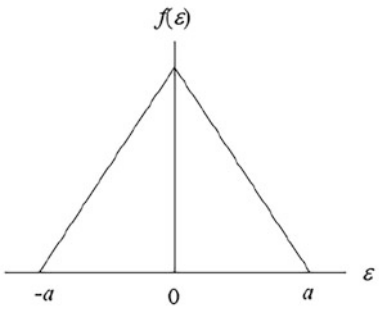

Fig. 2 pdf $f(\varepsilon)$ of triangular distribution of random variable ε having bounding limits $\pm a$ and mean as 0

the estimated mean, but we are unsure how the data is distributed between these points as in Fig. 2.

The pdf $f(x)$ for triangular distribution for a variable "ε" having lower limit as "$-a$," upper limit as "a," and central value as "0" is given by Eq. 4 (Magas 2019):

$$f(x) = \begin{cases} 0, & \varepsilon < (-a) \\ \dfrac{2\,[\varepsilon - (-a)]}{[a - (-a)][0 - (-a)]}, & -a \le \varepsilon \le 0 \\ \dfrac{2\,(a - \varepsilon)}{[(a - (-a)][(a - 0)]}, & 0 \le \varepsilon \le a \\ 0, & \varepsilon > a \end{cases} \tag{4}$$

The variance for the triangular distribution in Fig. 2 can be determined as follows using Eq. (2) and the above pdf as defined in Eq. (4) for the given distribution:

$$\sigma^2 = \int_{-a}^{a} f(\varepsilon)\varepsilon^2\, d\varepsilon = \frac{1}{a^2}\int_{-a}^{0} (a+\varepsilon)\varepsilon^2\, d\varepsilon + \frac{1}{a^2}\int_{0}^{a} (a-\varepsilon)\varepsilon^2\, d\varepsilon = \frac{2}{a^2}\int_{0}^{a} (a-\varepsilon)\varepsilon^2\, d\varepsilon = \frac{a^2}{6}$$

$$\text{Standard deviation,}\quad \sigma = \frac{a}{\sqrt{6}} \tag{5}$$

Eq. (5) is the measurement uncertainty for the measurement data having triangular distribution.

The U-Shaped Distribution

The U-shaped distribution is a probability distribution for outcomes likely to occur at the extremes of the range. The distribution is useful for specifying sinusoidal phase-varying subject parameters. This type of distribution can be attributed as an example to the temperature of a laboratory where thermostat is installed, but there is no PID controller. The thermostat will try to control the temperature only when it reaches the extremes. So, we know the limits and the estimated mean, but we are unsure how the data is distributed between these points as shown in Fig. 3.

The variance for the U distribution in Fig. 3 can be determined as follows using Eq. (2) and the pdf as $1/\pi\sqrt{(a^2-\varepsilon^2)}$ for $-a < \varepsilon < a$ and 0 otherwise (Rab et al. 2019):

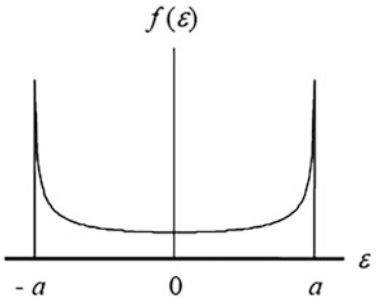

Fig. 3 pdf $f(\varepsilon)$ of U distribution of random variable ε having bounding limits $\pm a$ and mean as 0

$$\sigma^2 = \int_{-a}^{a} f(\varepsilon)\varepsilon^2 \, d\varepsilon = \frac{1}{\pi}\int_{-a}^{a} \frac{\varepsilon^2}{\sqrt{a^2-\varepsilon^2}} \, d\varepsilon \quad = \frac{1}{\pi}\left(-\frac{\varepsilon\sqrt{a^2-\varepsilon^2}}{2} + \frac{a^2}{2}\sin^{-1}\left(\frac{\varepsilon}{a}\right)\right)\Big|_{-a}^{a}$$

$$= \frac{1}{\pi}\frac{a^2}{2}\pi = \frac{a^2}{2}$$

$$\text{Standard deviation,} \quad \sigma = \frac{a}{\sqrt{2}} \tag{6}$$

Eq. (6) is the measurement uncertainty for the measurement data having U distribution.

For all the above three distributions, it may be noted that for the standard deviation determined, "a" in the numerator can be easily expressed in the terms of the range of distribution which is "$2a$"s as range/2. Based on the integration method, Table 1 shows the values of divisors to the range of data which are used for calculating type B measurement uncertainty.

Numerical Statistical Data Analysis for the Evaluation of Type B Measurement Uncertainty

Another way to determine the type B measurement uncertainty is by calculating the standard deviation of the given data sets of "n" observations. For this section, it has been done using the various statistical data analysis tools and functions available in Microsoft Excel. "n" number of random numbers have been generated for observations of the various distribution patterns individually. The standard deviation is then calculated using the function STDEVP. To generate histograms for each distribution, Sturges Rule (1+ 3.3 log n) has been applied to calculate the number of groups or classes. This range (maximum observation-minimum observation) can further be divided by the number of classes to get the class interval. Starting from the minimum observation and adding a class interval to each subsequent value, the histogram bins can be evaluated. The data can then be used to generate the histogram using data analysis tools. A histogram is a graphical representation used to understand how numerical data is distributed. The height of the bars indicates how frequently the outcome it represents occurs. As shown in Table 1, standard deviation can be

Table 1 Divisors for type B measurement uncertainty for data distributions using integration method

Distribution		Standard deviation expressed as range/divisor	Divisor
	Rectangular	$2a/(2\sqrt{3})$	$2\sqrt{3}$
	Triangular	$2a/(2\sqrt{6})$	$2\sqrt{6}$
	U-shaped	$2a/(2\sqrt{2})$	$2\sqrt{2}$

expressed as range/divisor. This concept can be applied to calculate the divisors using the standard deviation and range obtained by statistical analysis. The same has been computed in Table 2 for rectangular, triangular, and U-shaped distributions.

The divisors for type B uncertainty have been calculated by both integration method and numerical statistical analysis in Tables 1 and 2. This provides a better understanding of the divisors used for the particular calculation in the LPU method. For very expensive data or complex functions which are not necessarily linear, the error propagation may be achieved with a surrogate model, say based on Bayesian probability theory and other advanced theories such as Monte Carlo simulation which are further discussed in the subsequent sections.

Monte Carlo Simulation (MCS) Approach

The way to estimate measurement uncertainty known as Monte Carlo simulation (MCS) involves setting up a model equation for the measurement in function of each individual parameter of influence, selecting the significant sources of uncertainty,

Table 2 Divisors for type B measurement uncertainty for data distributions using numerical statistical analysis

Distribution		Divisor = range/Std deviation
	Rectangular	$3.47 \approx 2\sqrt{3}$

No. of observations	Minimum value	Maximum value	Range	Standard deviation
10,00,000	25	26	1	0.29

	Triangular	$4.85 \approx 2\sqrt{6}$

No. of observations	Minimum value	Maximum value	Range	Standard deviation
10,000	40.0000	49.8895	9.89	2.04

	U-shaped	$2.83 \approx 2\sqrt{2}$

No. of observations	Minimum value	Maximum value	Range	Standard deviation
10,000	4.00000	6.00000	2.00	0.71

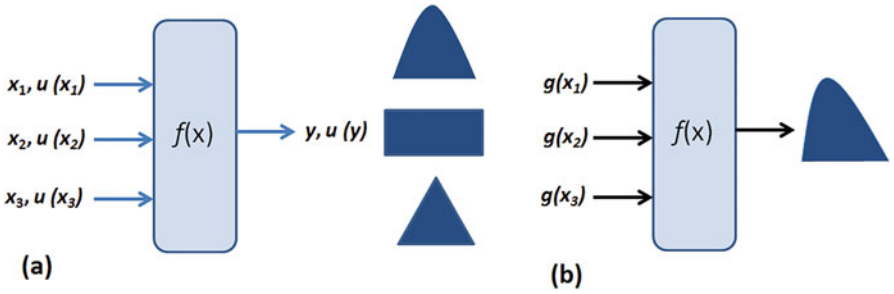

Fig. 4 (**a**) Uncertainty propagation (**b**) Probability density function (PDF) propagation

identifying the probability density functions corresponding to each source of uncertainty selected, and choosing the number of Monte Carlo simulations to be used (Garg et al. 2019; Singh et al. 2019, 2021a; Moona et al. 2021).

An illustration of the distribution of uncertainties is shown in Fig. 4 (a). In this case, three input quantities – x_1, x_2, and x_3 – as well as the corresponding uncertainty for each of them, $u(x_1)$, $u(x_2)$, and $u(x_3)$. As can be seen, the propagation simply uses the input quantities' main values (expectation and standard deviation). When probability density function (PDFs) in Fig. 4 (b), complete information included in the input distributions is propagated to the output without any approximations.

Software for generating random numbers is a prerequisite for using MCS. The period of the numbers generated in this way should be as large as feasible. This period is normally in the order of one billion, which is typically sufficient for a vast majority of applications (Singh et al. 2021b; Elizabeth et al. 2019).

Numerous domains, including metrology, reliability engineering, risk analysis in finance, physical chemistry, nuclear and particle physics, probabilistic design, statistical physics, quantum physics, and others find extensive use for MCS.

As previously discussed, JCGM 101:2008, the GUM supplement 1, and its discussion of uncertainty estimation provide the necessary instructions for the use of MCS in the assessment of measurement uncertainties in metrology. In order to reduce measurement uncertainties, the Monte Carlo simulation has recently been used widely to estimate measurement uncertainty for a variety of measurement challenges, particularly for apex level standards in National Metrology Institutes.

Recent studies discuss the advantages and disadvantages of several guides for estimating uncertainty, including JCGM 100 and JCGM 101, and the main advantages and disadvantages of various methodologies are listed. There are two main approaches to MCS: fixed and adaptive. The latter uses adaptive trial selection, where the trials proceed until the various findings of value are sufficiently Monte Carlo simulation (MCS) stabilized. The former uses a set number of trials, where the number of trials is chosen prior to or before simulation. Therefore, MCS can be classified into two categories: fixed Monte Carlo simulations and adaptive Monte Carlo simulations, depending on the approach used to choose the number of trials. Based on a review of various studies, Table 3 highlights the strengths, weaknesses, opportunities, and threats related (Garg et al. 2019).

Table 3 Analysis of the Monte Carlo simulation (MCS) method's strengths, weaknesses, opportunities, and threats (SWOT) for evaluating measurement uncertainty

Strengths	Weaknesses	Opportunities	Threats
The MCS approach provides for the calculation of uncertainty when the input quantities have complex distributions, such as asymmetric or U-shaped distributions, etc. There is no need to compute partial derivatives, simplifying the measurement model, committing simplification in calculations The effective degree of freedom does not need to be estimated The distribution of measurand is not presumptive in nature A coverage interval corresponding to a specified coverage probability is provided by the MCS method	A good random number generator and the necessary software are required. Less than 2×10^5 random numbers may give erroneous results Using MCS, obtaining the sensitivity coefficients is challenging Due to a lack of information on the physical/chemical process, it may sometimes be challenging to choose the proper PDF for specific input values Due to the variable random numbers generated in each simulation, this method could have varying solutions for a particular problem	It is a beneficial alternative to the GUM strategy. The simulations do not use the GUM's approximations since it rely on the propagation of distributions rather than the propagation of uncertainty The MCS technique works effectively when the model exhibits significant nonlinearity The central limit theorem's validity can be verified using MCS method There is no requirement to estimate the effective degrees of freedom and partial derivatives Can accept models with any number of output quantities and nonindependent input quantities	Choosing the incorrect PDF as an input parameter could give ambiguous results The results computed by MCS may not always match those of LPU/GUM when the model equation lacks parameters such as the impact of environmental variables, bias, etc. MCS may be done repeatedly to ascertain the repeatability of the results Problems involving various PDFs other than regular and rectangular distributions require for specialized software tools

Bayesian Approach

In the Bayesian technique, model parameter uncertainties are expressed as probabilities. Before any new data are obtained, parameter uncertainty is first measured by inserting a prior probability distribution, which represents prior information or expert knowledge. Simply, the interpretation of probability as levels of belief is the foundation of the Bayesian approach to statistical analysis. This method uses priors – previous knowledge about the model or hypothesis under investigation – along with data from sampling and Bayes' rule to draw conclusions. The Bayesian approach's key distinction between data and sought-after model or hypothesis parameters is that the latter is supposed to be random variables, whereas the former is fixed known numbers. The outcomes of Bayesian analyses are posteriors, which are probability distributions. Modern uncertainty evaluation approaches would

advance the Bayesian method for measuring measurement uncertainty. The uncertainty evaluation approach would completely combine the prior and the current sample information since it is based on Bayesian information fusion. In order to achieve both the evaluation and updating of uncertainty, the prior distribution is determined by the historical data, and the posterior distribution is derived by combining the prior distribution with the current sample data and the Bayesian model (Abdar et al. 2021; Harakeh et al. 2020; Ovadia et al. 2019; Zadeh et al. 2019). The main advantage of the Bayesian approach over the GUM and Monte Carlo procedures is the inclusion of the prior distributions and the synthesis of the data to produce the posterior distributions (Van der Veen 2018; Elster and Wübbeler 2015). In addition, the Markov Chain Monte Carlo (MCMC) method is used in the Bayesian uncertainty analysis approach's practical numerical implementation (Klauenberg and Elster 2016; Possolo and Bodnar 2018).

Innovations and Other Futuristic Scenario

The conventional methodology of LPU, as specified by JCGM 100:2008, has been successfully applied to evaluate the measurement uncertainty of various metrological problems for decades. However, the LPU approach faced some limitations due to which the MCS and Bayesian methodology have been used by researchers in recent times. In the coming times, these advanced approaches are being extended to solving more complex problems such as real engineering problems represented by partial differential equations (PDE). With adequate modeling of the inputs of PDE and their introduction in the solver, discrete output statistical data can be conveniently processed using the Monte Carlo approach to obtain standard uncertainties for real practicing engineering problems. Advanced techniques such as principal component analysis (PCA) may prove useful for sensitivity analysis of uncertainties influenced by many competing random variables. A PCA approximates a high-dimensional measurement model with a low-dimensional measurement model by considering just the most statistically significant terms and that this method may have future impact to avoid the constraint of dimensionality (Hasan and Abdulazeez 2021; Wu et al. 2018). Exploratory data analysis (EDA) and predictive data mining based on advanced tools of statistical estimation have high utility for the evaluation and control of uncertainty of measurements. Robust regression methods can prove useful for measurements having outlying or anomalous measurements due to their resistance to the presence of such outliers.

Concluding Remarks

For a measurement to be complete, the evaluation of measurement uncertainty is also essential, and it is crucial for preserving the standard and dependability of product development, free trade, innovation, etc. The last few decades have seen a growth in the need for precise measurements with less uncertainty due to scientific and

technical developments. All measurements are subjected to uncertainty which is the expression of the statistical dispersion of the values attributed to a given measured quantity. There are many factors that contribute to this uncertainty. Any measurement result is incomplete without a statement of associated uncertainty such as standard deviation. But the calculation of this measurement uncertainty seems to be misunderstood, and the concept of its evaluation is not truly clear. With a variety of modelling approaches, this chapter provides an overview of measurement uncertainty analysis. The work has also thoroughly explored the measurement uncertainty quantification methodologies, implications, and future prospects.

Notations

X: Measurement value
MU: Value of measurement uncertainty associated with measurement value X
y: Confidence level associated with measurement result expressed in terms of X and MU
ε: Value of random variable
μ: Mean of the random variable ε

Abstract

Several instruments are available in the market for the accurate and precise measurement of pressure. Due to numerous influencing elements and the lack of a well-defined mathematical model, calculating the uncertainty in the category of electromechanical pressure transducers has long been a laborious task for researchers. The "Guide to the Expression of Uncertainty in Measurement (GUM)" and "Guidelines on the Calibration of Electromechanical Manometers (Calibration Guide EURAMET/Version 4.1)" are the main directional guides for harmonizing the method of evaluation of measurement uncertainty associated with pressure measuring instruments. The present chapter describes the various uncertainty estimation models developed for the evaluation of measurement uncertainty associated with the electromechanical type of pressure transducers.

For the evaluation of the measurement uncertainty of such pressure measuring equipment, a thorough comparative study using Least Square Fitting (LSF), Monte Carlo simulation (MCS), and EURAMET approach is presented. It is shown through an example of a case study on a digital pressure transducer (DPT) up to the pressure range of 800 MPa. The results obtained using three different approaches are in excellent agreement and quite comparable, allowing us to assess the viability and practical applicability of these modern techniques.

Introduction

High-pressure technology has been used rapidly and steadily in science and engineering over the past few decades, which has drawn interest from researchers looking for better equipment and technologies with lower measurement uncertainties across a variety of applications (Mao et al. 2016; Rab et al. 2019a, 2022a, b; Sabuga et al. 2017). This makes it evident that the challenge of calibration and traceability for the equipment utilized is being addressed through the development of new and advanced measurement techniques and standards. The value obtained by a measuring device is compared to a standard whose accuracy is known and traceable to National/International standards in a calibration technique (Meškuotienė et al. 2022; Rab and Yadav 2022). A quantitative result's format and the information it conveys are both influenced by concepts like measurement uncertainty, traceability, and numerical significance. Due to the error-prone nature of all measurements, it is sometimes claimed that a measurement result is only complete when it is accompanied by a quantitative estimate of its uncertainty. This uncertainty analysis is necessary to determine whether the result is sufficient for the intended use and to determine whether it is consistent with comparable or earlier outcomes. The Evaluation of Measurement Data: A Guide to the Expression of Uncertainty in Measurement (also known as, GUM) offers broad guidelines for assessing and expressing measurement uncertainty (BIPM, IEC, IFCC, ISO, IUPAC, IUPAP, and OIML 2008, 2010; Guidelines on the Calibration of Electromechanical and Mechanical Manometers 2022; Guidelines for Estimation and Expression of Uncertainty in Measurement 2020).

Uncertainties in the input quantities will propagate through the calculation to an uncertainty in the output Y when a measurand, Y, is calculated from other measurements using a functional relationship. Most of the mathematical difficulties arise from how these uncertainties spread through a functional relationship. Furthermore, in the case of electromechanically type sensors, the input stimulus to the sensor could be any quantity, property, or situation that transforms into an electrical signal (Fig. 1). Because many of the influencing quantities are uncertain, calculating the calibration values and the related measurement uncertainties using the type A and

type B methods is always a complex and time-consuming process (Rab et al. 2019b; Singh et al. 2021a; Zafer et al. 2022; Türk et al. 2021; Yadav 2007; Yadav et al. 2010a).

The current work demonstrates modern models based on the least square fit line method, the EURAMET approach, and the Monte Carlo method. As a case study to validate the methods given, the chapter covers the uncertainty calculations of a basic, specific example of a digital pressure transducer (DPT) with a range of atmospheric pressure to 800 MPa.

Experimental Setup

In the present case study, the calibration of a DPT is performed against the national hydraulic primary standard, the dead weight tester (DWT). By direct comparison with the standard pressure obtained by the primary national hydraulic pressure standard, the test pressure transducer is calibrated. Figure 2 shows the schematic connection of DWT as the standard and DPT as the testing gauge for the calibration.

A synchronous motor rotated the standard gauge's piston at about 30 rpm while the test gauge was being calibrated. The calibration was carried out in both ascending and descending pressure order. The other procedures and presumptions needed for the calibration process are also available elsewhere. For the calibration, Controlled Clearance Type Piston Gauge (CCPG), a primary pressure standard at CSIR-NPL used as a standard that has a relative measurement uncertainty of 125×10^{-6} (i.e., ± 125 ppm) for pressures greater than 500 MPa and less than 1000 MPa, and a relative uncertainty of 67×10^{-6} (i.e., ± 67 ppm) for pressures below 500 MPa (Fig. 3).

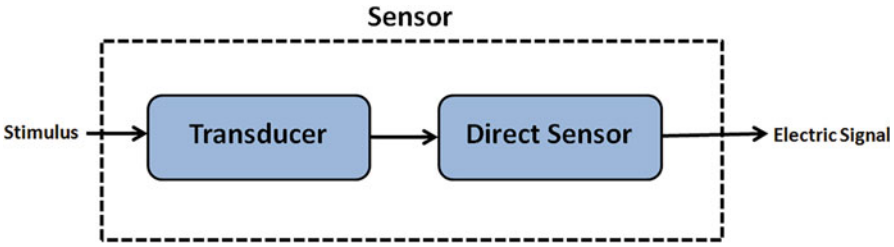

Fig. 1 Sensor schematic with input and output signals

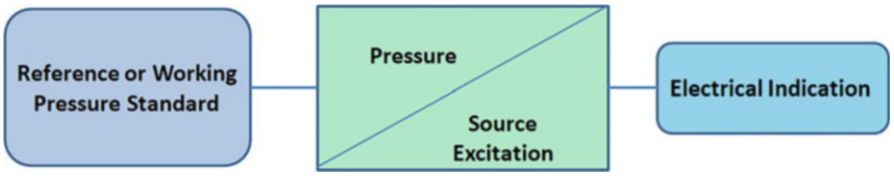

Fig. 2 Schematic connection of DWT and DPT

Fig. 3 Experimental Setup

It is a national primary pressure standard, which in turn is compatible with international standards through participation in international key comparison exercises (Yadav et al. 2007; Dogra et al. 2010; Bandyopadhyay et al. 2006). The measured pressure is then computed using the standard pressure equation after applying all corrections, i.e., air buoyancy, surface tensions, temperature correction, and hydrostatic head correction. The details of the correction and pressure measurements have already been published (Singh et al. 2020; Zafer et al. 2022; Yadav et al. 2002; Yadav and Bandyopadhyay 2009; Rab et al. 2021).

Mathematical Modeling

This section discusses the mathematical modeling for the uncertainty calculation while using a DPT in accordance with the GUM and EURAMET approaches. All the factors that contribute to measurement uncertainty, including experimental and standard factors, are covered in the following sections of the uncertainty calculations.

Mathematical Model of LSF

The GUM depicts the use of the method of least squares to obtain a linear calibration curve (BIPM, IEC, IFCC, ISO, IUPAC, IUPAP, and OIML 2010). It also outlined

how the parameters of fitted line and their estimated variance and covariance are used to obtain the correction value and the standard uncertainty of predicted correction. This method uses the least squares method to fit a curve to the experimental data in order to define the output of a DPT. Let's assume that (x_i,y_i) is a collection of n empirically observed ordered pairs. Using a polynomial, the corrected pressure y is linked to the device's x_i's indication as follows:

$$y = a_0 + a_1x + a_2x^2 + a_3x^3 + a_4x^4 \ldots\ldots + a_mx^m \tag{1}$$

where m is the fitting order for the n sets of observations with the m + 1 constants that need to be assessed. The simplest type of modeling for DPTs is linear regression. The Eq. (1) became (2); when a linear relationship was assumed.

$$y = a_0 + a_1x \tag{2}$$

The standard deviations of the constants a_0 and a_1, are represented by the constants $\sigma(a_0)$ and $\sigma(a_1)$ respectively. The sum of squares of the residual errors divided by the number of degrees of freedom is how the s^2 is obtained. One of the key contributions is the standard deviation of the residual errors between the experimental and fitted values. The following relationship is used to calculate the contribution's value, which is very low and optionally included in the uncertainty budget:

$$\sigma(y_c) = \sqrt{s^2} \tag{3}$$

Finally, the standards uncertainty associated with estimate y for a given value x by linear curve fitting is estimated as follow:

$$u(y_c) = \sqrt{\left[\left(\frac{\delta y}{\delta a_0}\right)\cdot u(a_0)\right]^2 + \left[\left(\frac{\delta y}{\delta a_1}\right)\cdot u(a_1)\right]^2 + 2\left[\left(\frac{\delta y}{\delta a_0}\right)\cdot\left(\frac{\delta y}{\delta a_1}\right)\cdot u(a_0)\cdot u(a_1)\cdot r(a_0,a_1)\right] + [\sigma(y_c)]^2} \tag{4}$$

where $(\delta y/\delta a_0)$ and $(\delta y/\delta a_1)$ are the sensitivity coefficients of a_0 and a_1, evaluated by partial derivations of Eq. (2). Discussions of the extensive mathematical models can be found elsewhere (Rab et al. 2019b; Yadav et al. 2010b; Yadav et al. 2005a, b). Since, $u(y_c)$ is calculated statistically using polynomial curve fitting, its contribution is being assessed using the Type A calculation. However, it is necessary to employ Type B calculation to analyze the uncertainty contribution of the measurement standard. The major uncertainty contributions thus evaluated for DPT by Type B method are discussed in the subsequent sections.

Zero Setting (u_{zero}) Contribution

Zero error is calculated by using the equation:

$$\delta P_0 = \max\{|Z_{2,0} - Z_{1,0}|, |Z_{4,0} - Z_{3,0}|, |Z_{6,0} - Z_{5,0}|, \ldots\ldots |Z_{n,0} - Z_{n-1,0}|\} \quad (5)$$

where $Z_{1,0}$, $Z_{3,0}$, $Z_{5,0}$, $Z_{n-1,0}$ are the zero pressure values recorded at the starting of each pressure cycle while $Z_{2,0}$, $Z_{4,0}$, $Z_{6,0}$, $Z_{n,0}$ are the zero values recorded at the end of each pressure cycle. The following estimations represent the uncertainty contribution to the pressure measurement induced by the zero setting error:

$$u_{zero} = u(\delta P_0) = \sqrt{\frac{\delta P_0}{\sqrt{3}}} \quad (6)$$

Resolution (u_{res}) Contribution

The resolution is defined as its smallest measurement or digit step in case of DPT. The following equations estimate the error due to resolution and its associated uncertainty contribution if "r" is the device's resolution:

$$\delta P_{res} = a = \frac{r}{2} \quad (7)$$

$$u_{res} = u(\delta P_{res}) = \frac{a}{\sqrt{3}} \quad (8)$$

Hysteresis (u_{hys}) Contribution

Hysteresis is the difference between comparable values in the ascending and descending orders of pressures within a pressure cycle. At a specific pressure point, j, the hysteresis is assessed by:

$$\delta P_{hys,j} = \frac{1}{n}\{|x_{2,0} - x_{1,0}| + |x_{4,0} - x_{3,0}| + |x_{6,0} - x_{5,0}| + \ldots\ldots + |x_{n,0} - x_{n-1,0}|\} \quad (9)$$

The maximum value of $\delta P_{hys,\ j}$ is then selected to calculate the uncertainty contribution as follows:

$$\delta P_{hys} = \max\left\{\left|\delta P_{hys,j}\right|\right\} \quad (10)$$

$$u_{hys} = u\left(\delta P_{hys}\right) = \frac{\delta P_{hys}}{\sqrt{3}} \quad (11)$$

Uncertainty Contribution of Reference Standard (u_{B4})

This is an estimation of the standard's measurement uncertainty. In the present case, the relative measurement uncertainty mentioned in the pressure standard's calibration certificate accounts for 125×10^{-6} x P (where, P in MPa) at $k = 1$ for pressure more than 500 MPa range.

Combined and Expanded Uncertainty

Following this, the root sum square of the type A and type B uncertainty contributions is used to calculate the combined standard uncertainty associated with pressure measurement:

$$u_{\text{Test}} = \sqrt{u_A^2 + u_B^2} \tag{12}$$

The expanded uncertainty is then calculated using the Student's table for the value of k at various levels of confidence and the effective degree of freedom:

$$\text{U} = k \,\text{x}\, u_{\text{Test}} \tag{13}$$

Mathematical Model of Monte Carlo Method

Using a variety of probability distributions for the input variables, the Monte Carlo method has been used to determine the probability distribution function of the measurand (Cox and Siebert 2006; Singh et al. 2019, 2021b, c). It is expected that the consideration of the probability distribution contains richer information of a quantity, leading to better estimation of the measurand and their corresponding uncertainty. Having a reliable pseudorandom number generator is a need for the Monte Carlo approach. There are numerous pieces of commercial software that can generate such random numbers. To account for input unpredictability, the number of Monte Carlo trials (or iterations), M, must be carefully set. The standard deviation will drop when M increases and vice versa. Therefore, there is a higher likelihood that results will converge when there are more trials. JCGM 101:2008 provides specific instructions for evaluating measurement uncertainty (BIPM, IEC, IFCC, ISO, IUPAC, IUPAP, and OIML 2008) using Monte Carlo method. Defining the output and input quantities and their model equation are the first two steps in Monte Carlo as same as LSF. The electrical voltage is the output quantity in the present work (DPT), and each of the pressure parameter is the input quantity. As a result, the model equation for the calculations may be written as follows:

$$P_{\text{GUT}} = \left[P_{\text{Std}} + (T_{\text{out}} + m^* c) + \left(T_{hys} + m\right) + \left(T_{rep} + m\right) \pm (T_{res} + m) + (T_{zero} + m)\right] \tag{14}$$

where P_{GUT} is the pressure measured by DPT, P_{Std} is the average pressure obtained by standard. In case DPT, to take into account of uncertainty associated with the standard used, P_{Std} is considered as zero and only standard measurement uncertainty is considered. T_{out} is the digital reading of DPT. m and c considered as slope and constant respectively of the obtained readings. T_{zero} is the zero setting error, T_{hys} is the hysteresis error, and T_{rep} is the repeatability error obtained. Further, if the resolution (T_{res}) is greater than the resolution of GUT, i.e., 0.0002 in the present case, then, $[P_{\text{GUT}} + (T_{res} + m)]$ and if the resolution (T_{res}) is less than 0.0002, then $[P_{\text{GUT}} - (T_{res} + m)]$ is considered.

The following equation is used to determine the number of trials (M) necessary for the 95% confidence level:

$$M = \frac{10^4}{1-p} = 2 \times 10^5 \tag{15}$$

In order to calculate the output P_{GUT}, 2×10^5 random numbers were produced for each of the input quantities. As a result, 2×10^5 values for P_{GUT}, were obtained. The histogram that is generated from these data depicts the actual probability distribution of the output quantity. The average of 2×10^5 random values of P_{GUT} is its estimate; the standard deviation, which is standard uncertainty; and the low and high ends for the 95% coverage interval were also obtained from the histogram.

Mathematical Model of EURAMET Method

According to the document (Guidelines on the Calibration of Electromechanical and Mechanical Manometers 2022), for DPT cases, the indicator error and associated uncertainty are calculated independently for values measured at increasing and decreasing pressure using the sum/difference model. The model equation can be written as follows:

$$\Delta p = p_{\mathrm{indication}} - p_{\mathrm{standard}} + \sum\nolimits_{i=1}^{2} \delta p_i = p_{\mathrm{indication}} - p_{\mathrm{standard}} + \delta p_{zero} + \delta p_{rep} \tag{16}$$

$p_{\mathrm{indication}}$ is taken to remain constant during the various pressure cycles. Corrections will be made in order to bring them to the same value of $p_{\mathrm{indication}}$ if the changes are significant in terms of the resolution of $p_{\mathrm{indication}}$. The mean values of indication are written as follows:

$$\overline{p}_{\mathrm{indication}} = \frac{p_{\mathrm{indication,up}} + p_{\mathrm{indication,dn}}}{2} \tag{17}$$

The contribution of the hysteresis effect must be included when calculating $\overline{\Delta p}$ of the mean indication:

$$\overline{\Delta p} = \overline{p}_{\mathrm{indication}} - p_{\mathrm{standard}} + \sum\nolimits_{i=1}^{2} \delta p_i \tag{18}$$

$$\overline{\Delta p} = \overline{p}_{\mathrm{indication}} - p_{\mathrm{standard}} + \delta p_{zero} + \delta p_{rep} + \delta p_{hys} \tag{19}$$

A further contribution must be added to account for the limited resolution of the indication. Next, for the measurement uncertainty calculation separate analyses of the series at increasing (up) and decreasing (dn) pressures indicate an expanded measurement uncertainty ($k = 2$).

$$U_{\mathrm{up/dn}} = k\sqrt{\left(u^2_{\mathrm{standard}}\right) + u^2_{zero} + u^2_{res} + u^2_{rep}} \tag{20}$$

Results and Discussion

As previously noted, in the article, we investigated a DPT at pressures between 0 to 800 MPa. In this study, we first carried out an experiment to calibrate the DPT with the national hydraulic primary pressure standard (setup shown in Fig. 3). Nine evenly spaced pressure points are used for the calibration, within the range of 0 to 800 MPa. One complete cycle is the progressive increasing of the pressure up to 800 MPa (increasing cycle) and the subsequent decreasing to atmospheric pressure (decreasing cycle), in this way, the experiment was performed for three complete cycles. As a result, we have 54 calibration data for this experiment, for which three distinct methods have been used to compute the uncertainties.

The LSF approach is used to calculate the measurement uncertainty (shown in Table 1). Since u(yc) is calculated statistically using LSF, its contribution is seen as being evaluated through type A uncertainty. In type B uncertainty calculation uncertainties, zero setting and uncertainty contribution by the reference standard is predominate.

In the case of MCM, at first, for each of the input quantities, random numbers were initially produced based on their probability distribution function (PDF). After obtaining of 2×10^5 data for each input quantities, the P_{GUT}, was evaluated using Eq. 15 and is tabulated in Table 2. Thereafter, all values were sorted in ascending order, and histograms were plotted. P_{GUT} was evaluated at each pressure point. The other parameters thus obtained are also presented. The standard uncertainty in the Monte Carlo approach is generated in the form of standard deviation, as stated in section "Mathematical Model of Monte Carlo Method." As can be observed from Table 2, the standard deviation is increasing with the increase of pressure; however, the relative uncertainty is decreasing with increasing pressure. The reason for decreasing relative uncertainty with increase of pressure may arise from the fact that some of the contributing uncertainty factors such as zero error, resolution is constant thought the pressure cycle and at higher pressures, their contribution is lesser which resulted in lower relative uncertainties at higher pressures.

The uncertainty interval is conveniently shown as low end-point (LEP) and high end-point (HEP) at 95% confidence level. Further, as mentioned above, histograms were plotted at each pressure point which reflect the actual probability distribution of P_{GUT} and is found to be normal at all pressure points. Two such representative graphs are shown here in Fig. 4 at 100 MPa and 800 MPa. The LEP and HEP is represented by two verticals lines in the histograms.

Uncertainty was also estimated as per the EURAMET procedure described in the section "Mathematical Model of EURAMET Method." In this, the indicated pressure/output signal of DPT was modeled using linear characteristic obtained by linear regression between DPT output in mV and standard generated pressure. The

Hysteresis)	0	3.33333E-05	R	1.73	0.000010	99.9849	0.001	9.26E-07
Standard uncertainty							0.0999	9.97E-03
Expanded uncertainty	0.1997							

sum/difference model is used to calculate the uncertainty, for pressure measured at increasing and decreasing pressures cycles separately. The various contributing input quantities, with their estimates and uncertainties are tabulated in the form of uncertainty budget in Table 3 at the highest studied pressure. The combined uncertainty turns out to be 0.10 MPa.

Conclusions

The aim of the current work is to discuss the use of several approaches for estimating the associated uncertainties in the calibration of DPT, which involves a variety of influencing quantities. Using these methods, the uncertainty related to a set of calibration result is calculated, and the results are presented with practical uses provided as case studies. At a maximum pressure of 800 MPa, the relative percentage uncertainty computed using three different approaches is 0.098%, 0.099% bar, and 0.099% for least square calibration, Monte Carlo, and EURAMET methods, respectively. It is clear from the case study that the user who requires comparable results may utilize the current procedures. The methods described here used for the DPT with voltage as an output but can be easily adapted to other electrical outputs, such as capacitance, frequency, etc. Furthermore, such approaches can also be utilized to analyze any physical or chemical data.
